
A cross-section of the stele of a young root of the buttercup, *Ranunculus acris.*

and lignified; other cells, called passage cells, retain their thin walls and permit free flow of water to the xylem. In Monocots the walls are all thickened.

Within the endodermis is the stele, or central cylinder. The first cells to differentiate in this region are the water-conducting **xylem** elements, which arise in discrete groups. The number of these groups is usually constant for any given species of plant, cross-sections through the root at this stage showing a number of isolated groups of cells surrounded by unmodified cells. Between these groups of cells and somewhat farther from the center of the root other groups of cells become evident as the root grows older. These are the **phloem** cells. While the walls of xylem cells soon become thickened by the formation of **ligno-cellulose** against the primary wall, those of the phloem cells remain constantly thin. With continued growth of the root, the cells of the central portion gradually become changed into additional xylem cells, so that finally, in most roots, no unmodified cells remain in the center; that is, characteristically the root does not contain pitch cells, though many **monocots** do. Remaining outside the phloem and xylem cells are many only slightly changed cells which form the pericycle. This is the region from which branch roots originate, and also the region which by the division of its cells forms the cork cambium which produces the cork and secondary cortex in the outer bark of tree roots after

the first year of growth. The root therefore contains the following tissues derived entirely from the modification of the cells originally resulting from the divisions of the apical meristem; a central cylinder of alternate masses of xylem and phloem cells, surrounded by a sheath of slightly modified cells called the pericycle, these composing the central cylinder. Outside this is the endodermis, with its cells showing characteristic thickenings of the walls. Around the endodermis is the cortex. All these tissues are collectively known as primary tissues.

With further growth of the root, secondary tissues appear. These are formed from a special group of cells known as **cambium** cells. Cambium cells first appear in the region inside the phloem patches, appearing in cross-sections of the root as crescent-like patches which gradually extend radially until they unite to form a continuous sheath around the xylem. By their divisions new cells are formed both inside and outside the cambium band. Those inside gradually develop into secondary xylem cells, while those outside become secondary phloem cells. Continued development of the **cambium** band causes the primary phloem cells and all other cells formed externally to be pushed outward and gradually crushed. Since growth often occurs periodically in the root, especially in regions having alternations of favorable and unfavorable seasons, **annual rings** are found in roots as in stems. As root enlargement occurs, the pericycle cells become meristematic and by their divisions form a mass of cells around the central cylinder as described above.

The functions of the root are primarily anchorage of the plant, absorption of water and mineral salts in solution, and conduction of these to the stem, and also storage of food. Anchorage is obtained by the much-branched far-reaching root system, which penetrates deeply into the ground and resists such forces as wind acting on the top of the plant.

The water of the soil, together with substances in solution, is taken into the plant largely through the portion of the root which is covered by root hairs. The outer wall of the latter soaks up water readily. The wall of the cell is permeable, permitting water to pass through easily. The outer surface of the cytoplasm of the cell is also a membrane, which is semipermeable, that is, readily permits certain substances such as mineral salts in solution to pass through, but does not allow organic substances to pass. A similar condition exists in the membrane of the cytoplasm which separates it from the cell sap in the vacuole. This cell sap has a high concentration of organic solutes dissolved in it, so that it has an osmotic pressure of 4 to 10 atmosphere, which is much greater than that of the soil solution. Since these two solutions are separated by a semipermeable membrane, it is but natural that water molecules should pass more freely into the cell than out, causing water to move from the soil into the plant. Once in the root hair, the water increases the turgor of the latter. This water then passes into the cortical cells and through them to the xylem. There it enters the vessels and moves up through the root into the stem. (See **Ascent of Sap.**)

In many plants, the root, once formed, shortens, apparently by a change in the shape of its cells, and as a result pulls the top down against the ground or even under the surface. Such a phenomenon occurs in the Dandelion.

Food storage, one of the main functions of roots, results from the movement of foods downward from the green leaves into the roots. Often food is stored in such quantities as to cause considerable enlargement of the root. In addition to foods, water is also stored, especially in many desert plants.

Of secondary importance is the habit which many plants have of propagating themselves by means of roots. In this process, **adventitious buds** appear on the root, especially when the latter is exposed to the air. These gradually develop into new plants. This is very important to man, since it is a way of propagating many plants. Sweet potatoes are propagated in this way. (R.M.W., B.S.M.)

ROOTS OF NUMBERS. An n^{th} root (where n is a positive integer) of a given number a is a number whose n^{th} **power** is equal to a. The number n is called the index of the root.

Thus, x is a square root of a if $x^2 = a$; that is, the square root of a number when multiplied by itself produces the given number. Every positive number a has two real square roots, one of which is positive and the other negative, both having the same **absolute value.** The positive square root of a is called the principal square root of a, and is generally denoted by the radical symbol $\sqrt{a}$.

Every negative number has two **imaginary** square roots; either of them may be chosen as the principal square root.

Every real number has n distinct n^{th} roots. One of these is selected as the principal n^{th} root as follows:

If n is even and a is positive, the one positive n^{th} root of a is called the principal n^{th} root of a.

If n is even and a is negative, any one of the **complex** n^{th} roots of a may be called the principal n^{th} root of a.

If n is odd and a is positive, the one positive n^{th} root of a is called the principal n^{th} root of a.

If n is odd and a is negative, the one negative n^{th} root of a is called the principal n^{th} root of a.

The principal n^{th} root of a is denoted by the **radical** symbol $\sqrt[n]{a}$, or by the **fractional exponent** symbol $a^{1/n}$.

The n n^{th} roots of any number (real or complex) are given by one form of **DeMoivre's theorem.**

Tables of principal roots of numbers, usually square roots and cube roots, are often contained in collections of mathematical tables. (L.L.S.)

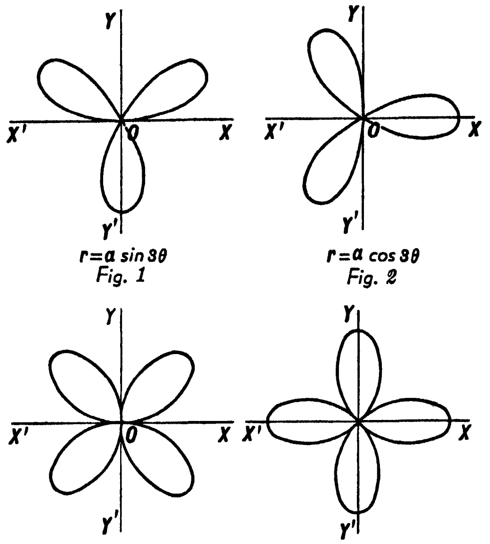
ROPE DRIVE. Ropes passing, in the manner of belts, over **sheaves** are used for the transmission of mechanical power between rotating shafts. Rope drives have been used where conditions were unsuitable for leather belts. Center distances from 50 to 300 or 400 ft. are possible with rope transmission, but not with belts. Ropes are suitable for outdoor location, and for transmission of large amounts of power between shafts which are not parallel. Belting is not suitable for these drives. Extremely long rope drives using wire ropes have been built, but they are rarely constructed today, because the electrification of industry offers more economical transmission of power over long distances. The ropes of rope drives are made of Manila, cotton, or steel; 4- and 6-strand Manila ropes are commonly found in this country, varying in size from 1–1½" in diameter. These ropes run like belts over grooved sheaves, and any amount of power can be transmitted merely by providing enough rope and sufficient number of grooves on the sheaves. It is readily possible to obtain driving efficiencies of better than 90% in rope drives. (F.T.M.)

RORQUAL. Whale.

ROSE CHAFER. Insecta, Coleoptera. A medium-sized gray-brown **beetle** which eats the flowers and fruit of roses and various fruit trees. Spraying has not been found an effective method of control although damage to grapes is said to be prevented by the use of **lead arsenate.** The spray recommended is made up of 3 lbs. of lead arsenate and 2 gals. of molasses to 100 gals. of water. It should be applied when the beetles first appear and again after the lapse of a week. (A.W.L.)

ROSE COLD. Hay Fever.

ROSE CURVES. The 3-leafed roses with equations in polar coordinates $r = a \sin 3\theta$ (Fig. 1), and $r = a \cos 3\theta$ (Fig. 2) are shown in the accompanying figures.



$r = a \sin 3\theta$ Fig. 1 $r = a \cos 3\theta$ Fig. 2

$r = a \sin 2\theta$ Fig. 3 $r = a \cos 2\theta$ Fig. 4

Rose curves.

The 4-leafed rose with equations in polar coordinates $r = a \sin 2\theta$ (Fig. 3), and $r = a \cos 2\theta$ (Fig. 4), are shown in the figures.

The equation $r = a \sin 4\theta$ represents in polar coordinates an 8-leafed rose. (L.L.S.)

ROSE FAMILY. Rosaceae. Comprising this family are some 2000 species of plants, a few of which are of tremendous value to man. Most of them are perennial plants, either trees or shrubs or herbs. Nearly all have alternate leaves, either simple or compound, with stipules present. The flowers are of many forms, and grow in **racemes** or **cymes**. Frequently the receptacle is more or less hollowed and often forms a part of the mature fruit. The flowers are commonly perfect and have their parts in multiples of five. The fruit may be either dry or fleshy, and in many species is an aggregate of many individual fruits. The flowers are usually conspicuous and insect pollinated. The most important economic members are found in three of the five or more suborders. One of these, the Pomoideae, has the **carpels** often united together and fused with the inner wall of the receptacle, which becomes fleshy; such a fruit is called a pome. In this subfamily are found the apple, pear, and quince.

The apple, *Pyrus Malus,* is a medium-sized tree, usuless than 40′ in height. The wood of the tree is red in color, hard and dense, and frequently used for making tool handles. The flowers are borne on short lateral branches known as spurs, and are pink and pleasantly fragrant. They are self-sterile and insect-pollinated, particularly by the honey-bee. The fruit is a pome, the fleshy part of which is regarded as modified stem tissue, the receptacle. When unripe the fruit contains much malic acid and starch. On ripening the amount of malic acid decreases, while much of the starch changes to sugar. At the same time characteristic aromas and flavors develop. When ripe a change occurs in the middle **lamella** of the cell wall, the substance dissolving away in part so that the cells become more or less separate. On further ripening the flesh in certain varieties becomes mealy and loses most of its tastiness. Each of the five carpels which form the parchment-like core of the apple contains two seeds.

Propagation of the apple tree may be accomplished by seed planting, but with doubtful success since the new plant will usually bear small undesirable fruits. To perpetuate desirable strains, therefore, **grafting** or budding is usually practiced. Many people top-graft old apple trees; frequently a single tree may have a dozen or more varieties grafted thereon.

Apple trees do best only in regions having a fairly cool climate; they are not entirely hardy, temperatures below −20° F. seriously damaging old and well-established trees. Many varieties of apple trees are grown. These fall into three main classes, according to the time when the fruit is mature; summer apples appear first, being ready for use in late July and August; fall apples follow, with Gravenstein one of the most popular varieties of this class; the principal class is the winter apple, the fruits of which keep well so that they are available throughout the winter months. Apples of this class stand storage and shipment through long distances.

Apples are used in several ways. Many are eaten raw; others used as sauce or made into pies and tarts. The high **pectin** content causes them to be much used in the making of jelly. Large quantities of apples, particularly cull fruit, are ground up and the juice pressed out to produce cider. Fermentation causes cider to acquire a considerable percentage of alcohol, it then being known as hard cider. By the action of acetic acid **bacteria,** cider may be changed to vinegar. From the crushed pulp, called pomace, remaining after the juice is expressed, commercial pectin is obtained.

The pear tree, *Pyrus communis,* of Eurasian source, differs in several ways from the apple. Usually it is a taller tree, with a tendency to more upright growth. In contrast to the rough leaves of the apple, those of the pear are smooth and glossy. The wood is very dense and used much as apple wood is used. The flowers are white. The fruit is more juicy and sweeter than is the apple, and the flesh especially when green contains an abundance of stone cells. Pears are used almost entirely as edible fruit, eaten either fresh or canned.

The quince, *Cydonia oblonga,* is a far less important member of this group than are the pear and apple. It is a small, rather shrubby tree. The fruit is large, more or less hairy during growth and hard and yellow at maturity. Each carpel contains several seeds which are invested with a mucilaginous pulp. The main use of quinces is for jams and marmalade.

Another genus included in this group is *Crataegus,* the Hawthorn, many of whose species are planted for ornament. The wood of the larger species is sometimes used in inlay work and for engraving. The genus contains many species, which hybridize freely, offering great difficulty to the taxonomist.

A second subfamily is the Rosoideae, a large one containing many genera and species. Here the fruit is one-seeded and indehiscent, with usually many carpels borne on an enlarged central stalk or carpophore. In some genera the floral axis encloses the **carpels** in the mature fruit. Shrubs or herbs with simple or compound leaves and various inflorescences comprise the group. Several are important plants extensively cultivated.

One of these is the genus *Rubus,* which includes Raspberries, Blackberries, and Dewberries. In these the **fruit** is an aggregate of many drupelets, which cling closely to the axis in the Blackberries and Dewberries, but slip free therefrom in the Raspberries. An erect habit distinguishes Blackberries from the prostrate Dewberries. All have a perennial root system and annual or biennial stems. Propagation is mainly by suckers and root cuttings. The fruits are largely consumed fresh near the place of growing, or canned. Another large genus in this subfamily is *Rosa,* grown widely for its beautiful fragrant flowers. In this genus the fruit or hip is a hollow urn-shaped torus surrounding the many carpels.

From the flowers of certain species, notably *Rosa damascena,* **Rose oil** is obtained.

Another very important genus is *Fragaria,* the Strawberry. Strawberries are low herbs with short thick stems, tough fibrous roots, and trifoliate leaves. The fruit is composed of many small achenes irregularly scattered on the surface of a very much enlarged fleshy receptacle. The hull of the fruit is the persistent calyx and the remains of the stamens. Propagation is mainly by means of the numerous long slender runners, modified branches, which root at their tip and are then severed from the parent plant. Strawberries are used as dessert, for making preserves or jams, and in ice cream. The many varieties are derived from *Fragaria virginiana* of Eastern North America and *Fragaria chiloensis* of the Andean region of South America.

The third subfamily containing genera of importance to man is the Drupoideae, members of which are trees or shrubs with simple leaves and the fruit, a **drupe,** usually one-seeded, in which the **ovary** wall or **pericarp** is differentiated into a fleshy outer portion, the exocarp and mesocarp, and an inner endocarp which is very hard or stony. In these plants the bark contains a gum which frequently exudes in masses. The leaves, bark and seeds are bitter, due to the presence of a glucoside amygdalin which in the presence of an **enzyme** emulsin, produces prussic acid, a deadly poison. Due to this reaction animals eating these parts are frequently killed. The important economic members are *Prunus Persica,* the peach, *Prunus Armeniaca,* the apricot, *Prunus domestica* and related species, the plums and prunes, and *Prunus avium* and *P. Cerasus,* the cherries.

Peaches are derived from a native Chinese tree. The trees are small and usually not very long-lived. They are only semi-hardy, and due to their habit of producing flowers very early in the growing season, before the leaves appear, are frequently badly damaged by late heavy frosts. The flowers are borne singly, are brilliant pink and fragrant. The calyx tube of the flower surrounds the pistil, but is not adnate thereto. The **ovary** is 1-celled, but frequently contains two **ovules** when young, only one of them developing. Peach fruits, the largest of any member of this subfamily, are of two types. In one, the fleshy **mesocarp** slips readily from the stony **endocarp;** these are freestone peaches. In the other the two layers are closely adherent, giving clingstone fruits. Peach fruits are very perishable when mature, and are mostly consumed fresh, canned, or dried. Almond oil may be made from the kernels. During World War I charcoal made from the hard endocarp was used in filters for gas masks.

The apricot likewise is a Chinese plant. The trees are usually rather larger than peach trees, and not so hardy. The flowers are pink, and the fruit smooth-skinned, smaller than peaches, and of the freestone type. Apricots are consumed fresh or dried or canned. Commercial growing is largely restricted to California.

Plums are small to medium trees of several different species, some of which have been cultivated since before the Christian era. Many kinds of plums are consumed fresh. Others are unpalatable when fresh, being used mainly for making preserves and marmalades. Others are very sweet and capable of being dried without souring. When dried these are known as prunes. To prepare prunes, the ripe fruits are picked from the trees and cleaned. The skins are broken to expedite drying. If the climate is suitable the fruits are then spread in the sun to dry. Otherwise drying is done by artificial means. The dried fruit is finally dipped in hot water or scalded in steam, thus destroying any insect eggs which might later develop and cause spoilage of the product. The prunes are now ready to market. California leads the states in prune production.

Cherries are relatively small-fruited trees of medium size, indigeous to Europe. In cultivated kinds, the flowers are borne in small **umbels,** usually opening just as the leaves develop. Sweet cherries are largely consumed fresh. Sour cherries are canned, and used for making pies. Maraschino cherries are artificially colored cherries, the flesh of which has been hardened by soaking in brine and sodium sulfite. Wild cherries, especially black cherries, are frequently used in making jellies and wine.

To this subfamily also belong the **Almonds.** (R.M.W.)

ROSE OF SHARON. Mallow Family.

ROSE REAMER. Reaming.

ROSEMARY. Mint Family.

ROSEMARY, OIL OF. Volatile Oils.

ROSIN. Rosin is a yellow non-crystalline substance of unknown structure produced as a residue on distillation of **turpentine.** (See **Resins.**) (R.K.S.)

ROSS EFFECT. A contraction of the developed photographic image, observed by Ross (1920), occurring in drying and due to the hardening of the gelatin in the immediate vicinity of the image by the by-products of development. As a result, the tanned gelatin in the higher densities dries at a different rate from the unhardened gelatin in the background, setting up strains in the gelatin layer which results in contraction of the image. The effect is of great importance in astronomical photography, particularly in studying double-stars. (C.B.N.)

ROSTELLUM. A projection at the end of the **scolex** of a **tapeworm** which bears the hooks. It serves as an organ of attachment. (A.W.L.)

ROSTRUM. A snout. The term is applied particularly to the elongated snouts of certain fishes and to the **labium** of the **bugs** (Hemiptera). The latter is grooved or folded to form a troughlike support for the slender **mandibles** and **maxillae.** (A.W.L.)

ROTARY DRIER. Drying.

ROTARY ENGINE. At one stage during the course of development of aircraft engines, the rotary engine made its appearance. This engine, although eventually superseded by engines with static cylinders, was sufficiently interesting mechanically to justify some brief description, and had, furthermore, the interest attached of being a type employed on aircraft engaged in military service during World War I. Often today uninformed persons confuse the radial engine with the rotary, which it resembles in appearance. The rotary engine is so called because the cylinders and crankcase rotate. One reason for its early adoption was that this rotation aided in effectively cooling the cylinders. Since that time much has been learned about the scientific dissipation of heat from static finned cylinders. The crankshaft was made stationary on the rotary engine, and in this respect the rotary engine is a kinematic inversion of the modern radial engine. (See **Aeronautical Engine.**) The introduction of a gasoline-air mixture was through a hollow crankshaft into the crankcase. A valve in the piston head allowed this gas to flow from the crankcase into the cylinder during the suction stroke. Castor oil had to be used for lubrication, since ordinary mineral oil would be cut by the gasoline in the crankcase. The crankshaft bearing on the crankcase was more complicated than in static engines, and lubrication was difficult due to the rotation of the crankcase. Also, gyroscopic effects were noticeable when maneuvering an aircraft having the **flywheel** effect provided by these rotating cylinders. (F.T.M.)

ROTARY MILLING ATTACHMENT. Milling.

ROTARY POWER. Polarized Light.

ROTARY PUMP. A rotary pump is one in which the driving element is a rotating shaft, but which, unlike the centrifugal pump, is a positive displacement device. In this class of pumps may be found the **gear** wheel pumps, in which two spur gears meshing together fit tightly in a casing, one driving the other. The spaces between the casing and the teeth are filled with a liquid being pumped, but on the return the teeth meshing together leave no such space, so that the liquid must be passed out through a discharge opening. The efficiency of this pump depends upon the elimination of clearances between teeth and casing, and upon close fit of the meshing teeth. This is the type of pump most often used to circulate oil in the lubrication systems of automotive engines. Of similar nature is the Roots rotary pump with its 2-lobed impellers. Another type of rotary pump has the rotating element located eccentrically with respect to a circular casing. A number of blades are provided to slide radially in the rotor, and close the gap between rotor and casing. Still other types use screws. These rotary pumps may be direct-connected to electric motors. (F.T.M.)

ROTATION. **Kinematics; Dynamics of Rotation.**

ROTATION SPECTRUM. **Molecular Spectra.**

ROTATORIA, ROTIFERA. The wheel animalcules, minute animals with a circlet of cilia at one end of the body, whose movements in some species give the appearance of rotation to the entire disk. They live in water, even in the small quantities found in matted vegetation and temporary pools, and are adapted to withstand long dry periods in such situations. The group is a **phylum** of minor importance.

Although rotifers are minute their bodies are complex in structure. The body wall consists of an external **cuticle** and a syncytial ectodermal layer which bounds the internal cavity. There are no muscle layers but bands of muscle are present. The alimentary tract (**digestive system**) is tubular and includes a **pharynx** with an elaborate grinding apparatus, known as the mastax, an expanded stomach, with a ciliated (cilia) lining, and a short intestine. Near the anus is an expanded **cloaca** which receives the ducts of the **excretory** and **reproductive systems.** The essential unit of the excretory system is the flame cell, like that of flatworms. The pair of ducts bearing these cells empty into a contractile vesicle or bladder. Reproduction in this phylum is complex, owing to the frequent occurrence of **parthenogenesis** and to the adjustment of the life cycle to fluctuating environmental conditions.

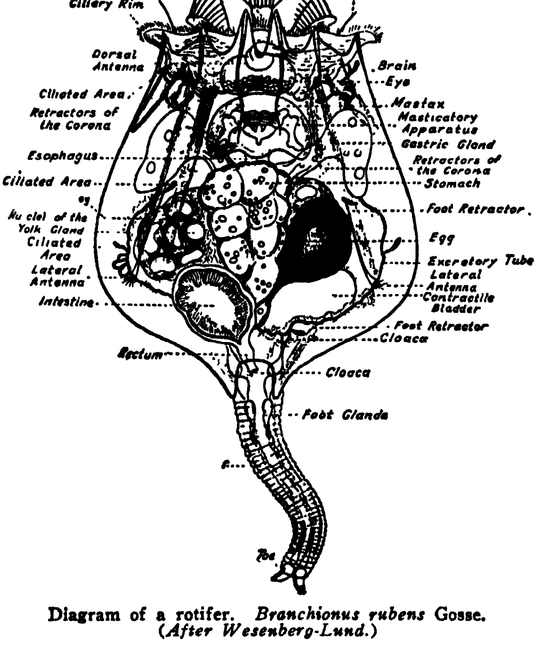


Diagram of a rotifer. *Branchionus rubens* Gosse. (*After Wesenberg-Lund.*)

Some authorities regard the rotifers as a phylum and others associate with them two other forms of animals, making each of the three groups a class in the phylum Rotifera, also named Trochelminthes. This classification is as follows:

Class Rotatoria. The true rotifers, as described above.
- Order Seisonidea. Ovary paired. The foot, a tapered posterior part of the body, is without subordinate lobes. Both males and females are well developed.
- Order Bdelloidea. Ovary paired. Males unknown. Foot sometimes with subordinate lobes.
- Order Monogononta. Ovary single. Males usually present but very small.

Class **Gastrotricha.** Minute worm-like creatures.

Class **Kinorhyncha.** Minute worm-like animals found at the bottom of the sea. (A.W.L.)

ROTATORY POWER. **Polarized Light.**

ROUND-MOUTHED EEL. **Cyclostomata.**

ROUNDTAIL. Pisces, Teleostei. A common fish (**Pisces**), *Gila robusta,* of the Colorado and Gila rivers, related to the chubs and dace. (A.W.L.)

ROUNDWORM. **Nemathelminthes.**

ROUTE SURVEYING. **Surveying.**

ROUTER. **Woodworking.**

ROVE BEETLE. Insecta, Coleoptera. A **beetle** of the family Staphylinidae, characterized by the long flexible abdomen which is exposed behind the short wing covers (elytra). (A.W.L.)

ROWLAND GRATING. **Diffraction Grating.**

ROYAL JELLY. The food given by worker **honeybees** to the young **larvae** during the first 3 days of their existence and to the larvae of queens until they are fully developed. It is a thick white liquid formed in the stomach of the worker by partial digestion of honey and pollen, and is apparently a highly concentrated food. Queen cells are supplied with the material in excess of the needs of the larva. If conditions within the colony deprive queen larvae of this abundance they fail to become as large, and in some cases they may even develop as intermediate forms between queen and worker. Such individuals may, however, have the instincts of queens and so may mate and lay fertile eggs. The change from royal jelly to a less concentrated food in the case of worker larvae apparently is responsible for the development of worker bees, since both queens and workers may develop from identical eggs. (A.W.L.)

RUBBER. Rubber is a product obtained from **latex,** a milky secretion which is found in the tissues of a large number of different plants. When the plant is injured, latex flows from the wound. On exposure to air latex coagulates and darkens. Rubber particles occur in the latex in the form of minute spherical globules. While it is true that the latex of many plants will yield rubber, yet few do so in quantities sufficient to give them commercial value.

Rubber was known to early American peoples before the arrival of Columbus. Several tribes used hard balls of rubber in playing a game, other tribes made use of it to render their shoes waterproof, while still others chewed the product. For a long time no use was made

of the substance by civilized races. French explorers discovered the source plant and used the native name for the product, changing it, however, to the form caoutchouc, a name by which rubber was long known. The word rubber was a result of its use to rub out pencil marks, discovered by Priestley.

Of the many plants yielding rubber in quantity, the Pará Rubber Tree, *Hevea brasiliensis,* stands in first place. This plant, a member of the **Spurge Family,** is a tree of the Amazonian jungle. It grows as high as 125′, has three-parted leaves of large size, the smooth leaflets being about 2′ long. The flowers are **monoecious** and without petals, and the fruit three-parted, **dehiscent** and containing three large seeds with mottled seed coat very similar to castor beans. These seeds are ejected rather forcibly from the ripened fruit. While attempts have been made to establish plantations of cultivated *Hevea* in South America, little success has attended the attempt, most of the crude rubber being obtained from wild trees. These wild trees grow scattered widely and irregularly in the jungle. They are tapped by ignorant half-breeds who locate the trees. Tapping consists of hacking through the bark, a destructive method which leads the way to infection of the tree by various diseases which finally bring about its destruction. The latex is collected in small cups which are stuck by their edges into the bark below the cut. The flow continues through the morning, but gradually stops when the heat becomes great at noon. The latex is gathered from the cups into pails and rubber-covered bags. If allowed to stand the rubber globules contained in the latex gradually rise. Commercial preparation of rubber is a faster process; a rubber film is fastened around a stick. This is held in the smoke of a fire and additional latex gradually poured over the film, accumulating slowly to form an ever-increasing ball. Kneading and working cause the elimination of any uncoagulated material. Finished balls of crude rubber weigh about 150 lbs. Sometimes the latex is coagulated over the end of a flat wooden paddle, producing a flat pocket-like cake; this is known as knapsack rubber. Besides *Hevea brasiliensis* and other species of *Hevea,* several species of *Castilloa,* of the **Mulberry Family,** are used as a source of rubber. The product obtained from them is known as Gaucho rubber. It is relatively unimportant. In addition to these, many Euphorbiaceous plants are sources from which rubber may be obtained in South and Central America. In Africa, species of *Funtumia* and *Landolphia,* members of the Apocynaceae, are sources of rubber. The first genus contains large tropical trees; the second, vines of immense size growing in the Congo Free State. Methods of obtaining rubber were extremely destructive—mostly the plants were chopped down and cut up, a procedure which soon all but wiped out the African rubber supply. In recent years plantations of *Hevea* have been established in Liberia, mainly by American tire interests.

In Asia, native rubber is obtained from *Ficus elastica,* a member of the Mulberry Family. The plant is familiar to many as the ordinary "Rubber Plant" grown as an ornament in conservatories. In its native home the plant becomes an enormous tree with large spreading branches supported in part by the development of prop roots similar to those of its relative, the **Banyan tree.** It is not an important source of rubber at the present time, the product being inferior to that obtained from *Hevea.*

In North America, rubber has been obtained in quantities from various plants. Unlike the tropical rubber sources, those of North America are herbaceous or shrubby plants. Of these the one most used to date is *Parthenium,* a desert shrub occurring in Mexico. The plant has been extensively cultivated in various arid regions of the southwestern United States, and improved strains developed. Chewing of the plant will produce rubber, but in rather small quantities. In commercial preparation the entire plant is crushed and broken up in water. The particles of rubber thus liberated float to the surface of the water and are removed. They are cleaned, rolled into sheets, washed, and dried, yielding a dark gray product known as guayule rubber.

In the United States several plants have been examined as sources of rubber; among them milkweeds, Indian kelp, and goldenrod. At present none of them produce rubber in any quantity, and the expense of extracting any quantity of latex makes it unlikely that they will compete with the rubber trees.

Most of the immense amount of rubber demanded by present-day civilization is obtained from plantations of *Hevea brasiliensis* grown in the Dutch East Indies, in the Malay Peninsula, and in Ceylon. There the plants are grown from seed, the seedlings being planted out when large enough, or budded with desirable stocks from high-producing trees. Growth is rapid, trees being large enough to tap in 5 or 6 years. In tapping plantation trees, a spiral cut is made in the bark, care being taken not to injure the cambium. A spout is placed at the lower end of the cut and the exuding latex collected in porcelain cups. When exudation from the cut ceases, a thin shaving is removed from the lower edge, a new flow of latex at once resulting. Shaving continues over a period of 3 to 8 weeks, after which the tree is left undisturbed to recover. Complete renewal of bark over the cut area requires about 4 years of growth.

The latex is gathered from the cups and coagulated by different methods. In one of these **acetic acid** is added to the fresh latex, which has been set in shallow pans. The rubber then forms as a sheet on the surface of the liquid. The sheets are removed and squeezed between rollers to remove excess moisture. The resulting product is crepe rubber. Another method of obtaining the rubber is to spray the crude latex into a stream of hot dry air, which quickly evaporates the moisture of the latex, leaving fine particles of rubber, which settle down. Latex has been treated with **ammonia** and shipped in liquid form to the rubber factories.

The Russian dandelion, koksagyz, has been found to grow in the temperate latitude and to yield a satisfactory rubber.

Rubber is a terpene **hydrocarbon,** forms a pseudo-solution with **carbon tetrachloride, chloroform, benzene, turpentine, carbon disulfide,** petroleum naphtha, reacts with ozone to form an ozonide—Harries (1905) deduced the formula of rubber from this reaction as 1,5-dimethylcyclooöctadiene-1.5—reacts with sulfur to form the substances commonly known as hard and soft rubber. The hot vulcanization process was discovered by Goodyear in 1839. In this process rubber, alone or dissolved in naphtha, and **sulfur** are intimately mixed, after which the mixture is subjected to a temperature of 113° C. (melting point of sulfur) to 130° C., preferably under pressure, as in an autoclave. The cold vulcanization process was discovered by Parkes in 1846 and is used for thin rubber goods. In this process thin rubber sheets, formed from naphtha solution of rubber and then evaporating the solvent, are treated in a vat with **sulfur** monochloride, dissolved, in order to diminish the violence of the reaction, in carbon disulfide. Rubber may be electrodeposited on metals.

The rate of vulcanization depends upon the percentage of sulfur present, the temperature, and the presence of a **catalyzer.** In the hot cure, **magnesium** oxide was early found to act as a catalyzer or accelerator, and since then organic bases have been found to be excellent accelerators—**aniline** and piperidine were among the first to be used. Para-nitrosodimethyl aniline (0.4 part, by weight) shortens the time of vulcanizing a 90% rubber–10% sulfur mixture at 140° C. from 60 mins. to 20 mins. The activity of many accelerators may be improved by the addition of such substances

as zinc oxide, lead monoxide, magnesium oxide, stearic acid, oleic acid, pine tar. Something like 80 different rubber accelerators are in use, and in 1940 the quantity of these produced in the United States was over 33,000,000 lbs. The hardness of the product depends upon the percentage of sulfur present and the time of heating. Soft rubber contains 5–10% sulfur, hard rubber 25–40% sulfur, and the latter takes about three times as long as the former for heating. Hard rubber is softened by heating, may then be molded and pressed (an important plastic), when cold may be machined and polished, is hard and inelastic, in contrast to the high elasticity of soft rubber. Vulcanized rubber is not reactive with ordinary acid solutions of moderate strength, including hydrofluoric acid, but excluding concentrated nitric and sulfuric acids, nor reactive with alkaline or salt solutions. Certain types of synthetic rubber, for example "Neoprene" (see below), are notably resistant to the softening action of gasoline and other petroleum hydrocarbon fractions.

Vulcanized rubber is subject to deterioration due to light, heat and oxygen of the air, but see the action of antioxidants below. Natural rubber, on the other hand, may be stored for years without noticeable loss of quality.

Rubber may be compounded or have blended with it in the process of manufacture, various materials, such as pigments, fillers, waxes, oils, fibers, to obtain a wide range of properties, and may be combined with various structural materials, e.g., with textile fibers to produce rainproof clothing, machinery belting, and automobile tires, with metals, concrete, and wood, to produce acid-proof vessels. Natural hydrocarbon gas black (carbon black) is a reinforcing material imparting high tensile strength to rubber, and is used notably in making automobile tires to increase their resistance to abrasion and cutting.

The permanence of rubber is increased by the use of antioxidants (0.5–2%) in the mix before vulcanizing. Paraminophenol, phenylalphanaphthylamine, phenylbetanaphthylamine, and about 30 other substances are used. Some 20,000,000 lbs. of antioxidants were produced in the United States in 1940. The use of antioxidants has greatly increased the useful life of soft vulcanized rubber, as in automobile tires.

Unvulcanized rubber in pseudo-solution is used as adhesive. Vulcanized rubber is remarkable for its resistance to abrasion, its flexibility, elasticity, extensibility (10 times the original length for soft rubber bands), resilience, absorption of shock, inertness to water, solutions, gases, high frictional resistance when dry, low frictional resistance when wet, high electrical resistance, low heat conductivity, resistance to moderately high temperature (about 200° C.), plasticity under proper conditions. These properties enable rubber to be utilized in a variety of ways, possibly not exceeded in this respect by any other material.

The uses of rubber hardly need enumeration. They include automobile and airplane tires and tubes, rubber boots, rubber tubing, belting, and rubber hose. Ebonite or hard rubber is used in making battery boxes, combs, and many other products.

The advent of synthetic rubber on a large scale was directly due to the loss of Malaya and the Southwest Pacific plantation rubber producing regions to the Japanese early in 1942. Our economy requires immense amounts of rubber in peace and even larger quantities in war, since automobiles, buses, and trucks run on rubber tires, and to these there must be added during war the rubber for military vehicles and airplanes on a scale hitherto unimagined.

The United States consumed in 1941 approximately 800,000 long tons of plantation rubber, of which 90% came from the Far East region later lost to Japan, and we had on hand, according to the Rubber Survey Committee, on July 1, 1942, only 578,000 long tons of natural and 47,000 long tons of reclaim rubber. Important was the fact that less than one-half of 1% of our total consumption consisted of our own synthetic rubber. Notwithstanding this terrific handicap, in 3 years the synthetic rubber industry was expanded to a production rate greater than our prewar consumption. This is the greatest single development in chemical industry on record.

Chemical and Metallurgical Engineering signalized this accomplishment by awarding its biennial medal in 1943 not to one company as hitherto but to the whole cooperating group of 65 companies directly responsible for the success of the U.S.A. synthetic rubber program. Statistical evidence strikingly supports the Baruch report (Reports of the Rubber Survey Committee) and the "Chem & Met" award, as the following data show:

YEAR	U.S.A. PRODUCTION OF SYNTHETIC RUBBER (long tons)
1935	2,500
1940	5,000
1941	12,000
1942	30,000
1943	325,000
1944	1,000,000

Five principal types of synthetic rubber are recognized, namely, Buna-S, Buna-N, Neoprene, Butyl, and Thiokol Polysulfide. Of these the Buna-S type was selected to be produced on the largest scale, and the name was changed to Government Rubber-S (GR-S). GR-S requires styrene (this accounts for the letter S in the name) and butadiene. Styrene is made by chemically combining benzene and ethylene to form ethyl benzene and then dehydrogenating, thus:

$$C_6H_6 + C_2H_4 \rightarrow C_6H_5\cdot CH_2\cdot CH_3 \xrightarrow{-2H} C_6H_5\cdot CH{:}CH_2$$

Butadiene ($CH_2{:}CH\cdot CH{:}CH_2$) is made from ethyl alcohol or from petroleum fractions. Styrene is a liquid of boiling point 145° C., but butadiene is a gas at ordinary temperature having a boiling point of −4.4° C. so it must be cooled or maintained under pressure if it is to be handled as a liquid as is desirable.

Completed in 20 months under war emergency conditions, the plant at Institute, W. Va., illustrates well the procedure in making GR-S. Before showing this process it would be well to compare its output with the situation if the same quantity of plantation rubber had been contemplated. The land for the plantation product would have to be 400 sq. mi. or 270,000 acres, in the proper climate, and 24,000,000 trees would have to be set out. The trees would have to be tended for 5 years before they would *start* producing rubber. The estimated expenditure would be $80,000,000, and there would be required 90,000 laborers—and a waiting time of 5 years without any rubber. The GR-S plant at West Virginia cost $56,000,000, took 20 months to erect, and requires only about 1500 persons to operate it. Here is the way the Institute plant is arranged:

Unit no.	1	2	3	4	5	6
Long tons (2240 lbs.) per year	20,000	20,000	20,000	20,000	12,500	12,500
Production	80,000 long tons of BUTADIENE of 98.5% purity				25,000 long tons of STYRENE of 99% purity	

Unit no.	7	8	9
Long tons per year	30,000	30,000	30,000
Production	90,000 long tons of GR-S		

As is evident, the process consists in mixing 80 parts by weight of styrene and 25 parts by weight of butadiene. The mixture is put in 175 parts by weight of soapy water, and a colloidal milky liquid results, called the latex. The reaction is purposely stopped before it goes to completion, and the unreacted materials are recovered from the latex by vacuum distillation. The latex contains about 25% rubber. Some antioxidant is added and the latex then *coagulated* by the addition of sodium chloride and sulfuric acid in dilute concentration. The coagulated rubber, or "curds," is filtered on continuous filters, from which it comes as a sheet. The sheet is broken up into particles of uniform size, and these are dried in a vacuum to produce the crude rubber. The plant at Institute produces about one-seventh of our prewar consumption of rubber.

The constitution of various rubbers is shown here:

ethylene dichloride 1,2-dichloroethane — sodium tetrasulfide — "Thiokol" rubber

(R.K.S.)

RUBELLA (GERMAN MEASLES). An acute, very contagious disease probably caused by a filterable **virus** which has not been definitely isolated. Infection occurs by direct contact with infected individuals. The disease is most prevalent during the first half of the year with a peak incidence in May and June.

The incubation period is longer than that of **measles** or **scarlet fever**, being usually from 16 to 18 days. Children who have had measles are more likely to develop rubella. One attack usually protects against another, but does not protect against measles or scarlet fever.

Symptoms resemble those of a light attack of measles with the following exceptions: the mouth is not involved, the rash lighter, less persistent, and complications are rare. A characteristic and diagnostic finding is the enlargement of the **lymph** nodes at the back of the neck and behind the ear.

The disease can be prevented or modified by the administration of **gamma globulin.** Treatment is symptomatic. (R.S.M., D.M.H.)

RUBELLITE. Tourmaline.

RUBICELLE. Spinel.

RUBIDIUM. Symbol: Rb. Atomic number: 37. Atomic weight: 85.44. Density: 1.53. Melting point: 38.5° C. Boiling point: 700° C. Isotopes: 85 (72.8%) and 87 (27.2%).

Rubidium is a silver-white, very soft metal; tarnishes instantly on exposure to air, soon ignites spontaneously with flame to form oxide; best preserved in an atmosphere of **hydrogen** rather than in naphtha; reacts vigorously with water forming rubidium hydroxide solution and hydrogen gas. Discovered by Bunsen and Kirchhoff in 1860 by means of the spectroscope.

Rubidium occurs in **lepidolite** (lithium aluminosilicate, in amount up to 1% Rb), in certain mineral waters and rare minerals. Rubidium salts may be recovered from the mother liquor upon crystallization of (1) **lithium** salts, (2) **potassium** salts, Stassfurt, Germany. Rubidium metal is obtained by **electrolysis** of the fused chloride out of contact with air.

Chloride: Rubidium chloride ($RbCl$), white deliquescent solid, melting point 715° C., soluble.

Hydroxide: Rubidium hydroxide ($RbOH$), white, deliquescent solid, melting point 300° C., soluble.

Oxide: Rubidium oxide (Rb_2O), pale yellow solid, by heating rubidium metal in oxygen or dry air, reactive with water to form soluble rubidium hydroxide.

Other soluble salts: Rubidium sulfate (Rb_2SO_4); rubidium nitrate ($RbNO_3$); rubidium carbonate (Rb_2CO_3).

Slightly soluble salts: Rubidium perchlorate ($RbClO_4$), insoluble in alcohol; rubidium chloroplatinate (Rb_2PtCl_6); rubidium periodate ($RbIO_4$); rubidium permanganate ($RbMnO_4$); rubidium fluosilicate (Rb_2SiF_6).

Volatile rubidium salts, such as the chloride, color the bunsen flame violet. (R.K.S.)

RUBY. Corundum.

RUDACEOUS. A term proposed by A. W. Grabau in 1904 for coarsely graded **clastic** sediments. (R.M.F.)

RUDD. Pisces, Teleostei. A common European fresh-water fish (**Pisces**), *Scardinius erythropthalmus*, related to the roach and ide and belonging to the carp family. Also called the red-eye. (A.W.L.)

RUDDER, AIRPLANE. A hinged or movable auxiliary airfoil on an aircraft, the function of which is to impress a yawing moment on the aircraft. (F.T.M.)

RUFF. Aves, Charadriiformes. A European bird (**Aves**), *Machetes pugnax*, related to the sandpipers. The name comes from the seasonal development of a large ruff about the neck of the male. The females are called reeves. (A.W.L.)

RUFFE. Pisces, Teleostei. A small species of **perch**, *Acerina cernua*, found in slow gravelly streams of England. It is also called the pope. (A.W.L.)

RULED SURFACES. A **surface** generated by a moving straight line is called a ruled surface. Cylinders and cones are the simplest examples.

The **hyperboloid of one sheet** and the **hyperbolic paraboloid** have two systems of rectilinear generators and are ruled surfaces. (L.L.S.)

RUMINANT. An animal that chews its cud. The term applies to the **oxen, sheep, goats, antelopes** and **deer, camels,** and **chevrotains.** It does not indicate a taxonomic group, although the term Ruminantia has been applied to this part of the order **Artiodactyla** in some classifications. The stomach of the ruminant consists of four chambers. When food is swallowed it passes into the rumen or paunch, where it is stored temporarily while the animal eats. Chewing and digestion are carried out at leisure. The food passes from the rumen to the reticulum or honeycomb, where it is formed into small masses and elevated to the mouth to be chewed. When swallowed the second time it follows a different course through the esophagus to another chamber, the omasum or psalterium, whence it continues to the abomasum. In these two parts gastric digestion is completed and the food is passed on to the intestine. (A.W.L.)

RUNNER. The principal revolving part of a hydraulic reaction turbine is called the runner. It consists of suitably curved blades, the hub, rim, crowns, etc. The runner of a hydraulic turbine is usually quite massive. The corresponding part of an impulse turbine is called the wheel. (See **Hydraulic Turbine.**)

In foundry practice, the channel, made in the sand of the mold, which connects the pouring basin and gate is called a runner. (F.T.M.)

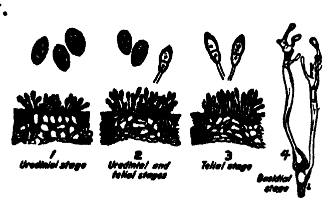
RUNNING FIX. Fix.

RUPTURE. Hernia.

RUSSELL EFFECT. This effect is also known as the Vogel-Colson-Russell effect as it was independently observed in different forms by all three. It is the general term applied to the formation of latent developable images on photographic films and papers by agents other than radiant energy and specifically by resins, metals, printing inks, volatile liquids, gaseous fumes, etc. In many cases the effect appears to be due to the release of hydrogen peroxide which is capable of rendering the silver halides developable without exposure to light. (C.B.N.)

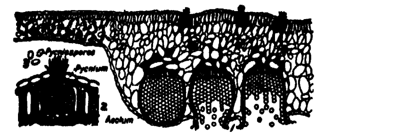
RUST FUNGI. Uredinales. The rust fungi are parasitic **basidiomycetes** which owe their popular name to the reddish color of the **spore** masses in some of the commonest species. Because many of the thousand species found in North America attack important cultivated and wild plants, they are of great economic importance. The group possesses a remarkable variety of spore types. Many species have five kinds of spores. It is notable that any given species has a very limited range of host plants.

One of the best-known species of Rusts is the common Wheat Rust, *Puccinia graminis,* which has long been known. Five spore forms are included in its complex life-history.



Puccinia graminis in wheat leaves. 1, uredinial stage; 2, uredinial stage changing to telial stage; 3, telial stage; 4, basidiospore germinating and forming basisia and basidiospores. (*After Tulasne.*)

On wheat plants, and on various **grasses,** there appear during the summer on the stem and leaves reddish spots which on examination are found to contain large numbers of 1-celled spores which are called urediniospores. These are scattered by the wind and reinfect wheat plants continuously during the growing season. Near the end of the growing season, when the host plant is maturing, a new form of spore appears either with the urediniospores or in separate **pustules.** These spores are



1, Section of barberry leaf infected with *Puccinia graminis* and producing pycnia and aecia; 2, section through pycnium; 3, three pycniospores.

2-celled, of dark color, and have a very thick wall. They are called teliospores, or winter spores, and are able to survive the winter season independent of any host plant, for they can neither attack one nor parasitize it. In the spring each cell of the teliospore puts out a short tube which becomes 4-celled. From each of the four cells a small spore is formed: this is the basidiospore and the 4-celled tube is therefore a basidium. The 1-celled basidiospores are carried by air-currents to suitable host plants, which in this case are not wheat plants, but barberry plants. In contact with the young leaves of the latter plant the basidiospore develops a short tube which penetrates the leaf epidermis and forms a mycelium within the leaf. After a time this mycelium gives rise to a new type of spore which appears on the upper surface of the barberry leaf in small pustules called pycnia or spermagonia. These contain masses of small **hyphae,** from the tips of which are cut off minute 1-celled bodies called pycniospores or spermatia, which seem incapable of reinfecting the host plant. Soon after the formation of the pycnia there appear on the under side of the leaf clusters of orange-colored cups. These are the aecia or cluster cups, in which are formed chains of tightly packed aeciospores. These spores, when released. cannot reinfect barberry plants but must be carried to wheat plants before they can grow. On the wheat plant each aeciospore puts out a short germ tube which penetrates the tissue of the leaf or stem within which it forms an extensive mycelium, from which the urediniospores and later teliospores are formed. So it is apparent that for the completion of its life-history *Puccinia graminis* must have two very different host plants. Many rusts show this character of requiring alternate hosts, and are called heteroecious. Other rusts complete their life cycle on a single host: they are said to be autoecious.

Another rust of great economic importance, especially in the northern United States and Canada, is the white pine blister rust, *Cronartium ribicola,* which, like wheat rust, has two alternate hosts, white pine having the pycnia and aecia, and currants and gooseberries the uredinia and telia stages.

In many rusts one or more of the spore forms may be entirely lacking. For example, in *Gymnosporangium Juniperi-virginianae* there is no uredinial stage, while in the common hollyhock rust, *Puccinia malvacearum,* pycnia, aecia, and uredinia are all lacking, only the teliospores and basidiospores being formed.

A study of the nuclear condition of the various types of rust spores reveals several interesting facts. The basidiospores are uninucleate, as are the minute pycniospores which follow them in the life cycle of wheat rust. For a long time these pycniospores were considered to be without function, they being held to be either degenerate male cells or an asexual type of spore. Recent evidence, however, has been offered that they may actually function as male cells, in some rusts at least.

It is considered that these minute spores, after discharge from the pycnidia, in some way come in contact with the mycelium within the leaf and unite with it so that a binucleate condition results. This binucleate condition then appears in the aeciospores, the urediniospores, and the teliospores. Each nucleus is haploid. Before the basidiospores are formed, nuclear fusion occurs, the basidium having but a single fusion **nucleus.** This undergoes meiosis, producing the haploid nuclei of the basidiospores. This leads to the conclusion that in the complex life cycle of the rusts there is a definite **alternation of generations,** the uninucleate diploid basidium, the haploid basidiospores, and the pycniospores being **gametophytic,** while the rest of the cycle is **sporophytic.**

In the control of rusts, three methods of attack are available. In those rusts which require alternate hosts, the removal of one of the hosts naturally suggests itself. This has been done with considerable success in combating white pine blister rust by destroying all currant and gooseberry plants in regions where white pine is an important timber tree. Similarly, removal of barberry serves to minimize wheat rust infection in regions where the winters are cold enough to prevent continuous infection by urediniospores. When constant reinfection of the same host occurs a second method of control may be found in the breeding of rust-resistant strains. Such strains now exist, for a great many susceptible plants are of great commercial importance. Control of rusts has also been attempted with various sprays with varying results. (R.M.W.)

RUSTING. Corrosion.

RUTABAGA. Brassica.

RUTHENIUM. Symbol: Ru. Atomic number: 44. Atomic weight: 101.7. Density: 12.06. Hardness: 6.5. Melting point: 2450° C. (**Isotopes:** page 290)

Compact ruthenium is a grayish-white metal, somewhat harder and more brittle than **platinum,** difficultly soluble in **aqua regia,** and attacked by **chlorine.** Discovered by Claus in 1845.

Ruthenium occurs native in platinum ores, sometimes to the extent of 2%. When **osmium** is present it is removed as volatile osmium tetroxide, and the residue is heated with a mixture of **nitric** and **perchloric acids** to fuming of the latter, whereupon ruthenium tetroxide distils over, and is absorbed in **sodium** hydroxide solution. The resultant orange-red solution is reduced to ruthenium sesquioxide by alcohol. **Ignition** of the sesquioxide in hydrogen forms ruthenium metal.

Ruthenium at 600° C., and ruthenium tetroxide at 106° C. yield a sublimate of ruthenium dioxide.

Hydroxides: Ruthenium trihydroxide ($Ru(OH)_3$); ruthenium tetrahydroxide ($Ru(OH)_4$).

Oxides: Ruthenium dioxide (RuO_2), green crystals; ruthenium sesquioxide (Ru_2O_3), black; ruthenium tetroxide (RuO_4), golden-yellow crystals. The last compound is volatile upon heating in a mixture of nitric and perchloric acids to fuming of the latter. (R.K.S.)

RUTILE. A mineral composed of **titanium** dioxide which occurs in three distinct forms: as rutile, a **tetragonal** mineral usually of prismatic habit, often twinned; as octahedrite, a tetragonal mineral of **octahedral** habit; and as **brookite,** an **orthorhombic** mineral. Both octahedrite and brookite are relatively rare minerals.

Rutile has a sub-conchoidal fracture; is brittle; luster, metallic-adamantine; color, commonly reddish-brown but sometimes yellowish, bluish or violet; streak, brown; transparent to opaque. Rutile may contain up to 10% of iron.

Experiments in the artificial preparation of titanium dioxide appear to show that rutile is the most stable form and produced at the highest temperature, brookite at a lower temperature, and octahedrite at a still lower temperature.

Rutile is found as an accessory mineral in many kinds of **igneous rocks,** and to some extent in **gneisses** and **schists.** In groups of **acicular** crystals it is frequently seen penetrating quartz as the "fleches d'amour" from Grisons, Switzerland. Rutile is found also in Austria, Italy, Norway, South Australia, and Brazil. In the United States it occurs in Vermont, Massachusetts, Connecticut, New York, Pennsylvania, Virginia, Georgia, North Carolina, and Arkansas.

Rutile derives its name from the Latin *rutilus,* red, in reference to the deep red color observed in some specimens when viewed by transmitted light. (E.S.C.S.)

RYDBERG CONSTANT. A quantity which enters into the frequency or wave number formulae for all **atomic spectra.** It has nearly the same value for all elements, and has only to be multiplied by a factor dependent in a regular way upon the ordinal number of the line to give the wave number of each line in a given spectral series. Rydberg derives the following expression for the constant in the case of any atom, the mass of whose nucleus is M:

$$R = \frac{2\pi^2 me^4}{ch^3(1 + m/M)};$$

in which m is the mass and e the charge of the electron, c is the **electromagnetic constant** (speed of light), and h is Planck's constant. Since m/M is in any case very small, it is clear that R cannot vary much from element to element. Its smallest value (for hydrogen) is about 109,678 reciprocal cm., and it can never exceed 109,737 reciprocal cm. If R is multiplied by c, the result is the "Rydberg fundamental frequency" (called by some writers the Rydberg constant); and if this be used in place of R, the spectral series formulae give frequencies instead of wave numbers. (L.D.W.)

RYE. *Secale cereale.* Gramineae. Rye is an annual plant which has a tendency to become perennial. It is a sturdy cereal grass having a much-branched root system which penetrates 4–6′ into the ground and tough slender stems which may grow as tall as 6′. The leaves are like those of other **cereal** grasses, but have a definite bluish color, as does the stem. The **inflorescence** is a **spike,** with the individual spikelet 3-flowered and occurring singly at each of the twenty or more joints of the **rachis.** Of the three flowers in a spikelet, only the two lower ones mature, the third aborting. The two **glumes** are narrow, the **lemma** is broad, distinctly keeled, and has a long stiff terminal **awn,** while the **palea** is thin and blunt. Unlike most of the cereal grasses, rye must be cross-pollinated in order to set fruit abundantly. The fruit, a grain, is very similar to that of wheat in structure, and readily separated from the lemma and palea when mature. The grain is long and slender and of much darker color than wheat grains.

Rye apparently originated either in central or southwestern Asia, and is a grain of much more recent cultivation by man than are the other cereal grasses. Rye is now extensively cultivated, especially in cold or dry climates, since the plants are capable of growing in much colder regions than wheat, and also on poor soils deficient in moisture content. Russia produces a large part of the world's rye crop, with Germany a second large producer.

Rye is much used in making flour. From this flour is made the dark-colored, somewhat bitter-flavored bread which forms the principal bread of the poorer classes of Europe. Rye grain is also used as a stock food, while the grass is used as forage or dried for hay. The ripened stem, or straw, is much used for bedding, as packing material, and in the manufacture of straw board. Much of the mash used in distilling whiskey and **alcohol** is made from rye.

Rye is subject to attack by a parasitic fungus known as ergot, *Claviceps purpurea,* which causes the grains to hypertrophy. Ergot is a violent poison, and if ground up with rye into flour, may cause serious cases of poisoning. (R.M.W.)

S

SABATIER EFFECT. This effect, studied by Sabatier, is a reversal phenomenon observed with photographic materials under certain conditions as when the developed image is exposed to diffuse light and redeveloped. Reversal of the image, under these conditions, is usually due to the first negative image acting as a stencil during the second exposure, the positive image being formed by the exposure of the undeveloped silver halide through the negative image.

Reversal of the image, however, may also be produced by the substitution of certain chemicals, such as sodium arsenite, for the exposure to diffuse light. Exposure to x-rays under these conditions does not result in reversal. Students are now agreed that the Sabatier effect is not a simple case of second exposure as described above, but a different phenomenon connected apparently with the development of the images. (C.B.N.)

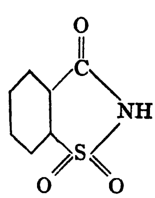
SABINE'S LAW. **Acoustics.**

SABLE. **Marten.**

SACCHARIDES. **Carbohydrates.**

SACCHARIMETER. This is a special type of polarimeter designed for use in the analysis of sugar solutions. It comprises a polarizing device, commonly a Nicol prism, to effect the polarization of the light, and an equalizer which permits the determination of the amount of rotation of the plane of polarization of this light that has been brought about by passage through a standard thickness of the solution undergoing analysis. Incidentally, such instruments are designed to use or produce monochromatic light since the angle of rotation varies inversely with the wavelength of the light. The specific rotation or specific rotatory power of optically active substances are known and, therefore, if there is only a single optically active substance present in the solution undergoing analysis its concentration may readily be calculated. (R.K.S.)

SACCHARINE. This is an artificial sweetening agent which is not a **carbohydrate** but a cyclic imide of ortho sulphobenzoic acid.



It is synthesized from **toluene** and is 700 times as sweet as ordinary sugar. The sodium salt is used in **diabetes.** (R.K.S.)

SACCHAROIDAL. Used by petrologists as a textural term meaning granular (sugary). (R.M.F.)

SACCULINA. Crustacea, Cirripedia. A parasitic **crustacean** which lives on crabs. The name is that of the genus to which the animal belongs. When first hatched sacculina is an active **larva** (Nauplius) without a mouth or alimentary tract. It transforms into a Cypris larva which attaches itself to a crab and undergoes a transformation including the development of a perforating organ. By means of this organ the body wall of the crab is penetrated and the parasite, an almost shapeless mass of cells, enters the body cavity. It becomes attached to the alimentary tract of the crab and forms root-like processes which extend ultimately to all parts of the body. As the parasite reaches adult life it bulges from the under surface of the crab's abdomen. A conspicuous effect of the attack is the castration of the host, with accompanying changes in its visible sexual characteristics. (A.W.L.)

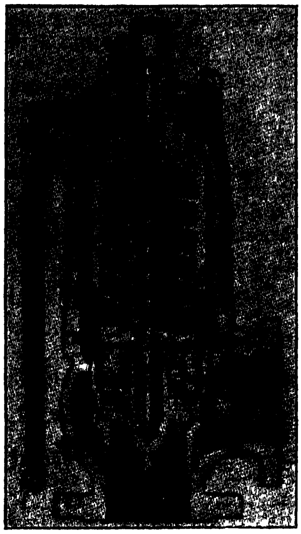
SACRUM. The portion of the spinal column of **vertebrates,** usually formed of several fused vertebrae, with which the pelvis is articulated. **Skeletal system.** (A.W.L.)

SAFELIGHT. In photography the term safelight is applied to a light filter which, when used with a suitable light source, provides illumination by which a photographic material may be examined with reasonable safety. The spectral transmission of the safelight is determined primarily by the spectral sensitivity of the photographic material for which it is designed. Thus a yellow safelight (transmitting green and red) may be used with photographic papers whose sensitivity is low and lies almost wholly within the violet and blue, while a red safelight (absorbing violet, blue and green) may be used with blue-sensitive and orthochromatic negative materials since the sensitivity of these beyond a wavelength of about 550 $m\mu$ in the green is so slight as to be of no consequence in practice. Since panchromatic negative materials are sensitive throughout the visible spectrum, the transmission range of the safelight is determined by (1) the wavelength range to which the material is least sensitive, and (2) the wavelength range at which the maximum visibility is obtained. In practice, the second consideration is the more important of the two; hence safelights for panchromatic material are designed to provide the maximum visibility with the smallest amount of light possible. Thus, for panchromatic materials a blue-green safelight provides the maximum visibility consistent with reasonable safety, since at low-intensity levels the maximum sensitivity of the eye is in the blue-green region. No light, however, which is of any value in practice is safe for most high-speed panchromatic materials. These must either be handled in total darkness, examined only briefly when development is almost complete, or desensitized (see **Desensitizing**).

Safelight screens are usually made by coating glass with dyed gelatin although progress has been made in incorporating the dyes in both plastics and in glass to produce screens less subject to fading and to damage by heat and water. (C.B.N.)

SAFETY VALVE. The common form of the safety valve is the pop valve held against its seat by a heavy spring and having a "huddling chamber" to make it open quickly and remain open until a predetermined pressure drop (2–4% of the working steam pressure) has occurred. The A.S.M.E. Boiler Construction Code requires **boilers** having more than 500 sq. ft. of heating surface, or those generating better than 2000 lbs. of steam per hour, to have two or more safety valves. The safety valves should have sufficient relieving capacity to prevent more than 6% pressure rise at maximum rate of **combustion.** Required discharge capacity of a safety valve may be based either on the heat units in the **fuel** consumed or on the amount of steam generated.

In case more than one safety valve is used the smaller one can be set to pop at the desired maximum pressure and the larger at 2 or 3 lbs. higher. The main safety



Pop safety valve. (*Crane Co.*)

valves of a large boiler operate to blow down several pounds pressure before closing. A smaller **"vernier"** safety valve giving less pressure drop between pop and close is installed, usually on the **superheater** outlet, though sometimes on the boiler lead, for the purpose of giving partial relief to the high pressure, warning the attendants of high pressure, preventing overheating of superheater tubes, and possibly forestalling popping of the main safety valves and the resultant waste of high-temperature potential heat. Since most safety valves discharge horizontally into a pipe that then turns upward, an impulse force is given to the vent piping which, at least for large valves, needs special anchorage.

The relief valve is a form of safety valve, but usually intended for less severe service and of less importance from the safety viewpoint. Relief valves are applied to air, water, and steam lines, also to tanks, heaters, etc. Among them could be mentioned the back pressure valves and atmospheric relief valves. (F.T.M.)

SAFFLOWER. *Carthamus tinctorus.* **Composite Family.**

SAFFRON. *Crocus sativus.* Iridaceae. *Crocus sativus* is a perennial herb, the native home of which is the eastern Mediterranean region. The stem is an underground flattened **corm,** the surface of which is covered by a few scaly leaves. At the top of the corm is a terminal bud, which develops into linear leaves 5–9″ long, and flowers. The flowers are white or lilac-tinted, with the **perianth** 6-parted and with a very long tube, so that the **ovary** remains below the surface of the ground. The three **stigmas** are bright red. These, when dried, are known as saffron, an orange-yellow dye with a considerable percentage of volatile oil present. Saffron is used in medicines, and in various liqueurs and dishes, to add a pleasant taste and color. (R.M.W.)

SAGE GROUSE, SAGE HEN. Aves, Galliformes. The largest species of **grouse** in North America, *Centrocercus urophasianus.* It ranges from southwestern Canada to Nebraska and central California, inhabiting chiefly the arid plains. It also wanders over grass lands and reaches high altitudes in the mountains. Sometimes called the cock of the plains. (A.W.L.)

SAGEBRUSH. *Artemisia tridentata. Compositae.* A number of other species of this genus are also called sagebrush but *A. tridentata* is more prominent and of wider distribution than the others. This shrub has an extensive root system and may attain heights up to 7′. The gray-green foliage and aromatic odor of this shrub are distinctive. The flowers occur in inconspicuous heads. This plant is distributed from the Black Hills to southern British Columbia to southeastern California to northern Arizona. It reaches its best development, however, in the Great Basin region where it may occur over large areas in nearly pure stands. (B.S.M.)

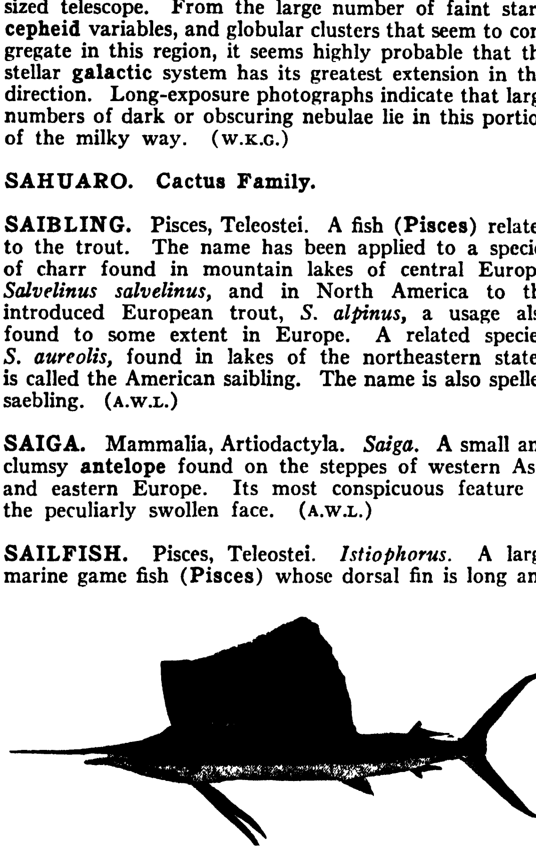
SAGITTARIUS (The archer) (Map, page 380). This large **constellation** is the ninth sign of the **zodiac.** Lying as it does in a particularly rich portion of the milky way, it contains a large number of star **clusters** and gaseous **nebulae** of great beauty in a moderate-sized telescope. From the large number of faint stars, **cepheid** variables, and globular clusters that seem to congregate in this region, it seems highly probable that the stellar **galactic** system has its greatest extension in this direction. Long-exposure photographs indicate that large numbers of dark or obscuring nebulae lie in this portion of the milky way. (W.K.G.)

SAHUARO. Cactus Family.

SAIBLING. Pisces, Teleostei. A fish (**Pisces**) related to the trout. The name has been applied to a species of charr found in mountain lakes of central Europe, *Salvelinus salvelinus,* and in North America to the introduced European trout, *S. alpinus,* a usage also found to some extent in Europe. A related species, *S. aureolis,* found in lakes of the northeastern states, is called the American saibling. The name is also spelled saebling. (A.W.L.)

SAIGA. Mammalia, Artiodactyla. *Saiga.* A small and clumsy **antelope** found on the steppes of western Asia and eastern Europe. Its most conspicuous feature is the peculiarly swollen face. (A.W.L.)

SAILFISH. Pisces, Teleostei. *Istiophorus.* A large marine game fish (**Pisces**) whose dorsal fin is long and



Sailfish, *Istiophorus gladius.* (*American Museum of Natural History.*)

exceptionally high, resembling a sail. The upper jaw is prolonged into a sharp sword like that of the related swordfish. Also called spike-fish. (A.W.L.)

SAILINGS, THE. The position of a vessel at sea, or in the air, is defined by the **latitude** and **longitude.** The position at any particular instant is connected with any other position, either the one just left or the one toward which the vessel is proceeding, by means of the **true course** and distance.

Any given course and distance may be resolved into two components at right angles to each other; the northing or southing and the easting or westing, each expressed in **nautical miles.** The northing or southing may be immediately converted into difference of latitude, expressed in angular units, for the nautical mile is, by definition, approximately equal to a minute of arc

along a great circle. However, the conversion from easting or westing, commonly known as **departure,** into difference of longitude, can be accomplished only after taking into account the shape of the **earth** and the approximate latitude of the ship.

The navigator is continually faced by one of two problems. 1. Given the difference of latitude and longitude between two points on the surface of the earth, to find the course and distance between them. 2. Given the course and distance followed by a ship, to find the difference of latitude and longitude between the point of starting and the destination. The different methods of solving these problems are known as the sailings, and include **plane, parallel, middle latitude, mercator, great circle,** and **composite** sailings. (W.K.G.)

SAILPLANE. A sailplane is a highly efficient **glider.** Being designed for the use of expert glider pilots, it is unsuited for primary training. It is characterized by very low sinking speed, nearly flat glide, and perfection of construction. It is capable of rising flight on weak thermal air currents and is the type of aircraft employed for cross-country motorless flights of a sporting nature. The sailplane has high **aspect ratio** (about 20), careful streamlining, clean and smooth external surfaces, and minimum weight consistent with structural safety. The gliding angle in still air is often as flat as 22:1 and the sinking speed as small as 2 ft. per sec. (F.T.M.)

SAINT ELMO'S FIRE. A brush-like discharge from charged objects in the atmosphere is known as St. Elmo's fire. It occurs on ship masts, on aircraft propellers, wings, other projecting parts, and on objects projecting from high terrain. St. Elmo's fire occurs when the atmosphere is charged and a sufficiently strong electrical potential is created between an object and the surrounding air. Aircraft most frequently experience St. Elmo's fire when flying in or near cumulonimbus clouds, thunderstorms, in snow showers, and in dust storms. (P.E.K.)

SAINT HILAIRE. Celestial Navigation.

SAINT VITUS' DANCE. Chorea.

SAKI. Mammalia, Primates. A New World **monkey** of the genus *Pithecia.* Most of the species bear the name of the group, as the white-headed saki and the whiskered saki, but native names have been adopted for some. The hairy saki is called the parauacu and the black saki is also known as the cuxio. No members of the genus have prehensile tails. (A.W.L.)

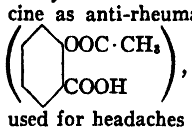
SAL. Latin term for various salts, much used. Sal ammoniac, **ammonium** chloride; sal soda, **sodium** carbonate; sal volatile, **ammonium** carbonate. (R.K.S.)

SALAMANDER. Amphibia, Urodela. A **vertebrate** with a slender body, short legs, and a long tail. The moist skin of the amphibians limits them to protected habitats, either near water or under some protection on moist ground, usually in the woods. Some species are aquatic throughout life, some take to the water intermittently, and some are entirely terrestrial as adults. The salamanders resemble the lizards superficially but they are easily distinguished by the moist skin, without scales. (A.W.L.)

SALIC. A term proposed by Cross, Iddings, Pirrson, and Washington, in 1906, for the group of relatively common or standard **aluminum-silicate** minerals such as **quartz, feldspars,** and **feldspathoids.** (R.M.F.)

SALICYLIC ACID AND SALICYLATES. Salicylic acid or $C_6H_4(OH)(1)(COOH)(2)$ is a white solid, melting point 159° C., sublimes at 76° C., insoluble in cold water, soluble in hot water, alcohol, or ether. With **ferric** chloride solution, salicylic acid solutions are colored violet (distinction from **benzoic acid**).

Salicylic acid may be obtained (1) from oil of wintergreen, which contains methyl salicylate, (2) by heating dry sodium phenate (C_6H_5ONa) plus **carbon dioxide** under pressure at 130° C., and recovery from the resulting sodium salicylate by addition of dilute **sulfuric acid.** Salicylic acid is a mild disinfectant and antiseptic, and has been used as a food preservative. Salicylic acid and certain salicylates are used in medicine as anti-rheumatics. **Aspirin** is acetylsalicylic acid



, white solid, melting point 135° C., used for headaches and colds.

The following are representative esters of salicylic acid:

Methyl salicylate.................$HOC_6H_4COOCH_3$
Boiling point 222° C.
Ethyl salicylate.. ....$HOC_6H_4COOC_2H_5$
Melting point 1° C., boiling point 231° C.
Phenyl salicylate......... ....$HOC_6H_4COOC_6H_5$
Melting point 43° C., boiling point 173° C. at 12 mm. pressure (R.K.S.)

SALIENTIA. Amphibia.

SALIVARY GLANDS. Glands whose ducts discharge into or near the oral cavity. In the **vertebrates** they are a group of digestive glands lying in various parts of the wall of the oral cavity, chiefly near the bases of the jaws, but among the invertebrates they are an extremely varied assemblage. Thus in the insects some of the salivary glands lie in the **thorax,** and the silk glands of some species are modified salivary glands which may extend through almost the entire length of the body.

The principal salivary glands of man are three pairs: the sublinguals lie in the floor of the oral cavity, the submaxillaries below the angles of the lower jaw, and the large parotids in front of and below the ears. They produce a digestive **enzyme,** ptyalin, which acts on starches, forming maltose, from which glucose is formed by the action of a second salivary enzyme, maltase (see **Carbohydrates**). The presence of digestive enzymes in the salivary secretions is by no means the rule among mammals in general. Among birds it is not common. (A.W.L.)

SALIX. Paleobotany.

SALMON. Pisces, Teleostei. Important game and food fishes (**Pisces**). The true salmons are found only in the northern hemisphere but some closely related forms are found in the Australian region. The family includes the trout also.

Salmon are remarkable for their migration into fresh waters from the sea for the breeding season. Although this is so common as to be almost distinctive, there are fresh-water species which never migrate. These are the so-called landlocked salmon of New England lakes and northward, which are regarded as among our finest game fishes. Two varieties, the ouananiche and the sebago salmon, are classified as subspecies of the Atlantic salmon, *Salmo salar,* an important game fish in the rivers of the Atlantic coast and Europe.

The rivers of the western coast of North America have several species of salmon which are taken in immense numbers to be canned and, to a less extent, to be

marketed fresh. The most important species is the chinook, king, or quinnat salmon, *Oncorhynchus tschawytscha,* and next in order come the blueback or redfish, *Oinerka,* and the silver salmon, *O. kisutch.* Other species are of little importance as food.

After the young salmon hatch in the headwaters of the rivers they work their way gradually to the sea, where they remain until mature. Many of the adults perish in their breeding migration but some return to salt water. (See also **Esters.**) (A.W.L.)

SALOL. **Drugs.**

SALPIAN. Urochordata, Thaliacea. A free-swimming tunicate (**Urochordata**) with a transparent body, marked by opaque muscle bands and internal organs. The salpians live near the surface of the ocean, some as solitary individuals and some in linear series as colonies. They resemble the sessile ascidians in early life, but differ in remaining motile after the transformation of the larva. (A.W.L.)

SALPINGITIS. Infection of the **fallopian tubes.** This common disease is most frequently due to a gonorrheal infection. More rarely, it may be due to tuberculosis, *streptococcus* or *pneumococcus* infection. Gonorrheal salpingitis is not only the most prevalent but is the most disabling in its after-effects. Salpingitis may not occur for months or even years after the original gonorrheal infection.

The symptoms of acute salpingitis are severe lower abdominal pain often colicky in type, with marked tenderness over lower quadrants. There is usually fever and marked leucocytosis. The symptoms and signs may closely resemble those of acute appendicitis and it is often very difficult to distinguish between the two conditions. Treatment of acute gonorrheal salpingitis with **sulfonamides** usually results in prompt control of the infection. If the organism is sulfa-resistant, **penicillin** will effect a cure. Untreated, the disease may run a chronic course lasting for years, lighting up at occasional intervals with a more or less acute attack.

Chronic gonorrheal salpingitis is of great seriousness because of the tenacity of the infection and because it is a common cause of sterility. The most constant symptom is intermittent, dull, dragging pain in the lower abdomen which is usually made worse by exertion. The dull pain often makes the subject irritable, nervous, and neurotic. Menstrual disorders are frequent. **Leukorrhea** is usually present. Pelvic peritonitis is a common complication, and the formation of peritoneal **adhesions** accounts for many of the direct and associated symptoms.

The recurrent flare-ups of acute salpingitis which occur during the chronic disease are treated with sulfonamides or penicillin. If pyosalpinx or distention of the tube with pus occurs, surgical intervention is necessary. Surgery may also be indicated for late complications, but is never carried out during or immediately after an active infection. (R.S.M.)

SALSIFY, OYSTER PLANT. *Tragopogon porrifolius.* **Composite Family.**

SALT DOME. **Halite.**

SALTATION. This term, as proposed by McGee, in 1908, is used by geologists to designate the particular mode of the stream transportation of **clastic sediments** by intermittent leaps or bounds. Probably an important factor in the ultimate transportation of the coarser fragments by streams and rivers. (R.M.F.)

SALTPETER. **Potassium** nitrate. **Sodium** nitrate is Chile saltpeter, and calcium nitrate Norway saltpeter.

SALTS. See individual salts under each metal; also **Acids, Bases, and Salts.**

SALVARSAN. **Arsphenamine.**

SALVE BUG. Crustacea, Isopoda. A marine **crustacean,** *Aega psora,* parasitic on various fishes. It is elongate oval in form and is a little more than one-half inch long. Found on both sides of the Atlantic. It is said to be used as a salve by fishermen. (A.W.L.)

SALVIA. **Mint Family.**

SAMARA. **Fruit.**

SAMARIUM. Symbol: Sm. Atomic number: 62. Atomic weight: 150.43. Density: 7.7. Melting point: $>1300°$ C. (**Isotopes:** page 290.) Type of compound: Sm_2O_3, white. Color of salts: Pink. Discovered by Boisbaudran in 1879. A member of the **cerium** subgroup of the rare earth metals. (R.K.S.)

SAMPLE. A sample is a portion of the **population** of the universe. Usually some type of random sample should be obtained, although in special circumstances stratified sampling, systematic sampling, or sampling in clusters may be preferable. (L.A.A.)

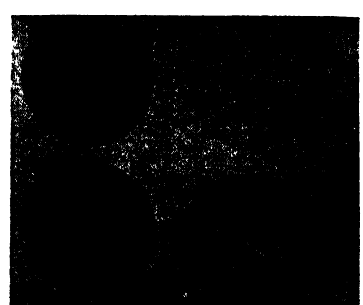
SAMPLING RELIABILITY. **Reliability, Significant Difference.**

SAND BOX TREE. **Spurge Family.**

SAND COLLAR. A thin collar-shaped plate formed of sand glued together with mucus. It is formed by marine **snails** of the family Naticidae in depositing their eggs. (A.W.L.)

SAND CRICKET. Insecta, Orthoptera. *Stenopelmatus.* Thick-bodied clumsy **insects** with large heads and long slender antennae. They live in loose soil, usually under some protective object, in the western United States. They are not true crickets but are more closely related to the long-horned grasshoppers. (A.W.L.)

SAND DOLLAR. Echinodermata, Echinoidea. A sea urchin (**Echinoidea**) with a very thin body, almost



Sand dollars. (*American Museum of Natural History.*)

circular in outline and with a diameter of less than 3″. It is common on both coasts of North America. (A.W.L.)

SAND EEL. Pisces, Teleostei. A long slender marine fish (**Pisces**) found near sandy shores on both sides of the Atlantic. They have a single very long and low dorsal fin and a much shorter median ventral fin. Used chiefly for bait. (A.W.L.)

SAND GROUSE. Aves, Columbiformes. A small group of birds (**Aves**) related to the pigeons but in some ways resembling game birds. They are found chiefly in Africa and Asia but extend to Europe and Madagascar. As the name suggests, they frequent open ground. Their flight is powerful, hence some species migrate over considerable distances. (A.W.L.)

SAND. **Sedimentation.**

SANDPIPER. Aves, Charadriiformes. Long-legged shore birds (**Aves**) related to the snipes and plovers. They are named from their association with the bare margins of streams and ponds, where their clear piping calls are a familiar sound. North America has a score of species, some bearing other names such as sanderling and knot, and every other continent has representatives of the group during at least part of the year. (A.W.L.)

SANDSTONE. Sand grains cemented by such substances as **silica, carbonate of lime** or **iron** oxide, so as to form a solid rock is called sandstone. It occurs usually in beds of varying thickness, depending upon the conditions under which the original sediments were laid down. Because it is normally well-jointed and easy to work, sandstone has been much used for building purposes. Unfortunately, however, as most sandstones are quite porous, the weathering action of the atmospheric agencies may have a very deleterious effect upon them. (E.S.C.S.)

SANDSTONE DIKES. Sandstone occurring in fissures which have been filled from above, or from beneath. The latter type are usually the result of earthquake fissures in great flood plain or delta deposits in which the sands have been injected from below. (R.M.F.)

SANIDINE. **Feldspar.**

SANITARY SEWER. **Sewerage System.**

SAP. **Ascent of Sap.**

SAPAJOU. Mammalia, Primates. A **capuchin monkey.** (A.W.L.)

SAPONIFICATION. This is a special case of **hydrolysis** of **esters** in presence of alkali. (See **Soap.**) (R.K.S.)

SAPPHIRE. **Corundum.**

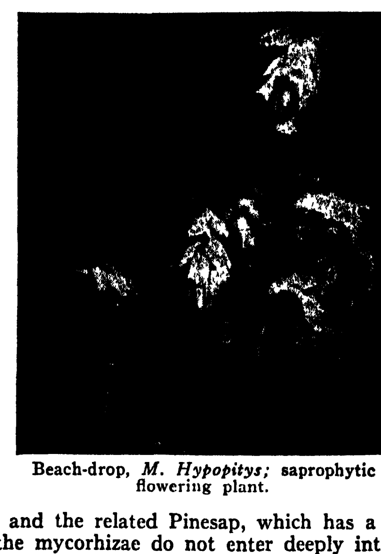
SAPROPEL. **Cannel Coal.**

SAPROPHYTES. These are plants which obtain their food from non-living organic material. Most of the saprophytes are **fungi.** Among the higher plants, a small number of flowering plants and perhaps a few **mosses** are also saprophytes. It is characteristic of these saprophytic plants that they have little or no **chlorophyll,** and so are not able to carry on **photosynthesis.** Their energy is derived from the complex organic substances which they absorb. In many instances the absorption of these substances is greatly advanced by the presence of **mycorhizae.**

Especially is this the case with various species of saprophytic **orchids** which have mycorhizae within the cells of the **roots** or **rhizomes.** The various species of Coral-roots (*Corallorhiza*) are common saprophytic orchids of American woods. These orchids have no roots, absorption occurring in the much-branched fleshy rhizome which gives the plant its name. In this rhizome the mycorhizae are found. These plants have erect stems, leaves reduced to scales, and no chlorophyll. Other saprophytic orchids occur in the continents of the Old World.

Another well-known saprophytic plant is the weird Indian Pipe or Ghost Plant, whose snow-white body is so striking an object, seen in the dark woods it inhabits.

Indian pipe, *Monotropa uniflora;* saprophytic flowering plant.



Beach-drop, *M. Hypopitys;* saprophytic flowering plant.

In this and the related Pinesap, which has a yellowish color, the mycorhizae do not enter deeply into the tissues of the plant roots. The latter form a considerable mass in the decayed vegetable substance on which they grow. On these roots **adventitious buds** appear and develop to the erect flowering shoots.

Other North American saprophytes are found in the Gentian family. These, species of *Bartonia,* have a little chlorophyll, which gives them a greenish color. The leaves are minute scales. Many other saprophytes are found among the **monocotyledonous** plants of the tropical forests both in the New World and the Old (R.M.W.)

SAPSUCKER. Aves, Piciformes. A North American **woodpecker** which cuts rows of small holes around the trunks of trees and visits them for the sap which exudes and the insects that are attracted by it. The rows of holes are so regular as to be conspicuous. They are said to damage some trees seriously and in some cases to kill them. The yellow-bellied sapsucker, *Sphyrapicus varius,* is the common eastern species. It is represented in the western states by a variety, the red-naped sapsucker, and two other species, the red-breasted and the Williamson sapsuckers, occur in the far west. (A.W.L.)

SAPWOOD. Wood.

SARCODINA. One-celled animals whose organs of locomotion are temporary or semi-permanent protoplasmic processes known as **pseudopodia.** These processes are thrust out and retracted at the surface of the body. A class of the phylum **Protozoa.**

These animals vary from formless masses of **protoplasm** to species which secrete an enveloping test or enclosed hard parts which give them a characteristic shape. Both free and parasitic forms are known. Among the latter the species which causes amoebic dysentery is the most serious to man.

The classification of the class is as follows:

Subclass Rhizopoda. With pseudopodia which are not of the straight semipermanent radial form known as axopodia.

- Order Proteomyxa. Without hard parts. Pseudopodia radiating and sometimes branched and united with each other.
- Order Mycetozoa. Without hard parts. Pseudopodia rootlike. These animals form a plasmodium consisting of an extensive mass of cytoplasm with many nuclei. Formerly classed as plants and called the slime molds.
- Order Foraminifera. With an enclosing test of various colors and forms, calcareous or silicious, and often of several chambers. Most species marine.
- Order Amoebaea. Without an enclosing structure. Pseudopodia thick and temporary.
- Order Testacea. With a test of one chamber, usually chitinous.

Subclass Actinopoda. With slender radiating pseudopodia.

- Order Heliozoa. Usually spherical, with radiating pseudopodia. Body not divided by a central capsule into distinct inner and outer zones. Chiefly in fresh water.
- Order Radiolaria. Usually spherical. Body divided into two regions by a central capsule. Marine. (A.W.L.)

SARCOMA. A malignant **tumor** originating in **connective tissue.** These growths are composed of densely packed cells, diffusely embedded in a homogeneous ground substance. Their degree of malignancy varies greatly. They spread by local infiltration and by blood stream invasion. The most frequent sites in which sarcomas develop are bone, lymph nodes, and subcutaneous tissue.

Sarcomas are much less common malignant tumors than are carcinomas or **cancers.** (D.M.H.)

SARCOSINE. Aminoacids, Polypeptides and Proteins.

SARCOSPORIDIA. Sporozoa.

SARD. Chalcedony.

SARDINE. Pisces, Teleostei. *Sardina.* A small fish **(Pisces)** related to the herrings. It is abundant in the English Channel and the Mediterranean, where it is also known as the pilchard. Immense numbers of these fishes are taken each season, to be marketed in tins. They are delicate, hence they must be prepared promptly in canneries located near the places where the fish are taken. (A.W.L.)

SARDONYX. Agate.

SARGASSUM. Algae.

SARGO. Pisces, Teleostei. Compactly built marine fishes **(Pisces)** of Eurasian waters. They have cutting teeth at the front of the jaws and strong molars. Used as a food fish in Italy under the name dentice. The sheepshead of the Atlantic and Gulf coasts of North America is a member of the same genus. (A.W.L.)

SAROS. The fact that **eclipses** occur in periodic intervals was known to the ancient Chaldeans, and probably even in prehistoric times. This period of 18 years, 11⅓ days (10⅓ days if there happen to be 5 leap years in the interval) is known as the Saros. If an eclipse should occur on January 1st, 1937, at noon, another similar eclipse would occur on January 12th, 1955, at eight o'clock in the evening. The eclipse would not occur at the same point on the earth but would be about 8 hours farther west in **longitude.**

During the course of a Saros there are about 29 lunar and 41 solar eclipses, each repeated during the next Saros, but not at the same portion of the earth. (W.K.G.)

SARRACENIA. Insectivorous Plants.

SARSAPARILLA. *Smilax* sp. Liliaceae. The genus *Smilax* contains some 200 species, most of which are tropical, though a few such as the carrion flower, *Smilax herbacea* and the cat briar, *Smilax rotundifolia,* occur as far north as the New England states. The tropical species are mostly climbing shrubs or vines, usually with prickly stems. The leaves are entire and of oblong to ovate shape. At the base of the leaf is a pair of **tendrils** which are perhaps to be interpreted as modified **stipules,** though such structures are not usually found in **monocotyledons.** The flowers are small, **dioecious** and borne in **umbels.** The fruit is a berry. Some of the South American species are the source of Sarsaparilla, which is obtained from the dried roots. Sarsaparilla is used as a flavoring for beverages and formerly in medicine in the treatment of rheumatism. (R.M.W.)

SASSABI. Mammalia, Artiodactyla. An African **antelope,** *Damaliscus lunatus,* also called the bastard hartebeest. It is almost 4′ high, with horns up to 15″ long. Their color is deep reddish, blending into black on the back. (A.W.L.)

SASSAFRAS, OIL OF. Volatile Oils.

SATELLITE. The term satellite is usually reserved in astronomy for small planet-like objects that are revolving about the individual **planets** in orbits. The **moon** is the satellite of the earth and has been known from remotest antiquity. The names and dates of discovery of the other satellites of the **solar system** will be found in the accompanying table. In this table there will also be found other data relative to the satellites. The definitions of the various column headings will be found elsewhere in this work. Further information regarding the different satellites will be found in the articles on the individual planets.

Satellites serve a useful purpose to astronomers since the mass of a planet can be determined accurately only if the planet has a satellite. By application of the rigorous expression for the harmonic **Keplerian law of planetary motion** the mass of any planet and satellite may be

found in terms of the mass of the earth-moon system after the distance of the planet from the satellite and its period of revolution are known. The problem of the determination of the masses of the satellites themselves is a more difficult problem. The mass of the moon can be determined in terms of the earth's mass by means of the so-called **barycentric parallax**. Approximate values of the masses of the satellites or Jupiter can be obtained by the mutual **perturbations** which they exert on each other. In the case of Saturn the masses of the satellites may be approximately determined from their mutual perturbations and an approximate check is provided by the positions of the divisions in the rings.

The three outer satellites of Jupiter, the outer satellite of Saturn, the four satellites of Uranus, and the satellite of Neptune all revolve about their primaries in the retrograde sense, i.e., in the direction contrary to that in which all other planets and satellites are revolving and rotating. This retrograde motion can be completely explained on the basis of modern **celestial mechanics**.

The influences which satellites exert on their primaries are very slight. The tidal forces which they exert have some slight effect upon the rotation periods of the primaries but such effects are so small as to be beyond observational measurement. The tidal effects which the planets exert upon the satellites, on the other hand, are in many cases so large that the satellites rotate in approximately the same period as that in which they revolve.

The question as to the origin of the satellite systems is still unanswered. The systems bear so much resemblance to the solar system itself that there is the suggestion that their evolutionary process may be the same as that discussed under the topic of **solar system**, but there are many objections to such a theory. Since the moon is the largest satellite in the solar system in comparison with its primary, and also being larger in proportion to the earth than any other planet is to the sun, it presents some very particular problems. If they ever formed one single mass, that mass must have been rotating with a period of approximately 4 hours, and have been greatly flattened at the poles. Such a mass would tend to break up under the influence of the rapid rotation, but would remain intact unless some external force was present. Such a force is found in the tidal effects of the sun, and the earth-moon system may have been formed by the breaking up of a large parent mass. However, the alternative hypothesis that the earth and moon were formed as two separate bodies at the time that the solar system was formed cannot be disproved. (W.K.G.)

SATURABLE REACTOR. This is a three-legged reactor whose **inductance** is controlled by passing d.c. through the winding on the center leg and thus altering the saturation of the **core**. The windings on the two outer legs are connected in an **alternating-current** circuit and serve as adjustable reactances. This operation is based upon the non-linear characteristic of iron, the permeability of the core and the consequent inductance of the a-c windings being high for low-core flux and decreasing as the saturation is increased. A wide range of reactance values may be obtained by the use of many turns and a small amount of d.c. (L.R.Q.)

SATURATED. In **geochemistry** this term is used by mineralogists and petrologists to designate minerals, such as **feldspar** which can form in the presence of an excess of free **slica**. The term was proposed by Shand, in 1911, and is frequently used to describe **igneous rocks** which are entirely composed of minerals of this type. (R.M.F.)

SATURATED LIQUID. Liquid which has absorbed the maximum quantity of heat possible, while remaining in the liquid phase, and has, consequently, risen in temperature to the boiling point is said to be "saturated." The quantity of heat contained, as well as the boiling temperature, is a function of the pressure existing on the surface of the liquid. (F.T.M.)

SATURATED VAPOR. A vapor whose temperature corresponds to the boiling temperature at the pressure existing on it, is said to be saturated. Expressing the same thought another way, a vapor is saturated when its temperature is a function of its pressure alone. A saturated vapor may be wet or dry, and the term does not imply, necessarily, a wet vapor. A vapor of 100% **quality**, having no superheat, is said to be dry and saturated. In contrast to a saturated vapor, the temperature of a superheated vapor depends both on the pressure and the degree of superheat. The temperature of a saturated vapor depends on its pressure and increases with increasing pressure. By virtue of the importance of water in both its liquid and vapor phases, its properties have been completely investigated and recorded in tables and charts. The properties of saturated steam will be found among such compilations. The physical attributes of saturated steam are the pressure, temperature, volume, **enthalpy**, and **entropy**. These are always given for steam which is dry and saturated, leaving the reader to apply the **quality** factor when it occurs. The increase of volume on vaporization and the latent heat of evaporation are present in wet steam to the extent of the percent dryness of the steam. One of the important entries in the saturated steam table is that for atmospheric pressure. At 14.7 lbs. per sq. in. absolute pressure, the saturation temperature of steam is 212° F. The heat contained in it as a boiling liquid is 180 B.T.U. (above 32° F.), and its latent heat of evaporation is 970.2 B.T.U. per lb. (F.T.M.)

SATURATION. **Color; Magnesium; Vapors; Humidity.**

SATURATION CURRENT. **Ionization Chamber.**

SATURATION OF THE ATMOSPHERE. If a free water surface is introduced into a box from which all gases have been removed, molecules of water will emerge from the liquid surface until the number of molecules escaping from the liquid equals the number returning to the liquid. When a balance is maintained between those evaporating or escaping from the liquid water and those condensing or impinging on and remaining in the liquid, the space within the box is said to be saturated with water vapor. It can hold no more water molecules and, if more are added, these will condense into liquid. If air is admitted into the box there will be no change whatsoever in the rate at which water molecules leave and impinge on the liquid. Component parts of the atmosphere, therefore, have no bearing on the number of molecules of water vapor present. Saturation of space above any liquid water surface depends solely on the number of molecules of water in the air as a vapor when a balance is achieved between the vapor molecules condensing on the liquid and the liquid molecules evaporating into the space above. This molecular balance depends almost entirely on the temperature of the liquid and the water-vapor molecules. The higher the temperature, the more molecules of water vapor can escape from the water surface before they begin to condense and return to the surface. In meteorological practice, as air is the medium in which weather phenomena take place, it is useful to relate saturation of water vapor to the air carrying it. Saturated air as a term is, therefore, used even though the presence of the air does not directly affect the number of molecules of water vapor at saturation. It is customary to speak of saturation specific humidity with particular reference to the weight of air carrying the water-vapor molecules. These satura-

tion specific humidities vary from a few tenths of a gram per kilogram of cold air to 30–40 grams per kilogram of very warm air. (P.E.K.)

SATURATION TEMPERATURE. Saturated Vapor.

SATURN. (See tables of planetary data, page 1109.) Saturn, the "ringed planet," is the sixth major **planet** in order of distance from the sun and was the outermost planet known to the ancients. In point of size Saturn is the second largest among the planets, having a diameter slightly more than 9 times that of the earth and but slightly less than the diameter of **Jupiter**.

The physical characteristics of the planet itself are approximately the same as those for Jupiter. The low density, high rotation speed, and variation of rotation period with planetary latitude all point to the probability that the solid core of the planet is relatively small and is surrounded by an atmosphere of very great thickness. As in the case of Jupiter, **spectroscopic** analysis indicates that the **atmosphere** is composed to a large extent of methane with some ammonia. All evidence, both observational and theoretical, indicates the surface temperature of the planet to be in the neighborhood of 123° K. (−238° F.). This low temperature coupled with the lack of oxygen in the planet's atmosphere indicates the impossibility of there being any life on Saturn such as we have on the earth.

To the naked eye, Saturn appears comparable to the brighter stars. In a telescope the planet itself has a belted appearance similar to that of Jupiter, but without as many distinctive surface features as are to be seen on the larger planet. From these semipermanent surface features the rotation period of the planet has been determined and found to be but slightly over 10 hours. There is also considerable evidence that the rotation period varies with planetary latitude, being the shorter at the equator.

Undoubtedly, the most remarkable and best known characteristic of Saturn is the ring system which surrounds the planet. These rings have the appearance of circular disks of paper, pierced with a hole in the center to admit the planet. The rings were first noticed by **Galileo** in 1610 when he first applied the telescope to astronomical observation, but it was not until 40 years later that Huygens was able to accurately describe them. Twenty years later, in 1675, Cassini found that the rings were separated into two parts, and in the middle of the 19th century Bond found a second division of rings, discovering the third or "dusky" ring, close to the planet itself.

Starting from the outside the rings are usually designated by the letters *A*, *B*, and *C*. The outer ring, *A*, has a diameter of approximately 171,000 miles and is about 10,000 miles wide. Cassini's division, between *A* and *B*, is about 3000 miles wide and ring *B* has a width of 16,000 miles. Between *B* and *C* there is a narrow space of about 1000 miles and ring *C* itself has a width of about 11,500 miles, leaving a space of about 7000 miles between the inner edge of *C* and the planet itself. In contrast to the great width of the rings their thickness is very slight. Actual measurements of the thickness are very difficult but it certainly is not more than 100 miles. On a model of 10,000 miles to the inch the ring system would have a width of about 17″ while the thickness would be less than that of the thinnest paper.

The rings are parallel to the planet's equator and, since the equator is inclined to the **ecliptic** at an angle of about 28°, the plane of the rings is inclined to the plane of the ecliptic by the same amount. Saturn revolves about the sun with a period of about 29.5 years and twice during this period the plane of the rings passes through the orbit of the earth. The plane of the rings takes nearly a year to pass the earth's orbit and during this period the earth may pass through the plane of the rings either once or three times. At these times the rings are seen edgewise from the earth and appear as thin needles of light extending out from the planet's equator. Intermediate between the passage of the earth through the plane of the rings they "open out" to their maximum angle at which time they appear as an **ellipse** produced by tipping a circle by about 27°, or an ellipse with an apparent width about half its maximum length.

The problem as to the constitution of the rings of Saturn was a problem which vexed astronomers from the time when they were first discovered down to the middle of the last century. It was recognized more than 100 years ago that such a wide, thin system could not be in stable equilibrium if it were composed either of a solid or a liquid. After the discovery of the inner ring by Bond and the discovery of a number of very fine divisions in both the *A* and *B* rings the mathematician, Clerk Maxwell, proved that the rings are in reality composed of millions of small particles each moving about the primary in orbits. It was further proved that the divisions in the rings are produced by perturbations due to the outer satellites of Saturn. The theoretical proofs were later verified experimentally by Keeler who, using the spectroscope and the Doppler principle, was able to show that the outer edges of the rings were revolving with longer periods than the inner edge. Such a condition could never maintain for a solid and could only be accounted for on the basis of a swarm of satellites moving under the Keplerian laws of planetary motion.

The question of the origin of the ring system of Saturn is still a much debated problem. The two main theories postulate either that a large satellite was "spoiled in the making," or that a large satellite was formed and then exploded under the influence of some unexplained force.

In addition to the millions of satellites that go to make up the ring system Saturn has a system of nine satellites. These outer satellites of Saturn are, on the average, smaller than the satellites of Jupiter, Titan the largest of them having a diameter of about 2600 miles. Titan is visible in a 3-in. telescope and seven of the others may be seen with telescopes of moderately large aperture. Phoebe, the faint outer satellite of Saturn, has a **retrograde** motion (i.e., revolves about the planet in the direction opposite to the revolution and rotation of the great majority of the other members of the solar system.) (W.K.G.)

SAUERKRAUT. Brassica.

SAUGER. Pisces, Teleostei. A North American fish (**Pisces**), *Cynoperca canadensis,* related to the walleye. A **pike**. Found in streams of the St. Lawrence basin and the upper part of the Mississippi River system. (A.W.L.)

SAURIA. Reptilia.

SAUROPSIDA. A term applied collectively to the reptiles and birds. It is not a taxonomic group but indicates the relatively close similarity of birds and reptiles as contrasted with the Ichthyopsida, consisting of fishes and amphibians, and the mammals, which stand alone. (A.W.L.)

SAW. See **Milling, Woodworking.** Hand sawing is often resorted to in metal work; a hacksaw consists of an adjustable frame for holding separate blades of various lengths. The blades are thin and comparatively narrow, and have teeth along one edge, and holes at each end to fit pins in the frame. Power metal-cutting saws are of three types: band saws, power hacksaws, and circular saws.

A power hacksaw consists essentially of a frame carrying a hacksaw blade and a vise for holding work. The

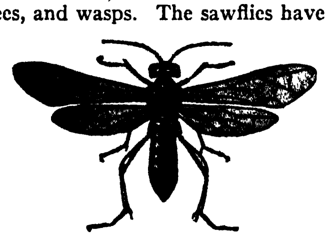
machine has an automatic feed with an arrangement to lift the blade clear of the chips on the return or non-cutting stroke. The vise is adjustable for angular cutting. The machine is usually motor-driven and has a pump to supply coolant for cutting.

A cold saw is a metal-cutting machine which uses a disk saw similar to a milling cutter. One type of machine has an hydraulic feed and a mechanically driven saw which cuts up. Cutting speeds of 35 to 70 ft. per min. can be obtained. Friction saws are used for cutting structural shapes and bars. The saw blades are circular, with vee-shaped peripheral teeth, are generally water-cooled, and are run at speeds up to 20,000 ft. per min. Large sections may be cut in but a few seconds. In some of the larger machines the work is rotated on an axis parallel to the blade axis, at a speed of about *e* ft. per min. to prevent contact with any large area of metal, produce a cleaner cut, and increase the rated capacity of the saw. Thin abrasive wheels are used for cutting extremely hard materials such as hardened high-speed steel, drill rod, glass tubing, or materials which may be abrasive in character.

Metal-cutting *band saws* are essentially similar to wood-cutting band saws. The saw blades are obtainable in widths from 1/16″ to 1/2″; as wide a blade as possible is employed; the blade width is generally limited by the minimum radius to be cut. Metal cutting band saws may be used for external or internal cutting. In internal cutting, a starting hole is drilled through the work and the saw band is cut or broken and inserted through the hole. The band is then clamped and welded in a special welding attachment on the frame of the machine. After welding, the joint is annealed and ground on its surface. The joint in the band is a butt-welded joint, can hardly be distinguished from any other part of the saw, and can be made in about one minute. The band saw also finds extensive application in the manufacture of sheet metal blanks where quantities are too large for individual production, but not sufficiently great to warrant the expense of a die set. (H.C.H.)

SAWFISH. Pisces, Plagiostomi. A large marine fish, *Pristis,* one of the rays. It has the upper jaw prolonged into a slender snout set with numerous sharp spines on each side. It is found in tropical America and Guinea. The name is also applied to *Pristiophorus,* a genus of sharks found in Japan and Australia. (A.W.L.)

SAWFLY. Insecta, Hymenoptera. A plant-feeding member of this order, whose more familiar species are the ants, bees, and wasps. The sawflies have four wings,



Sawfly.

somewhat like those of the wasps, but the abdomen is broadly connected with the thorax, in contrast with the thin-waisted bodies of the other forms. They are named from the sawlike **ovipositor** with which slits are cut in the tissues of plants to receive the eggs. Some species are of economic importance. Since the **larvae** eat leaves they can be destroyed by the usual arsenical sprays. (A.W.L.)

SAW-TOOTHED WAVE. Cathode-Ray Tube.

SCABIES. "The itch." A skin disease caused by an animal **parasite** (*Sarcoptes Scabiei*) characterized by an intensely itching eruption which involves the hands between the fingers, the **axilla,** nipples, lower abdomen, buttocks and external genital organs. The itching is always worse at night.

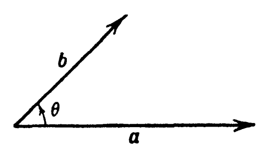
The female parasite burrows beneath the skin where eggs are laid, causing slightly elevated, grayish, tortuous, or dotted lines on the skin surface.

Treatment consists of the external application of various agents which kill the parasites. Sulfur is the most reliable of these, although balsam of Peru, tar, and other compounds are also effective. (D.M.H.)

SCAD. Pisces, Teleostei. A fish (**Pisces**) related to the pompanos, of the family Carangidae. One species, common in the region of the West Indies, is called scad, cigar fish, or round robin. Another, also common in warmer waters although it ranges north to Cape Cod, is known as the big-eyed scad, goggler, or chicharro. The name has also been applied to the related horse mackerel, a European species occasionally taken on the Atlantic coast of North America. (A.W.L.)

SCALAR. Vectors.

SCALAR PRODUCT OF TWO VECTORS. The scalar product (or dot product) of two vectors **a** and **b** is defined as a **scalar** equal in magnitude to the product of the magnitudes of the two vectors by the cosine of the angle between them.



The symbol for the scalar product of **a** by **b** in the Gibbs notation is $\mathbf{a}\cdot\mathbf{b}$; in another form of vector notation the symbol $(\mathbf{a}, \mathbf{b})$ is used, while in the Hamiltonian notation the symbol $S\,\mathbf{a}\,\mathbf{b}$ is used.

Then

$$\mathbf{a}\cdot\mathbf{b} = ab \cos \theta,$$

where θ is the angle between **a** and **b**.

The scalar product of two vectors may also be interpreted as the length of one vector multiplied by the **projection** of the other on it.

The scalar product of two vectors obeys the **commutative** and **distributive** laws:

$$\mathbf{a}\cdot\mathbf{b} = \mathbf{b}\cdot\mathbf{a}, \quad \mathbf{a}\cdot(\mathbf{b}+\mathbf{c}) = \mathbf{a}\cdot\mathbf{b} + \mathbf{a}\cdot\mathbf{c}.$$

If **a** is perpendicular to **b**, then $\mathbf{a}\cdot\mathbf{b} = 0$; and conversely, if $\mathbf{a}\cdot\mathbf{b} = 0$, then **a** is perpendicular to **b**.

If **a** is parallel to **b**, then $\mathbf{a}\cdot\mathbf{b} = ab$. Hence, $\mathbf{a}\cdot\mathbf{a} = a^2$.

For the unit vectors $\hat{\mathbf{i}}, \hat{\mathbf{j}}, \hat{\mathbf{k}}$, we have:

$$\hat{\mathbf{i}}\cdot\hat{\mathbf{i}} = \hat{\mathbf{j}}\cdot\hat{\mathbf{j}} = \hat{\mathbf{k}}\cdot\hat{\mathbf{k}} = 1, \quad \hat{\mathbf{i}}\cdot\hat{\mathbf{j}} = \hat{\mathbf{j}}\cdot\hat{\mathbf{k}} = \hat{\mathbf{k}}\cdot\hat{\mathbf{i}} = 0.$$

If $\mathbf{a} = \mathbf{a}_1\hat{\mathbf{i}} + \mathbf{a}_2\hat{\mathbf{j}} + \mathbf{a}_3\hat{\mathbf{k}}$, $\mathbf{b} = \mathbf{b}_1\hat{\mathbf{i}} + \mathbf{b}_2\hat{\mathbf{j}} + \mathbf{b}_3\hat{\mathbf{k}}$, then $\mathbf{a}\cdot\mathbf{b} = \mathbf{a}_1\mathbf{b}_1 + \mathbf{a}_2\mathbf{b}_2 + \mathbf{a}_3\mathbf{b}_3$. (L.L.S.)

SCALE. A flat structure developed as a covering. 1. The scales of fishes (**Pisces**) are in many cases arranged like shingles to form a complete armor at the surface of the body, and in other forms are small and scattered, merely adding to the resistant qualities of the skin. The elasmobranch fishes have placoid scales, whose form includes a broad base and a projecting enamel-covered point. This form of scale is much like the teeth of these fishes and is supposed to be ancestral to all vertebrate teeth. Ganoid scales, found in relatively few fishes, are regarded as a modification of the placoid type by the loss of the point and the addition of a hard outer layer known as ganoin. Some of the more primitive fishes of other groups have rounded scales with smooth margins, known as cycloid, and others have ctenoid scales, with comblike edges. The two last forms are found in the higher fishes. They bear neither enamel

nor ganoin. 2. The scales found over the entire surface of the body in **reptiles**, on the legs of birds (**Aves**), and to a much more limited extent in **mammals**, as on the tails of **rodents**, are quite different from the scales of fishes. Each is a modified area of the skin, thickened and hardened by the development of the horny substance, **keratin**. Scales reach their highest development among the mammals in the **pangolins** and **armadillos**. In the latter they are underlaid by bony plates. 3. The **butterflies** and **moths**, a few **beetles**, and some other insects have the surface of the body and wings more or less covered by flattened scales. These structures are modified **setae**. They often contain pigments and in many species are so formed that they produce iridescent, metallic, or glossy physical colors by breaking up the light rays which they reflect. 4. Scale **insects**, often called scales, are highly specialized sucking insects which live on plants. They belong to the order **Homoptera** and are related to the plant lice and phylloxerans. Most species are minute. The young and the female adults are simplified and remain closely attached to the plant, secreting over themselves a protective covering or scale which gives them their name. This covering is usually characteristic of the species.

Scale insects include many species of economic importance. Among them are the useful cochineal insect, a source of dye, and the lac insect whose scale is the raw material from which shellac is made. China wax is also a scale insect product. Among the harmful species the purple scale of citrus fruits, the San José scale, and the oyster-shell scale are important. Because of the protective scale these species are not easily destroyed by the usual contact sprays. They are controlled by spraying but the concentration of poison must be high and spraying during the dormant stage of the plant is often necessary as a result. Fumigation of citrus trees with cyanide is practiced extensively. This method requires special equipment since the tree must be enclosed in a tent.

In metallurgy scale is the oxide layer that forms on the surface of metals upon heating in air or other oxidizing gases. The heavy scale that forms on steel ingots or billets upon heating for rolling or forging breaks away as the metal is deformed in the mill or under the hammer; however a lighter, often very adherent scale always remains after hot-working operations and after annealing or other heat treatments unless a non-oxidizing protective atmosphere is provided. Scale is removed from steel by pickling, generally in warm dilute sulfuric or hydrochloric acid. The scale which forms on stainless steel is much more resistant and its removal requires strong acids such as mixtures of hot nitric and hydrofluoric. A tight adherent scale is often left on steel for its protective value; for example, steam-blued steel sheets are used for stovepipe. (A.W.L., R.H.H.)

SCALE, BOILER. **Water, Utilization.**

SCALE EFFECT. Any aerodynamic coefficient which changes with **Reynolds number** is said to be subject to scale effect. (See **Aerodynamics, Airfoil, Drag.**) (F.T.M.)

SCALING. **Feedwater Treatment.**

SCALLOP. Mollusca, Lamellibranchiata. *Pecten*. Marine **bivalves** of wide distribution in both shallow and deep water. The symmetrical shells are beautifully marked with radiating grooves which give them a scalloped edge. The large muscle which closes the shell of the scallop is eaten but the body is discarded. (A.W.L.)

SCALLOPED BUTT STRAP. **Riveted Joints.**

SCALP. The soft tissues covering the vertebrate cranium. The term is usually applied only to man, and usually only to the part of the covering of the **skull** which normally bears hair. (A.W.L.)

SCANDIUM. Symbol: Sc. Atomic number: 21. Atomic weight: 45.10. Melting point: 1200° C. No isotope, but of single atomic form: 45. Type of compounds: Sc_2O_3. Color of salts: Colorless. Discovered by Nilson in 1879, but predicted by Mendeleeff in 1871 as an element to be discovered with properties resembling **boron**. Occurs in a few uncommon minerals, e.g., **wolframite**, sometimes to the extent of 2% oxide. A member of the **cerium** sub-group of the rare earth metals. (R.K.S.)

SCANNING. **Television; Facsimile.**

SCAPHOPODA. The tooth shells. A small class of **mollusks** with slender tapering shells open at both ends. The foot projects from the larger end of the shell, together with a group of slender tentacles called captacula which arise from the poorly developed head. These captacula have sucker tips and are sensory. In many details of structure the animals are intermediate between the classes **Gasteropoda** and **Lamellibranchiata.** They are marine, burrowing in the bottom by means of the foot. (A.W.L.)

SCAPOLITE. **Wernerite.**

SCAPULA. The shoulder blade of the vertebrates. **Skeletal system.** (A.W.L.)

SCARAB. Insecta, Coleoptera. A species of **beetle** which was regarded as sacred by the ancient Egyptians. The term is applied especially to the sculptured likenesses of the beetle. From this name the family Scarabeidae has arisen, containing, among the many North American species, the **June bugs** or May beetles, the **tumble bugs**, and the **rose chafer.** (A.W.L.)

SARD. **Chalcedony.**

SCARLET FEVER (**Scarlatina**). An acute infectious disease caused by the hemolytic *Streptococcus*. Scarlet fever was first described by Sydenham in 1675. Previous to that time it had been confused with measles and **rubella.**

It is essentially a disease of childhood and the morbidity and mortality decreases with the age of the patient. The black race is more immune to the disease than the white race. Epidemics are more common in the fall and winter. The infective streptococcus usually enters through the throat, localizing at first in this area. Infection occurs by direct contact but may be conveyed indirectly by infected objects. The incubation period varies from 2 to 5 days. The more severe the disease, the shorter the incubation period.

The onset of the disease is acute. Vomiting, fever and sore throat are the commonest early symptoms. Often there is an area of pallor around the mouth and nose. The rash does not appear until 12–24 hours after the onset, and usually spreads over the entire body. The rash is quite characteristic: the skin is suffused with a reddish blush and is uniformly covered by a fine granular eruption. The palate and roof of the mouth are involved in the eruption, and the tongue is red, smooth, and dotted with a few large papillae. The throat symptoms may be severe and swelling of the neck glands may occur. The fever usually remains high for 3–5 days and then decreases gradually. Peeling or desquamation begins within 3–10 days after the disappearance of the rash and is complete in 2 or 3 weeks on the body, longer on the hands and feet.

The rash and the prostration of scarlet fever are due to the toxin produced by the hemolytic streptococci. Against this phase of the disease an effective antitoxin (see **Serum**) which neutralizes the toxin is available. **Penicillin** and **sulfonamides** may be used also, especially in complications such as purulent **sinusitis, otitis media,** etc. (R.S.M., D.M.H.)

SCARLET RUNNER. **Bean.**

SCARP. The word scarp is an abbreviation of escarpment, and either term may be used to designate a vertical or steep cliff which has resulted from **erosion** or **faulting.** If due to the latter cause, the term fault-scarp is commonly used. An erosional escarpment developed upon beds which tilt at a very gentle angle gives rise to an asymmetric ridge called a **cuesta.** If the beds are of variable hardness several cuestas, one behind the other may develop. Examples of this condition may be seen on the Atlantic and Gulf Coastal plains. (R.M.F.)

SCATTERING. When light enters a body of matter, however transparent, part of it is diffusely reflected or "scattered" in all directions. This is due to the interposition in the light stream of particles of varying size, from microscopic specks down to electrons, and the deflection of light quanta resulting from their encounters with these small obstacles. Similar effects are produced upon infra-red, ultra-violet, x-rays, and other forms of **electromagnetic radiation,** and upon streams of particles such as **cathode rays** or alpha rays.

The scattering of light was carefully studied by John Tyndall, who used fine suspensions in air and liquids; and also by Ångström and by Lord Rayleigh. The laws of scattering depend upon the nature of the scattering particles. For very fine dust, Rayleigh concluded that the intensity of the light of wavelength λ, scattered in any direction making an angle θ with the incident direction, is directly proportional to $1 + \cos^2 \theta$ and inversely proportional to λ^4. The latter point is noteworthy, in that it shows how much greater is the scattering of the short wavelengths. Thus the sky is blue, and tobacco smoke appears blue, because blue light is scattered more than red. The unscattered light is of course complementary to blue, that is, orange or yellow; which explains the "warm" hues of the sunset. Scattered light is also distinctly plane-polarized (see **Polarized Light**). By far the largest part of scattered monochromatic light is of the same wavelength as the incident; but that scattered by molecules contains faint components of different wavelength; this is known as the **Raman effect.** The scattering of electrons and other particles by **atoms** has given important information as to the structure of atoms. (L.D.W.)

SCAUP. Aves, Anseriformes. A **duck.** The scaup or blue-bill, *Nyroca marila,* is found throughout the northern hemisphere and the lesser scaup, *N. affinis,* is a common North American species. Both are principally black and light gray or white. The head of the scaup duck is glossed with green and that of the lesser scaup with purple. (A.W.L.)

SCHEELITE. The mineral scheelite is **calcium tungstate,** $CaWO_4$. It is a **tetragonal** with an octa**hedral** habit although also at times tabular, and may occur massive. It displays an octahedral **cleavage;** is brittle; hardness, 4.5–5; specific gravity, 5.9–6.1; luster, vitreous; color, white to yellowish, reddish, greenish and brownish; white streak; transparent to translucent. Scheelite is found in **pegmatite** and ore veins associated with **granites,** also as a contact **metamorphic** mineral. It is known from Czechoslovakia, Saxony, Italy, Alsace, Finland; Cumberland and Cornwall in England, Mexico; and in the United States in Connecticut, Colorado, South Dakota, Arizona, Nevada, and California. It is an ore of tungsten. The Swedish chemist, Karl Wilhelm Scheele, discovered tungsten in this mineral, which later was named for him. (E.S.C.S.)

SCHICK TEST. A test for immunity to diphtheria. (See **Diphtheria.**) (D.M.H.)

SCHIFF'S REAGENT. **Acetaldehyde** and **Aldehydes.**

SCHILLERIZATION. **Luster.**

SCHIST. The schists form a great group of **metamorphic** rocks chiefly notable for the preponderance of the lamellar minerals such as the **micas, chlorite, talc, hornblende, graphite,** etc. Quartz often occurs in drawn out grains to such an extent that a **quartz** schist is produced. Most schists have in all probability been derived from clays and muds which have passed through a series of metamorphic processes involving the production of **shales, slates** and **phyllites** as intermediate steps. Certain schists have been derived from fine-grained igneous rocks such as lavas and **tuffs.** Most schists are mica schists, but **graphite** and chlorite schists are common. Schists are named for the prominent or perhaps unusual mineral constituent, as **garnet** schist, **tourmaline** schist, **glaucophane** schist, etc. The word schist is derived from the Greek meaning to split, with reference to the easy separation of these rocks in a direction parallel to that in which the platy minerals lie. (E.S.C.S.)

SCHIZOPHRENIA (Dementia Praecox). A mental illness or **psychosis,** characterized by bizarre mental and emotial reactions and oddities of behavior and thought. The disorder is relatively common; approximately 60% of chronically ill patients in state hospitals are schizophrenics. Although its fundamental cause is not known, the disease may be thought of as basically the same type of disturbance which underlies a **psychoneurosis,** except that in schizophrenia the disturbance is deeper and more far-reaching in its effects on the personality. Conflicts between the individual's desires and urges and what his conscience or society consider to be "right," feelings of guilt, insecurity and frustration are all charged with emotional tension which may lead to a psychosis.

Schizophrenia begins most frequently in adolescence or early adult life. It occurs usually in the shy, sensitive, unsociable often imaginative and idealistic individual of asthenic body build. The early symptoms are merely an exaggeration of previous personality traits: the individual tends to be more shy, hypersensitive, quick to take offence. Gradually he retires into his shell and has less and less to do with activities and people. He thus protects himself from painful experiences in what seems to him a confusing, harsh, hostile world. Part of his protection comes from his ability to alter the meaning of things to suit his own needs. Like the child, for whom a broomstick becomes a lively horse, the schizophrenic exercises his imagination to interpret words or actions in a way pleasing to himself. This leads to apparently motiveless, senseless behavior since observers cannot understand the meaning that the actions have to the patient.

The protective shell of the schizophrenic is further strengthened by his ability to get satisfaction by imagining rather than by acting or doing. This is an exaggeration of the pleasure that normal people take in day-dreams. For the schizophrenic the world of day-dreams where all of his wishes come true without effort or risk to himself, where he is brilliant, successful, always loved by his beautiful wife, admired by his friends—this world becomes far more attractive and satisfactory than the world of reality. Gradually it supplants the world of reality for him and he comes to live completely in his day-dreams.

By these processes the schizophrenic comes to be remote from the ordinary world and inaccessible to its members. When the disease is far advanced, he may have **hallucinations** and delusions of persecution. These are projections of his own fears and misgivings about himself which he is able to interpret as coming from "other people" or "the world." This is a satisfactory form of defence because it relieves him of self-criticism and any feeling of guilt.

As the disease progresses, psychiatrists speak of deterioration of the individual, but this refers to behavior rather than mental processes. Many schizophrenic patients take no interest in the outside world; they may exhibit **catatonia**: they sit quietly without moving; they stand in rigid positions and stare at a blank wall; they hold their arms or legs in curious attitudes for hours at a time; or they soil themselves and seem completely indifferent. This may be called deterioration of behavior. Yet such patients may come out of their psychotic phase, return to normal behavior and exhibit an intact memory, intelligence, and education.

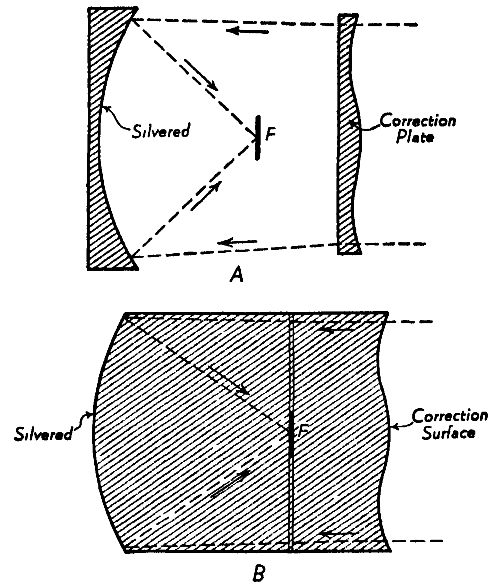
The prognosis in schizophrenia depends on the duration of the disease. In the early stages, when the patient still has insight into his difficulties, much can be done with **psychotherapy**. Later, when the individual has become accustomed to his private world and finds it pleasing and satisfactory in all respects, it is difficult to persuade him to give it up. The longer the disease has been present, and the more inaccessible the patient becomes to human contact, the less is the likelihood that he can be restored to normal. In cases of certain types, the convulsant drug, metrazol, electric or insulin-shock treatment, producing a profound stimulus to the central nervous system, have given good results. (D.M.H.)

SCHLIER. The term for streaky local segregations which occur in coarse-grained, **intrusive igneous** rocks, usually near the contact of the intrusion with the country rock. The segregations, themselves, appear to be local concentrations of minerals drawn out as lenses or stringers by the movement of the **magma** while still in the viscous state. The term is derived from the German, *Schliere* (singular), *Schlieren* (plural), referring to the streaks produced in artificial cements. (R.M.F.)

SCHMIDT CAMERA. Telescope.

SCHMIDT OBJECTIVE. An objective for reflecting **telescopes**, designed to correct the **aberration** of the spherical mirror without introducing the coma (blurring) to which even a parabolic reflector is subject for wide fields. The results are obtained in somewhat the same way that spectacles correct for defects in vision.

The Schmidt objective as originally designed consists of a concave spherical mirror, functioning in the same way as the objective of any reflecting telescope, but with a plate of glass interposed in front of it perpendicular to its axis at its center of curvature. This glass plate is not plane, but has one surface "figured" in such a way that, as the rays pass through it on their way to the mirror, it so modifies their course as to effect almost perfect correction for the spherical aberration and coma which the mirror would otherwise produce. In a later design, the objective consists of two coaxial cylinders of glass, in contact along a plane perpendicular to the axis. The rear surface of the rear piece is spherically convex and is silvered on the outside, thus presenting a concave spherical mirror to the interior of the glass cylinder. The front surface of the front piece, passing through the center of curvature of the mirror, is the correction surface, serving the same purpose as the glass plate in the older design. The reason for using two pieces is that the final real image F is of course produced between the mirror and the correction surface; and it is here that the plane of separation is located, so that the small photographic film used may be introduced. The general nature of these arrangements will be clear from the figures. (L.D.W.)



Schmidt objective: A, original design; B, the "solid Schmidt' (diagrammatic).

SCHORL. Tourmaline.

SCHUMANN REGION. Ultra-Violet.

SCHUPPEN (Literally, Scales). Used by many **structural geologists** to describe an assemblage of thrust slices which overlap like shingles on a roof. The term is used especially for this kind of structure in the Swiss Alps. Essentially synonymous with **imbricate** structure. (R.M.F.)

SCHWARZSCHILD EFFECT. A special phase of reciprocity law failure with photographic materials. (C.B.N.)

SCHWEITZER'S REAGENT. This is an ammoniacal **copper** hydroxide solution used to dissolve cellulose. (See **Carbohydrates.**) (R.K.S.)

SCIATICA. Painful irritation of the sciatic nerves, the large nerve trunks which supply the legs. Sciatica may be due to inflammation of the nerve as in **polyneuritis**, but unilateral sciatica is commonly caused by pressure on the nerve by a protrusion of the intervertebral disk between the lumbar **vertebrae**. This latter condition usually follows injury resulting from lifting. The patient complains of pain down the back of the leg, spasm of the muscles, and a limping gait. Treatment is rest in a hard, flat bed, with boards beneath the mattress, and local heat. Surgery is sometimes indicated. (D.M.H.)

SCIENTIFIC NOTATION FOR NUMBERS IN DECIMAL FORM. Standard Notation for Numbers in Decimal Form.

SCINTILLATION. Radioactive Changes; Spinthariscope.

SCINTILLOSCOPE. Spinthariscope.

SCION. Grafting and Budding.

SCLERENCHYMA. This is a tissue composed of thick-walled **cells** of various forms. These cells have small pits and walls so thick that in many cases the cavity of the cell is nearly obliterated. Mature sclerenchyma cells are dead, containing no **protoplasm.** They serve to strengthen the part of the plant in which they are found or to protect the more delicate structures within. Sclerenchyma cells are of two kinds, stone cells and fibers. Stone cells are small, irregular in shape, and only slightly if at all elongated. They may be found in the **cortex** of the stem or elsewhere in the plant, but are particularly abundant in the endocarp of certain fruits and in seeds. The flesh of pears and blueberries contains many grit particles, which are groups of stone cells. Fibers are very much elongated cells, generally with long pointed ends and with simple pits in the walls. **Hemp** and **flax** are bundles of fibers of great value to man. (R.M.W., B.S.M.)

SCLEROBLAST. Cells of **sponges** which secrete the material of the **spicules.** These cells lie in the middle layer of the sponge (the mesogloea) and are the only source of the hard parts. (A W.L.)

SCLEROSCOPE HARDNESS. Hardness.

SCOLECITE. This mineral is a **zeolite,** a hydrous **calcium-aluminum silicate,** $CaAl_2Si_3O_{10}3H_2O$. It occurs in slender **monoclinic** prisms and in fibrous and nodular masses. Hardness is 5–5.5; specific gravity, 2.16–2.4; luster, vitreous to silky; transparent to translucent. When heated, some specimens of scolecite curl up like worms, hence its name, derived from the Greek meaning a worm. This mineral occurs with other **zeolites,** at Baden, Switzerland; Iceland, Greenland; the Deccan region of India; and in the United States, at Golden, Colorado, and Paterson, New Jersey. (E.S.C.S.)

SCOLEX. The portion of an adult tapeworm (**Cestoda**) which is attached to the tissues of the host. It usually consists of a small rounded part at the end of a slender neck leading to the series of segments (proglottids), and usually bears hooks, suckers, or both. The suckers are usually two to four in number. In some species they are replaced by projections or grooves called bothria and in some they are accompanied by accessory suckers. Hooks may be located on a terminal prominence called a rostellum, and in one family they are at the end of slender retractile organs called proboscides. The scolex may be replaced by a modification of the anterior end of the segmented portion of the body (strobila) known as a pseudoscolex. (A.W.L.)

SCOLIOSIS. Abnormal lateral curvature of the spine. Although the curvature is to one side of the body or the other, there is always an element of twisting of the spine. Often it is not curvature of the spine that is complained of by patients, but instead they call attention to a high shoulder or hip, or a projecting shoulder-blade. A curvature that is mild and unnoticed in youth may become troublesome due to its increase after middle-age when there is shrinking of the cartilaginous disks between the vertebrae. Often there are no symptoms connected with this condition unless the scoliosis is of marked degree.

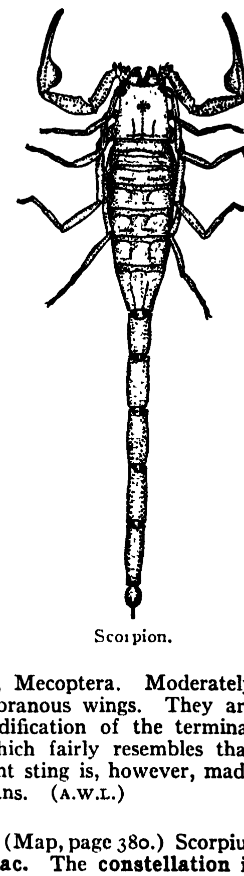
Scoliosis is usually divided into postural or functional, and organic. Many cases of the former condition are due to poor posture. With true or organic scoliosis there exist pathological structural changes in the vertebral bodies. The causes of this are usually congenital abnormalities of the spine, rickets, lung disease, tuberculosis of the spine, infantile paralysis, injuries to the vertebrae, tumor formation, etc.

Treatment of scoliosis depends on the severity, duration and damage to the vertebrae. Exercise and correction of posture play a part in the mild functional forms. In the more severe forms, various corrective braces are worn. In other cases, surgical fusion of the spine is indicated. (R.S.M., D.M.H.)

SCOLOPHORE. A spindle-shaped organ formed of sensory cells grouped about a nerve ending. It is the fundamental **auditory organ** of **insects,** appearing in a simple form in connection with the body wall and also in the more complex organs of hearing. (A.W.L.)

SCORIA. The term applied to lava which is highly vesicular and slaggy in appearance, due to the escape of the volcanic gases while the lava is still viscous. Scoria may be considered as a very coarse variety of **pumice,** the vesicles occupying approximately the same amount of space as the solid material, and extremely variable in size and shape. (R.M.F.)

SCORPION, SCORPIONIDA. A terrestrial **arthropod** with a conspicuous pair of pinchers and a slender terminal region of the body bearing a clawlike sting, and the order made up of these animals. They are grouped with the **spiders, ticks** and other forms in the class **Arachnida.**



Scorpion.

The order is characterized by the conspicuous pinchers and by the sting. The body is divided into **cephalothorax** and abdomen, and the latter consists of a broad anterior portion and a slender postabdomen. The sting, a modified **telson,** bears the opening of the duct of a poison gland. The genital ducts open on the ventral surface of the first abdominal segment, just in front of a pair of comb-like pectines of the second segment which are regarded as accessory reproductive organs.

Scorpions are common in warm dry regions. In the United States they occur as far north as Kentucky. Their poison is not virulent as a rule, although one species found in the region about Durango, Mexico, is said to be dangerous to man. (A.W.L.)

SCORPION FLY. Insecta, Mecoptera. Moderately large **insects** with four membranous wings. They are named from the peculiar modification of the terminal segments of the abdomen, which fairly resembles that of the scorpions. The apparent sting is, however, made up of the external genital organs. (A.W.L.)

SCORPIUS. (The scorpion.) (Map, page 380.) Scorpius is the eighth sign of the **zodiac.** The **constellation** is rather far south for observation in Europe and North America, but is a beautifully grouped constellation presenting more resemblance to the figure for which it is named than is the case with most of the others.

The brightest star in the group **Antares** (Alpha Scorpii) is one of the most beautiful stars in the sky. It is distinctly reddish in color and gets its name from the fact that it opposes or rivals **Mars,** the red planet, in color. It is the largest star whose diameter has thus far been measured, having a diameter approximately 450 times that of the sun. The star is so large that if it should replace the sun it would extend out beyond the planet Mars.

Beta Scorpii is a fine **double** for an observer with

a small telescope with the two components distinctly different in color. (W.K.G.)

SCOTER. Aves, Anseriformes. A **duck** found chiefly along the seacoasts, and less often on fresh waters. The American scoter, *Oidemia americana,* is a bird of the northern Atlantic, breeding from Alaska to Labrador. The white-winged scoter, *Melanitta deglandi,* breeds from the northern United States northward and is fairly common on the Pacific coast. The surf scoter, *M. perspicillata,* also breeds northward into the Arctic regions and is more generally distributed on both coasts and in inland waters. All of the species are dark colored birds with few lighter areas. (A.W.L.)

SCOTT TRANSFORMER. Transformer.

SCREAMER. Aves, Ciconiiformes. Peculiar South American birds (**Aves**), with moderately long legs and large feet. The beak is like that of the domestic fowl and the wings are provided with two stout spurs on the front margin. The birds are as large as geese and swim readily, although the toes are not webbed. (A.W.L.)

SCREE. Talus.

SCREEN GRID. This is a second **grid** introduced between the main or control **grid** and **anode** of a vacuum **tube** electrostatically to shield the control grid from the anode. In many applications the **feedback** between the anode and grid through the **interelectrode capacity** is very undesirable. By shielding these two electrodes from one another this feedback is reduced to a minimum. This extra grid converts the triode to a tetrode which has markedly different characteristics, among which are a much higher dynamic **plate resistance** and much higher **amplification factor.** The **mutual conductance** is about the same for the triode and tetrode. (L.R.Q.)

SCREEN PROCESSES. Processes of color photography in which color analysis and synthesis are carried out additively by the use of a mosaic screen of minute primary color filters. The screen may be composed of color filters in the form of a regular geometric pattern, or it may be an irregular mosaic. In either case the screen is between the color-sensitive photographic emulsion and the camera lens during analysis so that the resulting effect in the emulsion is that of three color-separation negatives side by side, completely intermingled by means of the screen's pattern.

Color screens may be prepared that are inseparable from the color-sensitive photographic emulsion, or they may be made so that they are on a separate support to be placed in contact with the emulsion. Separable screens are generally geometric and are made by ruling colored lines on the support. In 3-color screens the red, green and blue filter areas must be so adjusted that a satisfactory neutral black or white is obtained with the photographic emulsion and a suitable light source. When a negative is obtained after exposure behind such a color screen it may be reversed or printed onto another emulsion to give a positive image. When this positive is properly registered with the original, or another similar screen, the colors of the subject are reproduced.

Both regular and irregular screens are employed where the screen and emulsion are inseparable. Irregular screens may be made by dusting colored starch grains onto a sticky plate, or by mixing together small globules of colored resins. Such screens often have several thousand dyed particles per sq. in. The photographic emulsion is coated over the screen and the exposure made by light that has passed through the screen elements. The emulsion is reversed to a positive and the original screen is thus used in viewing the final color transparency.

Color screen processes have been widely used in the past but are largely being displaced by subtractive processes in the form of **integral tripacks** (see **Bipacks and Tripacks**). (H.C.C.)

SCREW FASTENINGS. Through bolts and nuts are extensively employed as removable fasteners where the bolt has an appreciable amount of clearance, usually 1/32 or 1/16", in the bolt hole. Turned or carefully fitted bolts are frequently used in reamed holes when the bolt is required to resist shearing as well as tensile forces. Bolts applied to unfinished castings or forgings are usually provided with *spot-faced* bolt head and nut seats. Cap and machine screws are used to join parts when one part has an internally threaded hole. These screws are preferable to bolts because they are easier to handle in installations where access to one end of the element is either difficult or impossible. Cap screws are available commercially in sizes from 1/4" diameter up. Oval and fillister head cap screws are often preferred to hexagonal head cap screws since the head may be recessed to avoid interference or to facilitate cleaning the part held by the screw. Hexagonal head cap screws may be fastened more tightly than screws with screwdriver slots. The fillister head cap screw with a socket head combines the advantages of the hexagonal head and the slotted fillister screw. This type is fastened by using a special wrench made of hexagonal bar stock. When a screw must be removed frequently, it is often advisable to substitute a stud that may be inserted into the threaded hole and jammed against the bottom so that it is only necessary to remove the nut, thus avoiding wear on the threads in the hole. (In aluminum alloy castings, the aero-thread may be employed instead of using a stud.)

Machine screws are similar in appearance to cap screws but have heads of somewhat smaller proportions. For major diameters see **Gauge Number.** Machine screws have American Standard thread forms in both Coarse-thread and Fine-thread Series.

Stove bolts are employed for assemblies where precision is of no great importance. They are made with either flat or round heads and the screw threads are generally rolled. The square nuts used with them are stamped from common steel. Carriage bolts have a square portion directly under the head to prevent rotation when the nut is tightened and are used for fastening wooden parts together or for fastening metal parts to wood. Expansion and hook bolts are used in semi-permanent fastenings in concrete and masonry. Electric motors and other machinery are usually equipped with one or more eye bolts so that they may be lifted readily and removed with an overhead crane. A turnbuckle is a nut that has both right-hand and left-hand threads, and is used to adjust the length of tie rods and similar devices. The turnbuckle is one of the few devices in which a left-hand thread is employed as a fastener.

Plain washers, Fig. 1, are placed under the heads of hexagonal head screws and under square and hexagonal

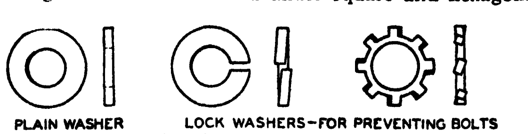


Fig. 1.

nuts to assist in seating the nut or head, or to distribute the pressure exerted. Collar screws, Fig. 2, are square head cap screws with integral washers. Rough washers are punched from common steel; finished washers may be machined from steel bar stock. Lock washers are

used to prevent accidental unscrewing of bolts and nuts, either by exerting additional tension on the threads or by biting into the surfaces in contact. It is possible to

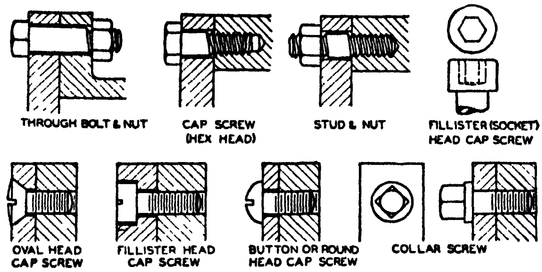

Fig. 2.

obtain button and flat head cap and machine screws with assembled lock washers that cannot drop off, a feature that will be appreciated by anyone who has ever tried to insert a screw with a loose washer in a comparatively inaccessible place.

Castellated and jam nuts, Fig. 3, are representative examples of parts for locking and fixing nuts in place.

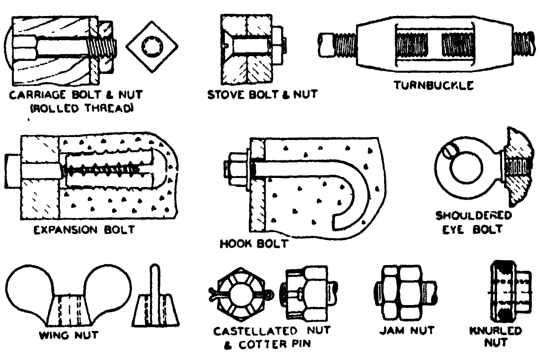

Fig. 3.

The castellated nut is held by a cotter pin and has six locking positions per turn; the jam nut holds the regular nut in position by being screwed against it. Wing and knurled nuts are designed for hand operation. Some forms of fillister head screws are supplied with knurled heads so that they may be screwed into place easily by hand, although the final tightening must be done with a screwdriver or wrench. (H.C.H.)

SCREW GEARING. Worm Gearing.

SCREW MACHINES, AUTOMATIC. Automatic screw machines are essentially full-automatic bar stock turret lathes. There are two important types: single-spindle and multiple-spindle machines. In one form of single-spindle machine, the work spindle is driven by open and crossed belts so that the spindle rotation may be reversed for threading operations. The turret rotates on a horizontal axis in a plane parallel to or coincident with the spindle axis, and has six tool stations. There are two cross-slides, front and rear, and both cross-slides and the turret slide are actuated by disk or plate cams. The bar stock is held in a collet chuck, and is advanced by a feed finger to a stop, held in the turret, or on a swinging arm. Drills, reamers, threading and knurling tools are carried in the turret; form and cut-off tools are carried on the cross-slides, but some turning tools such as knee tools and hollow mills are held in the turret and are used for heavy cuts, since end cutting imposes less strain on the work and the machine than side cutting. Side cutting and forming is generally performed with circular form tools illustrated in Fig. 1, although straight form tools are also used.

Straight and circular forming cutters are used for form turning and special profiles and can be ground without changing their shape. Fig. 1 illustrates the applica-

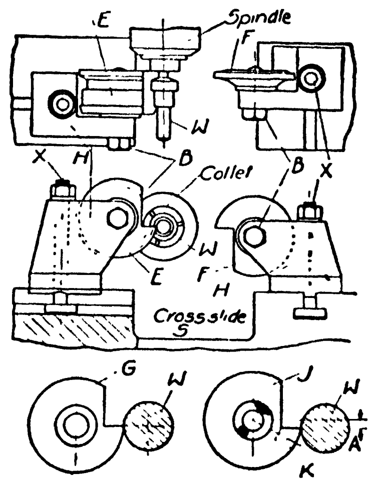

Fig. 1. Circular form tool application.

tion of front and rear circular form tools E and F on the cross-slide. Both cutters are held by clamping screws B in tool holders H; in most instances an auxiliary clamp is used to adjust the cutter to height and to give additional clamping effect. In the illustration, the front cutter is used for forming a shoulder screw blank, and the rear cutter for forming the top of the screw head and for cutting off the finished part. The holders H are keyed to the tee-slots in the cross-slide S and are clamped in place by tee-bolts X.

The cutting face of a circular form cutter is ground along a line parallel to and a distance A from a radial center line, in order to provide clearance for the cutting action and to avoid the insufficient clearance indicated in the radially-faced cutter G, Fig. 1. The center of the cutter J must therefore be set a distance A above the centerline of the spindle. The dotted line at K illustrates correct regrinding procedure.

End-cutting rough turning tools are of two general types: hollow mills and knee tools. Knee tools for automatic screw machines are generally made without an adjusting slide; the tool bit is held by two or three set screws in the solid body of the tool. Knee tools are used chiefly for taking roughing cuts on short work which is finished by a circular forming tool. Hollow mills usually consist of a hollow cylindrical body holding two or more adjustable blades, so arranged that the cutting pressure is axial rather than radial; they are usually, although not always, equipped with back rests.

Box tools are used more generally than any other type for turning straight diameters and are designed primarily for finish turning. The tools have blades which cut tangentially and are equipped with vee or roller back rests. Roller rest tools are preferred for heavy cuts when a diameter is to be turned in one cut; vee rest tools are used for finishing cuts or on free-cutting material such as brass. Box tools with several cutters for turning two or three diameters simultaneously are also employed. Tap holders and die holders are made in two styles: plain drawout type, in which the holder is sufficiently free axially in the body to permit the tap or die to lead itself after being started, and releasing type holders.

Fig. 2 shows a tool layout for machining a hexagon head screw on a single-spindle machine. In this illustration, in which the front elevation of the turret and the plan of the cross-slide is shown, T represents the turret, H a die holder, B a box tool for turning the body of the

screw, F a circular form tool for facing and forming the head, C a circular cut-off tool, and S the swinging stop. In operation, the hexagonal bar stock is brought against

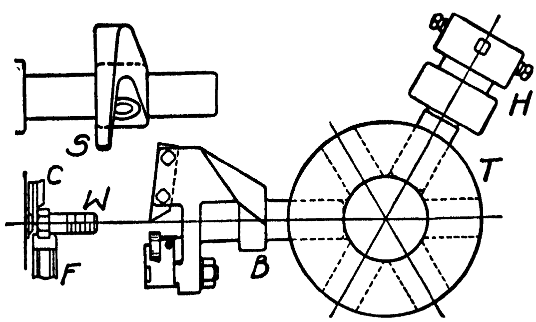

Fig. 2. Tool layout for hexagonal head screw. (*Brown & Sharpe Mfg. Co.*)

the stop S which has been swung into position; the stop is swung clear, and the screw body is turned with the box tool. During this period the spindle is rotating in a clockwise or backward direction at 780 rpm. The spindle rotation is reversed so that it runs forward at 165 rpm; during this time the turret had indexed to bring the die in the holder H to the work. The screw body is threaded and the spindle is again reversed to 780 rpm backwards, permitting the die to be withdrawn at a rapid rate. The turret slide then moves farther back and indexes to present a blank hole to the work. The circular form tool on the front slide forms the head and moves away from the work, and the rear form tool cuts off the screw, completing the cycle of operations.

Multiple-spindle automatic screw machines are made with two, four, five, six, or eight spindles for holding bar stock, and all stock is machined simultaneously. The spindles rotate in a spindle carrier which indexes around the main drive shaft that passes through the center of the carrier and drives the spindles. The turret slide carries one set of end-working tools for each spindle and can advance, feed and return in a direction parallel to the spindle axes; the machine also has two front and two rear cross-slides. Fig. 3 illustrates a threaded part made from square bar stock and shows a sequence of operations performed on a four-spindle machine. At the first turret station a forming tool held on the lower front cross-slide forms the work; a turning tool with a support or roller back rest on the end-working tool slide turns a portion of the diameter; and a spot drill held in the drill holder at the same station spots the work for the subsequent drilling operation. In the second position a forming tool held on the lower rear cross-slide completes the forming operation; a turning tool completes the turning operation; and the hole is drilled. In the third position a breakdown tool is used for chamfering the work and beveling the forward end for the next piece, and the thread is cut. At the fourth station the drilled hole is reamed to size and the part is cut off. The stock is then advanced against a swinging stop and the cycle is complete.

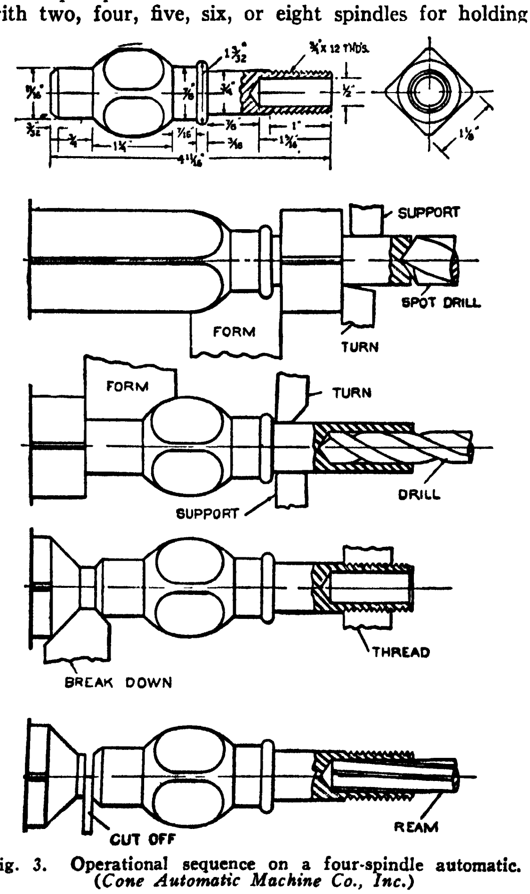

Fig. 3. Operational sequence on a four-spindle automatic. (*Cone Automatic Machine Co., Inc.*)

A multiple-spindle screw machine produces one finished part for every indexing movement of the spindle, or in the case of a four-spindle machine, four parts per complete cycle of the spindle carrier. The total production time for one part is equal to the time required to perform the longest single operation plus the indexing time. The successive turning operations at stations 1 and 2 illustrate the principle of operational divisibility; the turning operation, if handled at one station, would take far more time than any other operation and is therefore completed in two stages.

Fig. 4 illustrates a method of multiple production whereby three hexagonal nut blanks are produced for

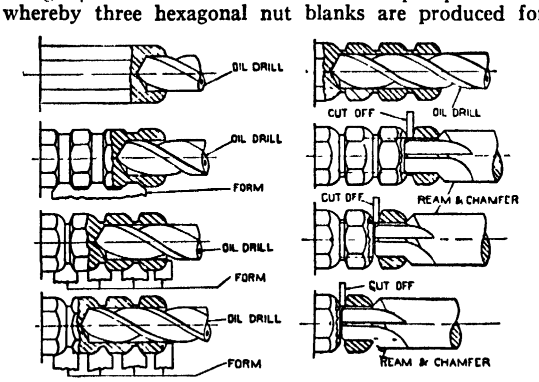

Fig. 4. Producing three nut blanks per index. (*Cone Automatic Machine Co., Inc.*)

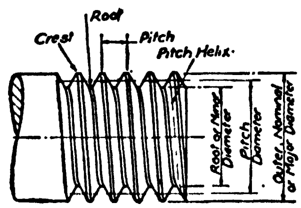
every index of the spindle carrier. Successive drilling operations are performed at the first five positions, and the three nuts are rough-formed at stations 2 and 3, and finish-formed at station 4. The first nut is reamed and chamfered and then cut off at station 6; the other two are finished at stations 7 and 8. Multiple-spindle automatics may also be equipped with magazines for second-operation work.

Multiple-spindle automatics are used for extremely high production, complicated work, or where a great deal of metal is removed. Overhead costs on multiple-spindle machines are usually higher than for single-spindle machines. Single-spindle machines are credited with more accurate work. The application of the principle of operational divisibility, however, is confined to multiple-spindle machines, and results in prolonged tool life as well as increased production rates. (H.C.H.)

SCREW PROPELLER. **Air Propeller, Water Propeller.**

SCREW THREAD. A groove with continuous helicoidal surfaces cut or formed on the external or internal surface of a cylinder. Screw threads are used as removable fasteners, or for the transmission of power. The pitch of a screw thread is the distance between adjacent crests; the lead is the axial distance the screw will advance in one revolution. The lead and pitch of the single-threaded screw shown are identical; in multiple-threaded screws two, three or more threads, 180°, 120°, etc., apart are arranged in parallel. The lead of a double-threaded screw is twice the pitch; of a triple-threaded screw three times the pitch.

Fastening screws have thread profiles with a 60° included angle with either sharp or slightly flattened crests and roots. The former, or sharp V thread, is the older form, but has been largely replaced by the American Standard form shown in the figure. The Whitworth



thread, used in Great Britain, has a 55° angle and rounded crests and roots. The Aero-thread system comprises an intermediate insert of spring wire between a threaded hole and the screw, and is useful where high-strength screws are to be fastened in soft non-ferrous parts.

Square, Acme, and Buttress thread form screws are used for power transmission. The surfaces of the Square thread are right helicoids, and the thread depth is equal to one-half the pitch. The Acme thread has an included angle of 29°, with a thread depth equal to half the pitch; it is easier to cut and stronger than the Square thread. The Buttress thread has an included angle of 45°, and one face of the thread is a right helicoid. It is employed for jack screws and gun breech-locks where power is transmitted in one direction only.

Wood screw and self-tapping or self-cutting screw threads permit the screw to cut its own thread as it is inserted in the material. The area of the thread profile on the screw is considerably smaller than the space between adjacent threads, so that greater strength is obtained in the internal threads cut in the weaker mating material.

Pipe threads differ from screw threads in that both internal and external threads are cut on a conical surface, so that the farther the pipe is screwed into the fitting, the tighter the joint becomes. The thread angle is 60°, cut on a conical surface with a taper of ¾" per ft. (H.C.H.)

SCROFULA. (Formerly called king's evil.) **Tuberculosis** of the lymph nodes of the neck. This was a common disease of childhood in many countries before the 19th century. The organisms are usually transmitted through milk, and tuberculin testing of cows and elimination of tubercle bacilli from milk are responsible for the present very low incidence of the disease in the United States.

The upper deep cervical chain of nodes is most commonly affected. The first sign is the appearance of small lumps in the neck; these gradually swell and become moderately tender; often the nodes form **abscesses** which break through the overlying skin and form chronically draining **fistulas.** Treatment consists of bed rest; at times, sunlight and x-ray; and sometimes surgical excision if abscess formation is extensive. (D.M.H.)

SCROLL CASE. **Hydraulic Turbine.**

SCROTUM. A sac-like structure containing the two testicles, situated behind and below the penis. It is divided into two compartments by a septum in the middle. (R.S.M.)

SCRUBBER. Gases produced in industrial plants usually originate laden with impurities which render them unfit for the use to which they are to be put. For example, the gas taken from a blast furnace is so dust-laden that, were it used directly in gas engines, the cylinders would soon become badly worn and scored. Scrubbers are means for removing such substances from gas. The scrubbing action is one wherein a liquid, commonly water, is brought in contact with the gas in various ways. Chiefly dust and sulfur dioxide are removed by scrubbers. Other substances in gases are removed by equipment in series with the scrubber; for example, tar extractors. The scrubber has competitors such as electrostatic dust precipitators, centrifugal cleaners, and chemical precipitators. Scrubbing is accomplished in a tower through which the gas is made to pass, generally in counter-current arrangement with respect to the water. The equipment available commercially includes rain-type scrubbers, spray scrubbers, and hurdle scrubbers, the latter being a maze of staggered slats which are wetted, so that the dust impinging upon them will be retained by the water film. (F.T.M.)

SCULPIN. Pisces, Teleostei. A fish (**Pisces**) of the family Cottidae. They are peculiar fishes, usually small, with a broad depressed head and large pectoral fins. They are of no importance as food fishes. Many of the included species bear other names, including the little miller's thumbs of fresh waters and the sea raven which ranges from Cape Cod to the Arctic. One species of the northern Atlantic coast is called the big sculpin, or daddy sculpin. (A.W.L.)

SCURVY. A deficiency disease due to lack of **vitamin** C in the diet. Scurvy was probably first observed as a disease by Hippocrates. In the 13th century it was a curse to Crusaders. In time of war it has killed untold numbers in armies and navies and besieged towns. During the days of sailing ships, often taking months between ports with the resulting lack of fresh food, it affected the crew as a plague. It was even of considerable importance in World War I. In civilized countries its chief importance is in pediatrics and in adult life it is seldom seen. It is rarely seen in breast-fed children but pasteurization of cow's milk destroys the vitamin C and an addition to the diet of this vitamin must be provided for infants under 1 year of age.

The disease can be produced or cured at will by depriving or increasing the vitamin C in the diet either in pure form, as cevitamic acid, or as fruit or vegetables. About 6 months are required to produce scurvy experimentally, as individual susceptibility and quantity of vitamin C previously stored in the body play a part. The earliest sign of scurvy is usually a sallow or muddy complexion, a feeling of tiredness, general weakness, and mental depression. Soon the bones are affected and increasing pain and tenderness develop. The teeth decay easily, become loose and often fall out while the gums bleed easily and are sore. Changes in the blood vessels occur, producing hemorrhages in different parts of the body. In infants, irritability, loss of appetite, fever, and **anemia** also occur. Untreated scurvy is always fatal but this is seldom seen at present due to the prompt curative response obtained from **vitamin C.** (R.S.M., D.M.H.)

SCUTUM. 1. A shield-like plate on the upper surface of the body of a **tick**. 2. A subdivision of the exoskeleton of an **insect**. The dorsal plate of each segment of the thorax may be divided into as many as four parts. In such a series the scutum is the second from the anterior end. (A.W.L.)

SCYPHISTOMA. A larval stage of the jellyfishes (Scyphozoa). The individual first becomes a **planula** larva. This stage develops into the **hydratuba** which is regarded as a greatly reduced polyp stage. The hydratuba is an attached form which may send out a creeping process (stolon) capable of producing other individuals by budding, but sooner or later it undergoes a transverse segmentation to form other individuals. In this stage it is known as a scyphistoma. The segments are saucer-like structures which break away from the scyphistoma as free-swimming ephyra larvae. Each of them develops into an adult jellyfish. (A.W.L.)

SCYPHOMEDUSAE. The jellyfishes. A synonym of **Scyphozoa.** (A.W.L.)

SCYPHOZOA. The jellyfishes. A class of the phylum **Coelenterata** made up entirely of marine animals which are, with very few exceptions, floating forms. The jellyfishes represent the highest development of the **medusa** form of coelenterates, and have lost the **polyp** stage with the exception of the reduced **hydratuba** larva.

Jellyfishes owe their name to the great development of the middle layer of the body (mesogloea), which is a bulky and jelly-like mass. They contain a high percentage of water, sometimes as great as 96%, and are consequently soft-bodied and without rigid support. In the water, however, they are delicate and beautiful. Many are filmy transparent creatures while others are beautifully colored. They are found at various depths and in various seas, and in size they range from species less than 1″ in diameter to the large *Cyanea* with a body 6–7′ in diameter and tentacles 120′ long. They are of no economic importance.

The class is divided into five orders:

Order Stauromedusae. Body conical, forming a short aboral stalk by which it is temporarily attached. Margin with eight lobes bearing clusters of knobbed tentacles.
Order Coronatae. Body constricted near the middle. Margin deeply lobed, usually with long tentacles.
Order Cubomedusae. Somewhat cuboidal, with one tentacle or a group at each angle.
Order Semaeostomeae. Mouth 4-angled, with a long lip, often frilled, at each angle. Tentacles often long.
Order Rhizostomae. Mouth with eight long branched lobes. Margin without tentacles. (A.W.L.)

SEA ANEMONE. A complex **polyp** of the class **Anthozoa.** Although closely related to the **alcyonarians** and **corals** the sea anemones are usually solitary and in some species are large and beautifully colored. They are without hard supporting structures such as the related forms possess. (A.W.L.)

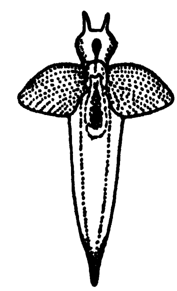
SEA ARROW. Mollusca, Chephalopoda. Small slender **squids,** *Omma strephes,* which swim very rapidly. Also called flying squids. (A.W.L.)

SEA BAT. Pisces, Plagiostomi. The giant **ray** or devil fish. (A.W.L.)

SEA BEAR. Mammalia, Carnivora. Fur **seal.** (A.W.L.)

SEA BREEZE. When coastal land is heated considerably by the sun a sea breeze springs up, blowing off the cool water onto heated land. A pure sea breeze is usually not more than 1500′ deep, above which there is a weak returning anti-sea breeze. (P.E.K.)

SEA BUTTERFLY. Mollusca, Gasteropoda. Mollusks with the foot formed into two wing-like lobes which propel the animal through the sea by slow flapping movements. They make up the order **Pteropoda.** (A.W.L.)



Sea butterfly.

SEA COW. Manatee. Sea Cucumber. Holothuroidea.

SEA ELEPHANT, ELEPHANT SEAL. Mammalia, Carnivora. *Mirunga.* A large **seal** once widely distributed in the southern hemisphere and represented by a variety on the California coast. The species reaches a length of 16′. The name refers to the short proboscis of the male. These seals were hunted extensively for their oil and are no longer found at some of their former haunts. (A.W.L.)

SEA FAN. Coelenterata, Anthozoa. Marine **polyps** of the order **Alcyonaria** whose colonies are in the form of thin lacy fans. (A.W.L.)

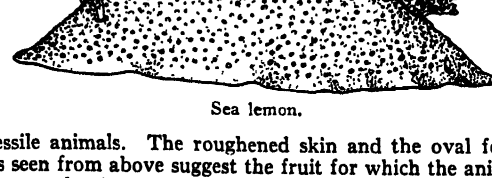
SEA FEATHER. Coelenterata, Anthozoa. Marine **polyps** of the order **Alcyonaria.** The colony has a central stalk bearing lateral branches, the whole resembling a feather in appearance. (A.W.L.)

SEA HARE. Mollusca, Gasteropoda. A marine **mollusk** of oval form with two ear-like tentacles near the anterior end which give it this name. The **mantle** almost conceals the shell and the foot forms two lobes by which the animal swims. Sea hares live on seaweed. (A.W.L.)

SEA HEDGEHOG. Pisces, Teleostei. Marine fishes (**Pisces**) with spiny skin. They are able to inflate the body to an almost spherical form by swallowing air, hence they are also called globe fishes. (A.W.L.)

SEA HORSE. Pisces, Teleostei. *Hippocampus.* Marine fishes (**Pisces**) found chiefly among seaweeds in the warmer seas. They swim weakly in a vertical position and attach themselves to some support by the prehensile tail when at rest. The body is marked by ridges in a pattern of rectangles, often prolonged into short spines or long leafy projections resembling the weed in which the animal lives. The elongate snout gives the head a faint resemblance to that of a horse. (A.W.L.)

SEA LEMON. Mollusca, Gasteropoda. A flattened oval marine **mollusk** which feeds on sponges and other sessile animals. The roughened skin and the oval form as seen from above suggest the fruit for which the animal is named. (A.W.L.)



Sea lemon.

SEA LEOPARD. Mammalia, Carnivora. A large **seal,** *Stenorhynchus leptonyx,* of the southern hemisphere. It is yellowish or tawny with gray spots. Also called the leopard seal. (A.W.L.)

SEA LEVEL. The mean level of the oceans is known as sea level. (P.E.K.)

SEA LILY. Crinoidea.

SEA LION. Mammalia, Carnivora. Animals closely related to the seals. They belong to the same family as the fur seals and with them differ from the other seals in having external ears. The common sea lion, *Zalophus californianus*, is found on the Pacific coast of Mexico and California and Steller's sea lion, *Eumetopias stelleri*, ranges from Bering Strait to southern California. (A.W.L.)

SEA MILL. Pot Hole.

SEA MOUSE. Annelida, Polychaeta. A marine worm, *Aphrodite hastata*, of compact oval form, covered above and on the sides with a felt-like material. It is recorded from Vineyard Sound on the Atlantic coast. (A.W.L.)

SEA PEACH. Chordata, Ascidiacea. An ovoid **ascidian**, *Halocynthia pyriformis*, found in European waters and along the north Atlantic coast of North America. It is ovoid in form and yellowish to pink or red in color, with a velvety surface. (A.W.L.)

SEA PEN. Coelenterata, Anthozoa. Colonial **polyps** related to the sea feathers but with much shorter lateral branches or none. (A.W.L.)

SEA SERPENT. Reptilia, Sauria. Although the term has come to mean almost invariably a fantastic myth of some great monster, there are true sea **snakes** of several species belonging to a group related to the cobras. They are only moderately large. The body is compressed as an adaptation for swimming and the snakes are so thoroughly aquatic that they are either clumsy or helpless when cast ashore.

These snakes are poisonous. The short fangs are near the front of the upper jaw and are grooved. The poison acts on the nervous system, like that of the related cobras.

Sea snakes are confined to the tropical oceans, chiefly the Indian ocean and the western Pacific. A single species, *Pelamydrus platurus*, extends to the eastern Pacific. (A.W.L.)

SEA SLUG. Mollusca, Gasteropoda. Marine **mollusks** with compact bodies and without shells. Some species have branching processes on the surface of the body by which they breathe. The creeping habits and general form are similar to those of the terrestrial slugs, although there is no closer relationship between the two. The sea slugs make up the order Nudibranchiata. (A.W.L.)

SEA SPIDER. Pycnogonida.

SEA SQUIRT. Ascidiacea.

SEA STAR. Starfish. **Asteroidea.**

SEA URCHIN. Echinoidea.

SEA WALNUT. Ctenophora.

SEA WOLF. Pisces, Teleostei. One of the wolf fishes, a group of species of fishes (**Pisces**) related to the blennies but much larger. The common wolf fish, *Anarrhichas*, attains a length of 4′ and is an important food fish in Norway and Greenland. Its range extends to Cape Cod. The name wolf fish refers to the large teeth with which the jaws of these fishes are armed. (A.W.L.)

SEAL. Mammalia, Carnivora. Animals whose bodies are highly specialized for life in the ocean although they are still able to move about on land rather clumsily. The fore limbs are paddlelike flippers and the hind limbs are shifted so that they lie close together on opposite sides of the rudimentary tail and serve as a powerful propeller, increasing the effectiveness of the vertical undulating movements by which the animal swims. The body itself is formed to offer little resistance to the water in swimming.

The fur seal represented on the Pacific coast by *Callorhinus alascanus* was once abundant in both hemispheres, but was threatened with extermination by the relentless hunting practiced until the present century. They are killed when they come ashore at their breeding grounds and under present conditions hunting does not interfere with the normal propagation of the species. The Pribilof Islands are an important center for these well-known seals. Fur seals are also called sea bears.

In addition to the fur seals the group includes many other species, among them the harbor seal, *Phoca vitulina*, hair seals, hooded seal, *Crystophora cristata*, and elephant seal, *Mirunga*, in addition to the related **sea-lions.** (A.W.L.)

SEAL OIL. Esters.

SEAPLANE. A seaplane is an airplane designed to rise from and alight upon the surface of the water. In common usage a float-type seaplane is meant. Flying boats are not often referred to as "seaplanes." Seaplanes may be classified as:

1. Float seaplanes. Floats attached below fuselage.
2. Flying boats. Hull and fuselage are one and the same.
3. Amphibians. May be either float seaplanes or boats. Auxiliary retractable wheels are provided. These are lowered into position when alighting on land.

The float seaplane is found in single- and twin-float types. Except for some military seaplanes which are single-float, seaplanes generally have 2 floats, these being placed approximately where the wheels would be located on a landplane. Some commercial aircraft have been designed to accommodate either wheels, floats, or skis on the undercarriage structure. Twin floats are always used for the large long-range bimotored seaplanes. The floats are attached rigidly to struts which extend from the fuselage or wing structure. No shock absorption device such as the oleo strut of a landplane, is used. The floats have rudders for use in slow taxiing. Air pilotage of a float seaplane differs but little from that of a wheeled airplane, but taxiing on the surface, taking off, and alighting are quite different and require special technique.

Flying boats replace the float-seaplane type in the larger categories. Although this does not mean that small boats are not built, it is a fact that most small seaplanes are on floats.

The flying boat has a hull which not only provides buoyancy but also houses crew, passengers, and cargo, and fulfills all other requirements of a fuselage. As the lateral stability of a boat is poorer than that of the two-float seaplane, it has wing-tip floats to prevent submergence of a wing tip when in rough water, making a fast turn, etc. Engines and wings need to be elevated well above the water surface to avoid waves and spray. There are different ways of accomplishing this, depending on the size and type of the airplane. Extremely large boats are deep-hulled, and a high-wing position is high enough off the water to allow engine nacelles on the wings. Gull-wing designs are sometimes adopted in order to increase this clearance (see Fig. 1). Smaller hulls will generally have a *cabane* structure to hold the wing above the hull. The engine is then mounted either on the wing or above it. Biplane boats have the lower wing mounted at the top of the hull, or above it, this making the wing cellule high enough so that the engine can be mounted between

the wings. When the engine thrust line is well above the center of gravity the thrust produces a nosing down moment which must be corrected by a heavy down-load

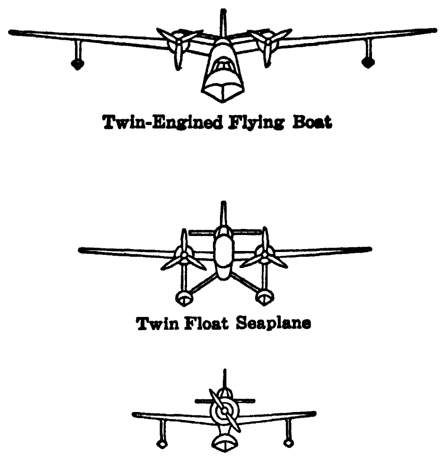


Fig. 1. Marine aircraft typical flotation systems.

on the tail. For this reason climbing after take-off must be slow and cautious until maneuvering altitude is gained for, if the angle of attack is held near the limit, a sudden partial or complete loss of thrust, due to engine difficulties, would result in a stall before the tail balance load could be relieved.

Since take-off distance of a flying boat is not as limited as for the land airplane, acceleration is of a lower order, permitting use of higher power loading. Comparison of large flying boats with large landplanes finds the boats with wing loadings (lbs. per sq. ft.) approximately the same as landplanes and power loadings (lbs. per hp.) 50% higher.

The hydraulic shapes of floats and hulls are similar. In Fig. 2 a typical flying boat hull is shown. The abrupt

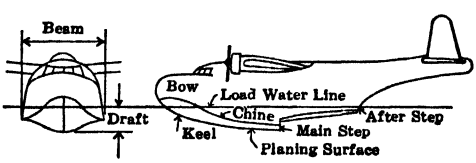

Fig. 2. Elements of the hull.

step on the keel is for the purpose of breaking the suction of the water on the planing surface so that the airplane can take off without the wing lift being greatly in excess of the weight. However, there is always some water suction and take-off speed must exceed stalling speed. The total water displacement of the floats or hull is from 2 to 4 times the airplane weight. This gives a factor of safety against excessive submergence in rough water and when alighting; also, it causes the hull normally to ride high in the water. The under surface must be shaped so that the airplane will "plane" the water at high speed, otherwise the power required to get up take-off speed would be prohibitive.

The take-off run of a seaplane is more often measured by seconds rather than in feet of travel since the water surface available is seldom restricted. Forces acting during the take-off run are pictured in Fig. 3. At the start the weight is supported entirely by buoyancy derived from the displacement of the hull. The propeller thrust moves the hull forward, creating water resistance and air drag. As the thrust is in excess of the combined air and water resistances, the boat continues to accelerate. Although air drag is small and increases slowly, water resistance increases rapidly until the hull rises and planes the water, thus substituting dynamic reaction of the water for most of the displacement buoyancy. The boat is then riding the water "on the step." Support of the airplane is gradually shifted from water reaction to wing lift as the airplane accelerates to higher speeds. As the hull shifts from buoyancy by displacement to water thrust by planing the resistance of the water to forward motion decreases because of the lower frictional drag of a planing hull and the gradual decrease of water reaction needed as the wings take more of the load. The peak of water resistance is at the

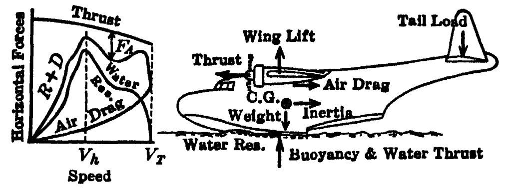

Fig. 3. Flying boat planing "on the step" (forces acting before take-off).

"hump" speed V_h. A hull with a 10-ft. beam will have its hump speed at about 40 m.p.h. Other hulls of similar shape, but different beams, will exhibit a hump speed varying in proportion to the square root of the beam. As Fig. 3 shows, the combined air drag and water resistance decrease for some increase in speed beyond the hump, then may rise if air drag increases faster than water resistance decreases. When the speed has increased to the point V_T, where wing lift is sufficient for air support of the seaplane, take-off occurs and water resistance becomes zero. In order to accelerate continuously the thrust must be in excess of the sum of water resistance and air drag. The difference F_A (Fig. 3) will produce an acceleration of F_A (mass of the seaplane). It is seen that this acceleration is not at all uniform during the take-off run. The take-off time can be estimated as the area enclosed by a curve of the reciprocal of acceleration plotted against speed.

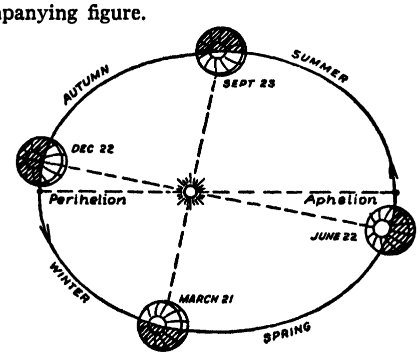
Hulls and floats are constructed of plywood or sheet metal. Customarily they are designed as stressed skin structures, with transverse bulkheads and longitudinal stringers stiffening the skin. The bulkheads divide the interior of floats into water-tight compartments so that punctures caused by accidental contact with floating debris will not result in sinking. (F.T.M.)

SEASICKNESS. This disorder and other similar disorders such as car and airplane sickness are caused by unusual and continuous movements stimulating the equilibrium apparatus of the ear. The unusual stimulation causes reflex symptoms such as headache, nausea and vomiting. The susceptibility of persons varies with the individual, and in certain cases is very marked. (R.S.M.)

SEASON CRACKING. Spontaneous cracking of brass and other metals on standing. Intergranular cracks result from the action of residual internal stresses from **cold-working** operations aided by surface **corrosion.** Cold-worked high-zinc brasses sometimes fail during storage in ordinary atmosphere. Ammonia salts and other specific reagents greatly accelerate cracking in brasses subject to this defect. Many other metals, including **stainless steels,** are subject to cracking under certain conditions of stress and corrosion. (R.H.H.)

SEASONS. The fundamental causes of the seasons are the inclination of the **earth's equator** to the plane of the **ecliptic** and the revolution of the earth about the **sun.** Since the equator is inclined at an angle of approximately 23°.5 to the plane of the ecliptic, and this angle remains approximately fixed, the **declination** of the sun varies between 23°.5 north on June 21st and

23°.5 south on December 21st. Intermediate between these two dates, on March 21st and September 21st, the declination of the sun is zero. The general characteristics of the earth's motion about the sun are shown in the accompanying figure.



The seasons in the northern hemisphere. This hemisphere is tipped farthest toward the sun at the summer solstice (June 21), and farthest away at the winter solstice (December 21). About the first of January the earth arrives at perihelion.

The amount of heat that a particular spot on the earth receives from the sun in 24 hours is dependent upon three factors: the angle which the line from the earth to the sun makes with the surface of the earth, the time that the sun is above the horizon, and the distance of the earth from the sun. The first two factors depend fundamentally upon the declination of the sun and are the most important effects in the production of seasonal changes. Neglecting for the moment the slight changes in distance of the earth from the sun due to ellipticity of the orbit, and neglecting also the effects of clouds, haze, and dust in the atmosphere, it may be shown that the amount of heat received in one day at any spot on the surface of the earth will be a maximum on that date when the declination of the sun is closest to the **latitude** of the spot on the earth. Points north of latitude 23°.5 north will receive the maximum amount of heat on June 21 while points south of 23°.5 south will receive the most heat on December 21. The zone on the surface of the earth bounded by the parallels of latitude 23°.5 north and 23°.5 south is known as the torrid zone. The boundaries called the tropics of **Cancer** and **Capricorn,** the names being derived from the signs of the **zodiac** in which the sun is located in June and January. Within the regions north of 66°.5 north and south of 66°.5 south the so-called midnight sun may be observed. The parallels of latitude bounding these zones are known as the arctic and antarctic circles.

Examination of the accompanying figure will show that the earth passes through **perihelion** during the winter season in northern latitudes. In accordance with the **Keplerian law of areas** the motion of the earth is most rapid during this period and the time required for the sun to go from the autumnal to the **vernal equinox** should be shorter than the remainder of the year. Examination of the **calendar** will show that there are 181 days from September 21 to March 21 as compared with 184 days between March 21 and September 21. Furthermore, at perihelion the sun is closer to the earth than at aphelion and hence the heating effect should be greater. While these effects are slight, nevertheless climatic statistics indicate that winter in the northern hemisphere is somewhat milder than the same season in corresponding southern latitude, while the northern summer is somewhat more temperate.

In accordance with the theory of the seasons the hottest portion of the year in the northern hemisphere should be about June 21 while the coldest should be about December 21. Examination of temperature statistics indicates that there is a distinct lag in the seasons, the warmest period coming about August 1 and the coldest about February 1. The temperature of a certain region on the earth depends upon two factors: the amount of heat received per day and the amount radiated away. The amount received depends upon the factors which we have just discussed while the amount radiated away depends in turn upon the temperature of the radiating substance, the rate of **radiation** being greater the higher the temperature. On June 21 the amount received is a maximum, but the temperature of the ground has not yet risen to a point sufficiently high to radiate away as much heat as is received. For the next few weeks, the amount received per day decreases, but, since the rate of radiation is not yet as great as the rate of reception of heat, the temperature continues to rise until about the first of August when the balance point is reached. From this date the temperature continues to fall. On December 21, the rate of reception is a minimum and the rate of radiation is in excess of the amount received per day. In spite of the fact that the amount received per day steadily increases from this date, the rate of radiation continues to exceed the rate of reception until about February 1 when the balance point is reached and the earth begins to warm up.

The seasonal conditions in any particular locality are greatly modified by local conditions of altitude, character of the soil, etc. Furthermore, the atmosphere serves both as a blanket and also as a method of transporting heat by convection from one portion of the earth to another. In this connection it is interesting to refer to an old problem of Professor Young in which he asked students to prove that "If weather was used on the spot where it is made, the hottest place on the earth would be the south pole on January 21st." (W.K.G.)

SEBACEOUS CYST. A **cystic** structure developing in the skin, due to plugging of a duct leading from a sebaceous **gland.** The cyst may increase in size, and some become infected. Sebaceous cysts are commonly called wens and are often seen on the scalp and face as well as other parts of the body. They always contain a white cheesy material.

Treatment is by surgical excision. If the entire cyst wall is not removed recurrence is certain. (D.M.H.)

SEBACEOUS GLAND. A gland of the skin of mammals which secretes an oily substance (sebum). These glands are usually associated with hair follicles and in man are especially abundant in the scalp, although they occur all over the body with the exception of the palms of the hands and soles of the feet. Their secretion keeps the skin pliable and anoints the hair.

In structure these glands are of the compound alveolar type. Their secretory parts are saccular, discharging to a common duct which often opens in the hair follicle. (A.W.L.)

SEBORRHEA. A variety of disorders of **sebaceous glands** are included in this clinical term. The dry, scaling form, "dandruff," is characterized by the presence of fine, branny, slightly greasy scales, which are readily shed. It is common on the scalp but may spread down over the face, neck and ears, and may even be a generalized **dermatitis.** The oily variety is associated with an excess secretion of oil by the sebaceous glands of the scalp and skin. The scalp is covered with a greasy layer which may mat the hair together; this type is associated with permanent baldness. Treatment consists of frequent washing of the hair, the application of olive oil, and of various lotions containing sulfur, resorcin, salicylic acid, or ammoniated mercury. (D.M.H.)

SECOND. **Time.**

SECONDARY. The secondary winding of a transformer is the winding from which the power is taken. Secondary **electrons** are electrons which have been

knocked from an electrode of a **tube** by bombardment by high-speed electrons. (See **Secondary Emission; Transformer; Induction Coil.** (L.R.Q.)

SECONDARY EMBRYO. An individual formed by budding from another that has not yet completed its development. The term is applied to the **bryozoans.** A modified chamber, the **ovicell,** forms a brood pouch in which the fertilized ovum develops into a primary **embryo.** From this individual the secondary embryos are derived. A similar succession of forms occurs in other **phyla,** as in the complex life cycle of the liver flukes, although different terms are used to designate the different stages. (A.W.L.)

SECONDARY EMISSION. This term refers to the result of any of several different processes, in each of which some kind of "primary" emission, when it encounters some form of matter, gives rise to another emission of the same or of different character.

The most familiar example of a secondary emission is the **x-rays,** which have their origin in the impacts of high-speed electrons (cathode rays) upon atoms of matter. The resulting x-rays may themselves act, in turn, as the primary emission and, falling upon solid bodies, cause a secondary x-ray emission. Or they may fall upon a fluorescent substance (see **Luminescence**) and give rise to a secondary radiation of visible light. X-rays, ultra-violet, or light, falling upon a photosensitive metal, may cause a secondary emission of photoelectrons. (See **Photoelectric Phenomena.**) The "recoil" electrons from the Compton scattering of x-rays constitute one form of secondary emission. (See **Compton Effect.**)

A general rule, known as Stokes' law, states that the energy quanta of a secondary emission do not exceed, and are usually less than, those of the primary emission causing it. In case both primary and secondary emission are radiation, this amounts to saying that the secondary radiation is of lower frequency and greater wavelength than the primary radiation (See **Quantum Theory.**) Thus "hard," short-wavelength, highly penetrating x-rays may pass right through the human body without serious damage to the tissues and then, encountering a metal or other solid object, give rise to much more dangerous secondary rays of longer wavelength, which must be guarded against.

In the investigation of the **cosmic rays,** much uncertainty arises as to what part of the observed effects are due to the cosmic rays themselves and what to secondaries induced by them. (L.D.W.)

SECONDARY ENRICHMENT. The concentration of valuable (ore) minerals in an ore body by the oxidation and leaching of the original ore above the **ground water** level. (R.M.F.)

SECONDARY FLAGELLUM. A small branch of the **antenna** of **crustaceans.** The whip-like terminal portion of the antenna is called a flagellum. In species with more than one of these structures the smaller flagellum is designated as secondary. The term is not to be confused with the flagella of 1-celled animals. (A.W.L.)

SECONDARY SEXUAL CHARACTERS. The characters of living things whose appearance is definitely associated with the sex of the individual, although the characters have no direct connection with the process of reproduction.

The different colors and patterns of the two sexes in many species of birds and insects are familiar examples of secondary sexual characters. Horns of some males, the manes of many male mammals, and the spurs of cocks are also in this category. In some species the differences resulting from such characters are so great that the two sexes can scarcely be associated by appearance. Cases are on record among the insects of the classification of males and females of the same species in different genera prior to the discovery of their relationship through other evidence. (A.W.L.)

SECONDARY STRESS. Stress.

SECRECY SYSTEMS. In much of the two-way radio telephone links it is highly desirable to make the transmission secret. Since the radiated energy may be picked up by any **receiver** tuned to its frequency and in its path, the transmission must be altered so it is unintelligible to anyone not having the necessary equipment to restore it to its original form. Not only is the equipment necessary, but these secrecy systems can be decoded only by a receiving station having the key to the original alterations. There are several methods of scrambling or altering speech transmissions so they will be unintelligible to the ordinary receiver. One method is to produce the usual amplitude **modulation** on some frequency other than that of the final **carrier.** All but one **sideband** of this modulation is discarded and this sideband is then modulated upon the desired carrier in such a manner as to invert the frequencies, i.e., the low frequencies now appear as highs and vice versa. A numerical example will perhaps serve to explain the process. Assume a speech range of 200 to 3000 cycles is modulated on a carrier of 100,000 cycles and the upper sideband is utilized. This is a band from 100,200 to 103,000 cycles. If this is now heterodyned with a signal of 103,200 cycles, there will result a band of frequencies from 200 to 3000 cycles but the 200 cycles is due to the original 3000 cycles and the 3000 to the original 200 cycles and in a similar manner all intermediate frequencies have been interchanged. This new band can then be modulated upon the final carrier and transmitted. To obtain the original speech channel at the receiver the reverse process must be followed and it is necessary for the receiving station to know all the intermediate frequencies used at the transmitter. Since as many intermediate steps may be interposed as desired almost any degree of secrecy may be obtained. Another method is to divide the audio band into narrow bands by using **filters** and then interchange them, or invert each band separately. Other modifications involve varying time delays for the various bands. (L.R.Q.)

SECRETARY BIRD. Aves, Falconiformes. A remarkable African bird (**Aves**), *Sagittarius serpentarius,* related to the eagles and vultures The bird is about four feet tall, with long legs, and is largely terrestrial in habits. It walks and runs very rapidly, and is also a strong flier on the relatively rare occasions when it takes to the air. (A.W.L.)

SECRETION. For the use of this term in geology, see **Concretions.** In biology, secretion is the production and discharge of special products by living **protoplasm.** In the complex body secretion may be carried out by single cells but is more often the function of many associated cells. All of these secreting units are called **glands.**

The details of the entire process are not completely understood. In many cases the special secretion is formed in the **cytoplasm** of the gland cell in granules, or these granules may consist of a foundation substance which is transformed into the secretion characteristic of the gland at the time of discharge. The transformation or the discharge or both may be brought about by a nervous stimulus or by the action of a **hormone.** Thus the salivary glands respond promptly to nerve stimuli resulting from the taste, smell or sight of food, and the pancreas is activated by the hormone secretin produced in the wall of the intestine.

The discharge of secretion may take place through the free end of the gland cell, or through the ruptured end of the cell. In some cases the terminal portion of the cell is converted into the secretion. The existence of these processes is accepted, although the action of many gland cells cannot be classed definitely with any particular one.

The secretions of endocrine glands are not discharged in the usual sense, but are taken up by the blood circulating through the gland. (A.W.L.)

SECTION MODULUS. An inspection of **flexure** will reveal that the stress in a member subjected to a transverse bending is directly proportional to the external bending moment, and inversely proportional to the ratio of

$$\frac{\text{moment of inertia}}{\text{distance of the farthest stressed element from the neutral axis.}}$$

It is apparent that this ratio is entirely a property of the shape and size of the cross-section of the structural member. This ratio is known as the section modulus, and is an important property of rolled steel sections and other shapes which are used as structural members. When the bending moment to be withstood by a beam or column is divided by this section modulus, the quotient is the maximum bending stress which will exist in that member. (F.T.M.)

SECTOR DISK. A device much used in physical apparatus to secure an accurately known control of the intensity of a beam of light or other emission. The simplest form is a circular, opaque disk with a sector or sectors of any desired angle cut from it. If the disk is interposed in the path of light rays and rotated rapidly about its center, the resulting intensity, as judged visually, is reduced to a fraction equal to the ratio of the area of the open sectors to that of the whole disk. This arrangement is useful, for example, in a photometer where it is desired to cut down the intensity of one beam to match that of another. By giving the sides of the openings suitable curved shapes instead of cutting them along radii, the intensity may be varied from center to circumference in accordance with any desired law. This affords, for example, a non-selective "wedge" for certain photometric purposes. When a sector disk is used in connection with photographic work, regard must be had for the so-called "intermittency effect," which renders the ratio not strictly accurate. (L.D.W.)

SEDATIVE. Any therapy that decreases excitement or activity. The sedative **drugs** commonly used are **bromides,** chloral (see **Chloral Hydrate**), barbital and its derivatives.

The chief action of sedatives is obtained by depressing the higher brain centers. The sedative measures other than drugs are hot baths and hot drinks. (D.M.H.)

SEDGE FAMILY. Cyperaceae. This family of **monocotyledons** is composed of grass-like plants which are found chiefly in marshy places. Most of its members are perennials with creeping **rhizomes** and grass-like leaves. The basal portion of the leaf is a sheath which completely surrounds the stem. The stem is generally solid and triangular in cross-section. The **inflorescence** is a **spike** or a **panicle,** composed of one- to many-flowered spikelets. Each flower, borne in the axil of a bract, has three **stamens** and a single **pistil;** in some sedges there is also a **perianth** of six or many bristles. The fruit is an **achene.** All sedges are wind-pollinated.

Few of the sedges are of any importance. Some of them yield a coarse hay which may be fed to live stock, and is sometimes used for packing material. **Papyrus,** used as **paper** by the ancient peoples, was made from the stems of *Cyperus Papyrus.* The erect stems and leaves of species of *Scirpus* are sometimes dried and woven to form chair seats; chairs finished with this material are called rush-bottomed chairs. The plants are sometimes called bulrushes. Several sedges form tubers which are sometimes used for food. (R.M.W.)

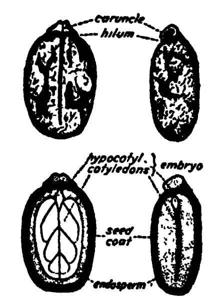
SEDENTARIA. Chaetopoda.

SEDIMENTARY ROCKS. Rocks.

SEDIMENTATION. Filtration.

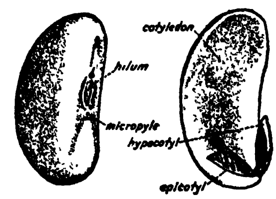
SEEBECK EFFECT. Seebeck observed that if a photographic emulsion is exposed to the point at which a visible image appears faintly, and is then exposed to colored light, the emulsion assumes the color of the light to which it is exposed. The colors, however, are weak and mixed with gray. Many attempts have been made to perfect processes of color photography of this character but without success. (See **Thermoelectric Phenomena.**) (C.B.N.)

SEED. A seed consists of a dormant embryo, together with a quantity of stored food which may be absorbed in the embryo, or may surround it, and one or two seed coats or integuments. The seed develops from an **ovule.** In **Angiosperms** it is completely enclosed by the ovary wall; in **Gymnosperms** it lies exposed on the surface of a scale of the cone.



Seed of the castor bean. Above, entire seeds; below, median longitudinal sections.

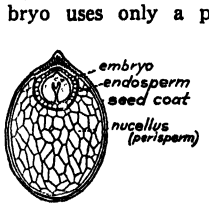
The fertilized egg develops into the embryo which is a young plant contained in a seed. This embryo may be an undifferentiated mass of cells, as it is in the **orchid** family, but usually is more highly organized. It then consists of a short axis which is called the hypocotyl. At one end of the hypocotyl there is a primitive root called the radicle. At the other end is a terminal bud, called the plumule. This plumule may be nothing more than a small mass of undifferentiated cells, recognizable only as a small bulge at the apex of the hypocotyl, or it may be a well-developed shoot having a short internode and two distinct leaves. Borne laterally at the apex of the hypocotyl there are one or more seed leaves or cotyledons. In many seeds these cotyledons are thin and more or less leaf-like, while in others they are very fleshy, filled with stored food material, and form the greater part of the seed. The number of cotyledons varies. In monocotyledons there is usually only one cotyledon, in dicotyledons there are two, and in gymnosperms there are often many.



Bean seed. Left, entire seed; right, embryo with seed coat and one cotyledon removed.

In **Angiosperms** the **endosperm** (see **Flower**) is the tissue which results from the triploid endosperm nucleus. It is a tissue which is rich in stored food. The food reserves stored in the seed are **carbohydrates,** especially starches and sugars, **fats** and **proteins.** The latter are present in all seeds, but are particularly abundant in the

seeds of the pea family. The developing embryo gets its food from the endosperm. In many seeds the embryo uses only a part of the endosperm during its development, so that the mature seed contains much endosperm surrounding the embryo. These are called albuminous seeds. In other plants, the food reserves of the endosperm have been entirely absorbed and restored in the embryo, especially in the cotyledons, which then becomes very fleshy. Such seeds are exalbuminous.

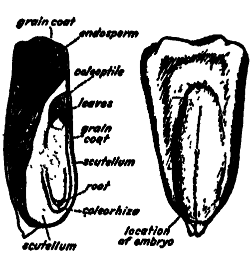


Longitudinal section of a seed of a water lily. (*After Conrad from Curtis, Nature and Development of Plants, Henry Holt & Co.*)

The embryo sac of the ovule is surrounded by a mass of tissue called the nucellus. In most plants this is completely absorbed before the seed reaches maturity. In some seeds it persists and becomes much enlarged. It is then known as the perisperm, and serves as an additional source of stored food.

Surrounding all these are the seed coats, which develop from the integuments of the ovule. The outer coat, called the testa, may be variously modified to aid in the dissemination of the seeds. The inner seed coat is the tegmen. On the seeds of many plants there is a fleshy structure called the aril which grows up around and more or less covers the outer integument. In some seeds, the testa produces an outgrowth called the caruncle, which seems to aid in absorbing water from the soil and passing it on to the seed. Passing through the integuments is a minute hole called the micropyle. It is through this that the pollen tube entered the young ovule; the radicle generally points directly towards it. The seed is attached to the ovary wall by a small stalk or funiculus which, when the seed falls off, leaves a scar called the hilum on the seed coats.

Once started, the plant must remain fixed in its position throughout its life. In higher plants the vegetative parts are very rarely able to colonize new territories. The fruit, or less frequently the seed, is the part which is carried to new regions. There are several agents effecting this transfer. The most important is the wind. Sometimes the seeds of a plant are very small and light, and so easily carried by the wind. The minute seeds of orchids are carried by this means; in these seeds additional buoyancy is gained by a loose thin case which surrounds the embryo tissue within and acts as a float. In other plants the seeds are carried away by hairs which grow from the seed. Milkweed seeds are provided with a tuft of long silky hairs attached at one end of the thin light seed. Cotton fibers serve the same purpose; they completely cover the cotton seed. In other plants the seed is provided with a wing, a flat thin outgrowth from the seed coats. Catalpa seeds are thus equipped, as also are pine seeds. The distances to which the wind carries seeds is considerable. By this means plants are disseminated over many square miles.



Corn grain. Left, longitudinal section, perpendicular to the broad face of the grain; right, surface view.

Another way in which new land is reached is by ejecting seeds violently from the fruit. When the fruit of the witch hazel is ripe, the dry thick wall of the ovary suddenly snaps and hurls the seeds violently to a distance of many feet. The common Jewel-weed or Touch-me-not scatters its seeds in similar fashion. At maturity the fruit abruptly splits open, and the valves roll back, throwing the seeds many feet away. In similar fashion the pods of many legumes split apart forcefully and scatter the seeds within. Seeds scattered by this means cannot attain the wide dispersal which wind-borne seeds do.

A few plants form seeds which float readily on water for some time without harm. Currents of water may carry the seeds, or the latter, floating on the surface, may be blown to new shores. Other seeds are provided with hooks or barbs or have a sticky surface which causes them to adhere to the bodies of passing animals which scatter them. In most plants, however, it is the fruit which is so carried. Such fruits, as beggar's lice, burdock, goldenrod and many others, are commonly mistaken for seeds.

Having reached an environment where suitable conditions exist, the seed germinates. The seeds of many plants must reach such a place in a very short time or perish, since they remain viable but a very short time. Those of the willow, for example, live only a few days after falling from the parent plant. The seeds of most garden vegetables grow best if planted within a year from the time they ripen, though they may retain their vitality for three or four years with decreasing vigor. On the other hand, some seeds lie dormant for a long time before germinating. Seeds of many weeds, including the common ragweed, the pollen of which causes hay-fever, may live for years before germinating, making it very difficult to eradicate the species by pulling up the plants for a single season. Tests show that the seeds of many plants may remain viable for 20–50 years, though few of them do. It is recorded that the seeds of the Asiatic lotus have germinated after lying dormant for 200 years. But records of viable seeds found in ancient vaults, such as contained the mummies of Egypt, are entirely unfounded.

Certain conditions favor the continued vitality of dormant seeds. Sometimes the seed has a very thick wall which is impervious to water or to oxygen gas, and so excludes the two things necessary to start germination. Until the wall has softened or rotted the seed does not germinate. In other seeds the thick wall resists the pressure of the developing embryo within. Many important crop plants have seeds which germinate slowly because of their thick coats. To hasten germination and to insure a uniform stand of plants the seeds are scarified before planting; that is, the seed coat is rubbed with abrasive substances which break down the impervious wall layers. Often the wall of the seed is sufficiently damaged during mechanical threshing to insure prompt germination when planted. Prolonged soaking sometimes hastens germination.

In other seeds dormancy is inherent in the embryo itself. The embryo may be entirely undeveloped, requiring a long period of slow development before it can break the seed coats. Other seeds germinate only after a period of "after-ripening" which varies from a single winter to many years. The changes occurring during this period are as yet not well understood. The time of "after-ripening" may be considerably shortened by burying the seeds in sand or other suitable material and keeping them cold and moist.

The external conditions necessary to cause germination are adequate water, suitable temperature and oxygen. With some seeds light is an important factor. Most seeds contain very little water, which is one of the reasons why they can survive under adverse conditions such as cold and drought. To germinate they must receive additional water. This added water favors digestion, a process which makes available to the plant the stored food. Both water and oxygen are needed by the germinating embryo, because of the great increase in

respiration, the process which frees to the plant the energy stored in the carbohydrates and other compounds.

The temperature at which a seed will germinate varies with different plants. For each there is a considerable range of temperature. The lowest temperature at which germination occurs is called the minimum temperature, and varies from 0–10° C. or even higher. The maximum or highest temperature at which germination takes place is usually between 45 and 50° C. The most favorable temperature, or optimum, is about 30° C. Light favors the germination of many common plants, such as many grasses and troublesome weeds. Other plants, including many common crop plants, are unaffected by light.

Germination is the development of the embryo into a young plant. It becomes completed when the young plant is independent of the food stored in the seed. In most seeds the first visible change is swelling of the seed, which is a result of the increased water content. Often the seed coats are ruptured by the swelling of the contents of the seed. Increased respiration makes available foods which are carried to those regions where active growth occurs, that is, to the hypocotyl and plumule. The radicle pushes out of the seed and attaches itself, by means of root hairs, to the soil particles. These then begin absorbing water from the soil. In some seeds the hypocotyl elongates considerably, often forming an arch which subsequently straightens, lifting the cotyledons and plumule out of the soil and into the air. In other seeds the cotyledons remain permanently underground, the plumule elongating and pushing out into the air. There the first leaves of the plant appear. With their formation the plant becomes independent.

The main foodstuffs of mankind are seeds, especially those of the cereal grains, rice, **wheat, corn, barley,** and **oats.** But seeds are used in many other ways. Many medicinal products are obtained from seeds. **Linseed** oil, **soybean** oil, and **coconut** oil are but a few of the many oils which come from seeds. **Poppy** seeds, caraway seeds, and mustard add flavor to other foods. Clothing is made from the hairy covering of the **cotton** seed. Beads, buttons, and ornaments of various kinds are also often made from seeds. (R.M.W., B.S.M.)

SEED SNIPE. Aves, Charadriiformes. South American birds (**Aves**) resembling quails but classed as intermediate between the true snipes and the gulls. They are closely related to the sheath-bills. (A.W.L.)

SEED-FERNS. Paleobotany.

SEEING. When meterological conditions are such that the atmosphere is very steady (i.e , the atmospheric density decreases with perfect uniformity with increase in height, and there are no strong air currents) the image of a star as seen in a telescope will be a perfectly round disk and very steady. The diameter of the disk depends upon the aperture of the **telescope,** being smaller the larger the aperture of the instrument.

When the atmosphere is unsteady the variations in the **refraction** produce a number of effects on the star images. The images become soft and "fluffy," jump around in the field of view, and are subject to abrupt changes in color. These irregularities in the star images are known as bad seeing. Bad seeing is evident to the unaided eye in the twinkling of the stars. When the stars are twinkling strongly the seeing is bad.

The statement is frequently made that the **planets** do not twinkle. In a sense this statement is true, for to the naked eye the planets do present much more steady images than do the stars. Every point in a planet does twinkle, however, but a planet is made up of a great many such points, since it presents a disk of finite size to the eye. The integrated effect of the twinkling of the individual points in the disk is not apparent to the unaided eye. In the telescope, when an attempt is made to study individual points on the image of the planet, bad seeing produces such blurring as to make good observations impossible.

Bad seeing is almost as fatal to most types of astronomical observing as actual clouds. Accordingly, in selecting a site for an observatory, expeditions are dispatched to various sites for the purpose of testing the seeing. That site is selected where the seeing averages the best over a long period of time. (W.K.G.)

SEGER CONE. A series of substances having different fusion temperatures might serve roughly to measure the temperature of high-temperature regions such as **furnaces,** since, with a series of substances having progressively increasing fusing temperatures, the temperature naturally lies between the fusion temperature of the last substance fused, and that of the next not yet fused. A series of artificially prepared mixtures, mostly of the oxides such as clays, lime, feldspar, have been designed to form a series of "Seger cones." There are 60 mixtures covering a temperature range from 590 to 2000° C. The variation in fusion temperature between cones of adjacent serial numbers ranges from 20 to 30° C. Such cones have some pyrometric value as control indices in the ceramic industry, and in any case where exact determination of temperature is not necessary, but some simple, inexpensive means for approximating the temperature is desirable. It is apparent that it is necessary to estimate what the temperature to be measured is in order to select the cones for use.

The Seger cones are triangular pyramids about ½″ on each side of the base, and 2″ high. In use, the temperature is estimated, and four cones of consecutive serial numbers which are thought to include the temperature to be measured are placed on a refractory slab and inserted in the high-temperature region. If the cones have been properly selected, they will exhibit a range of behavior in the furnace varying from complete fusion of some to others remaining unaffected. One will soften until its tip bends over to touch the base, and that one is taken as indicating the temperature. (F.T.M.)

SEISMOGRAPH. An instrument for recording earth tremors; usually housed for the purpose in a suitable seismological observatory. There are two classes of seismograph, one for recording horizontal and the other for recording vertical components of vibration. A well-equipped observatory has three, a north-south horizontal, an east-west horizontal, and a vertical recorder. The instruments are somewhat complicated, but the principle is that of a heavy mass poised in such a way that a vibration of its support, together with the inertia of the mass, causes a relative motion of mass and support; and this motion, suitably amplified, produces the record. In the older forms the recording was done mechanically by a stylus tracing on a revolving drum; in more modern types an electromagnetic current, generated by the motion, operates a **galvanometer** which, by means of a beam of light reflected from its mirror, produces a photographic record of the earth's vibration on a moving film. (See **Earthquakes.**) (L.D.W.)

SEISMOLOGY. Earthquakes.

SEISMOMETER. Earthquakes.

SEISMOSCOPE. Earthquakes.

SEISONIDEA. Rotatoria.

SELACHII. The sharks and dogfishes. A term applied in various classifications to a subclass of the class **Pisces** and to a suborder of the order Plagiostomi as used in this work. (A.W.L.)

SELAGINELLA. **Lycopodiales.**

SELECTED AREAS. To determine the form, extent, and general characteristics of the **sidereal universe** as a whole, knowledge of the **magnitudes, spectral types,** and other characteristics of all of the stars would be necessary. To solve completely a problem of such magnitude is obviously impossible, and the process of statistical discussion becomes necessary. In any problem of statistical analysis a sampling of the material under consideration is necessary. For this purpose, Prof. J. C. Kapteyn, a Dutch astronomer, proposed in 1906 a group of 206 "selected areas" distributed all over the sky in accordance with statistical theory, and requested international cooperation in the determination of the characteristics of all stars in these areas. During the past 40 years a large amount of work has been done on these selected areas, and from a statistical discussion of the results most of our information regarding the structure of the sidereal universe has been obtained. (W.K.G.)

SELECTION. A process controlling the reproductive sequence within a **species** either by preserving only a part of the included individuals or by limiting the range of their opportunity for mating. The latter process tends to split the species up into different groups.

The term applies to certain theories of **evolution,** including natural selection and sexual selection, and to methods of improving domestic animals and plants. Most of the varieties of domestic animals have been produced in this way, and the method is supplemented only by hybridization in the production of new breeds.

The simplest application of the process is mass selection, consisting merely of the preservation of the more desirable individuals as breeding stock. Although mass selection is effective and has, indeed, been the original source of many varieties of domestic animals, modern knowledge of heredity shows that it is a relatively crude method. Line selection, based on the study of progenies of single individuals, is a much more exact method of improvement. With the refinements made possible by modern genetics it discloses with reasonable precision the hereditary potentialities of the parents and makes possible the establishment of genetically pure strains embodying characters desired by the breeder. (A.W.L.)

SELECTIVE ASSEMBLY. **Interchangeable Manufacture.**

SELECTIVE RINGING. **Ringer.**

SELECTIVITY. This is the ability of a selective circuit to discriminate against undesired signals which are adjacent to the desired ones. The term is commonly applied to radio **receivers** and indicates the receiver's ability to select one station without interference from an adjacent one. It is measured in terms of the amplitude of the input signal at various frequencies necessary to produce a standard output from the set. It is expressed by a curve, usually of V shape, and the steeper the sides the more selective the receiver. (L.R.Q.)

SELENIUM. Symbol: Se. Atomic number: 34. Atomic weight: 78.96. Density: red, 4.50; gray, 4.84. Hardness: 2. Melting point: gray, crystalline, 220° C. Boiling point: 690° C. (**Isotopes:** page 290.)

Selenium exists in several **allotropic** forms, (1) crystalline red selenium alpha and beta, separating in **monoclinic** crystals from solutions of vitreous or amorphous selenium in **carbon disulfide.** The transformation temperature into metallic gray selenium B is 110–120° C. for the alpha and 125–130° C. for the beta, (2) crystalline gray selenium A, formed by heating the vitreous form to 175° C., and changes gradually into metallic gray selenium B, (3) metallic gray selenium B, insoluble in carbon disulfide, and produced when the other forms are heated to 200° C.; metallic luster, malleable, a **conductor** of electricity in proportion to the intensity of the incident light. **Nitric acid** and **aqua regia** dissolve selenium to form selenous acid; attacked by cold concentrated **sulfuric acid** to form a green solution which precipitates free selenium upon dilution with water. Discovered by Berzelius in 1817.

Selenium is used as a decolorizer of glass to counteract the green **ferrous** shade; as selenium or sodium selenite to produce clear red glass, and for red enamels on ceramic ware and steel ware; in vulcanized rubber—the presence of 1–3% selenium notably increases the resistance to abrasion. Selenium is not poisonous, but many of its compounds are exceedingly toxic.

Selenium occurs as selenide in many sulfide ores, especially those of **copper, silver, lead,** and **iron,** and is obtained as a by-product from the **anode** mud of copper refineries and the lead chamber mud of sulfuric acid plants. The mud is (1) fused with **sodium** nitrate and **silica,** or (2) oxidized with nitric acid, and the water extract is then treated with **hydrochloric acid** and **sulfur** dioxide, whereupon free selenium is separated. Chemically related to **tellurium.**

Acids: Selenous acid (H_2SeO_3), soluble, forms metallic selenites; with hydrogen sulfide forms free selenium and **sulfur** which becomes red on heating; is oxidized by **potassium** permanganate to selenic acid; selenic acid (H_2SeO_4), soluble, forms metallic selenates, less stable than selenites.

Chlorides: Selenium monochloride, selenium dichloride (Se_2Cl_2), brown liquid, boiling point 130° C.; selenium tetrachloride ($SeCl_4$), yellowish-white solid, sublimes at 305° C.; selenium oxychloride ($SeOCl_2$), yellowish liquid, boiling point 177° C.

Hydride: Selenium hydride, hydrogen selenide (H_2Se), gas of unpleasant odor, chemically related to **hydrogen sulfide,** hydrogen **telluride,** and **arsenic** hydride (arsine), formed by reaction of selenide with dilute hydrochloric or sulfuric acid.

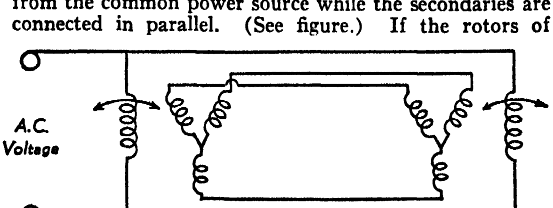
Oxide: Selenous oxide (SeO_2), white solid, sublimes at 317° C. to yellowish-green vapor, soluble in water to form selenous acid.

Selenides: Metallic selenides are formed by combination of selenium and the metal, or by precipitation of the metallic salt solutions with hydrogen selenide.

Numerous organic compounds of selenium have been prepared. (R.K.S.)

SELENIUM CELL. **Photoconductivity.**

SELSYN. These devices, also called synchros and autosyns, are used for transferring a mechanical displacement to some distant point electrically. In operation a transmitter or generator selsyn is used with one or more receiver or motor selsyns. They are somewhat similar to wound-rotor induction motors, having a stator winding and a rotor winding. In single-phase machines one of these is a single-phase winding excited from the single-phase power source and the other is a three-phase winding. In three-phase selsyns both are wound for three-phase. In either type the primaries are excited from the common power source while the secondaries are connected in parallel. (See figure.) If the rotors of



both generator and motor units are in identical positions with respect to the stators the voltages induced in them by transformer action will be identical and there will be no circulating current. However, if one is dis-

placed the induced voltages are no longer the same in magnitude and phase and there will be a consequent circulation of current. This will produce a **torque** in the undisplaced rotor which will cause it to rotate until the voltages are again the same and the rotors will occupy identical positions with respect to their stators. As usually applied the rotor of the generator unit is displaced and the rotor of the motor unit then follows it. A differential synchro is sometimes used for injecting still another control signal. The differential is connected in the circuit between the generator and motor synchros. Remote position indicating is an example of the application of these devices. The generator may be connected to a valve, let us say, while the motor is connected to a dial on the control board. The position of the motor dial will then indicate the position of the valve. Large units may be used to operate devices requiring appreciable torque. They are widely used in sizes ranging from small indicating units to large power units of several horsepower and over distances ranging from a few feet to several miles. (L.R.Q.)

SEMAEOSTOMEAE. **Scyphozoa.**

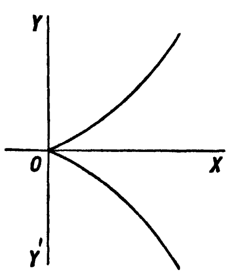
SEMEN. The thick grayish-white secretion of the testicles which contains the **spermatozoa,** or fertilizing male cells. It is secreted by the testicles, stored in the seminal vesicles, and ejaculated through the penis in intercourse or during nocturnal emissions. (R.S.M.)

SEMI-AUTOMATIC. Usually a machine, mechanism, or machine tool that requires manual attendance at the beginning and end of each operational cycle, or at definite stages during the cycles. (See **Turret Lathe.**) (H.C.H.)

SEMI-CARBAZIDE. **Amines; Amides.**

SEMI-CARBAZONES. **Amines; Amides.**

SEMI-CUBICAL PARABOLA. The semi-cubical parabola is a mathematical curve which is defined as the locus of the equation $ay^2 = x^3$ in rectangular coordinates; its form is shown in the accompanying figure. (L.L.S.)



Semi-cubical parabola.

SEMI-DIAMETER. When the **altitude** of a celestial object, that is close enough to the earth to present a finite disk (e.g., **moon, sun, planet**), is measured with reference to the visible sea **horizon** or to an artificial horizon, other than that contained in the bubble **sextant,** it is more convenient to use the upper or lower limb (edge) of the disk, than to estimate the center of the object. When solving the **astronomical triangle** using this measured altitude, as, in determining position at sea, the position of the object given in the **almanac** is that of the center. Hence to obtain the observed altitude of the center a correction must be applied known as the correction for semi-diameter. The correction is to be added or subtracted from that obtained with the sextant, depending upon whether the lower or upper limb of the object is observed. The value of the semi-diameter is given in the almanac for the given date of observation. In using the moon for accurate determination of position, an additional factor, known as **augmentation,** must be considered due to the fact that the distance of the object from the observer varies with the altitude of the object. (W.K.G.)

SEMI-LOGARITHMIC CHART. **Logarithmic Chart.**

SEMI-LOGARITHMIC PAPER. **Logarithmic Paper.**

SEMINAL VESICLE. An expanded portion of the genital duct of the male, or a pouch-like derivative of the duct, either for the storage of spermatozoa or the secretion of accessory substances. Structures of this kind are well developed in the **annelid** worms, the **arthropods,** and the **vertebrates.** Often known by the latinized term *vesiculae seminales.* (A.W.L.)

SEMSEYITE. A mineral sulfide of lead and antimony, $Pb_9Sb_8S_{21}$. Crystallizes in the monoclinic system. Hardness, 2.5; specific gravity, 6.08; color, gray to black; opaque. Named after Andor von Semsey, Hungary. (R.M.F.)

SENILITY. The gradual decrease of physical and mental function that accompanies old age. The aging process is a mysterious phenomenon which is not clearly understood. Certain measurable changes occur, but the impetus behind these changes is obscure. Diminution in the circulation to organs and tissues of the body, varying according to the degree of hardening of the arteries, accounts for many of the signs. The age at which senile signs and symptoms begin to appear depends on **heredity,** and to a less extent the amount of abuse and illness that the body has been exposed to during life. (D.M.H.)

SENSE ORGANS. Structures in the animal body which are influenced by certain factors in the environment. Also known as receptors. The action of the environmental factor on the living substance is known as a stimulus. It results in the transmission of a **nerve impulse** to some nerve center and from this point may influence appropriate reactions of the animal or may be stored in memory. Special sense organs are found only in animals with **nervous systems.** Their development involves high specialization in some phase of the general property of living matter called irritability, and to some extent this property persists in all living tissue, whether nervous or sensory or not.

Stimuli arise from contacts with solid objects, from chemical compounds, either dissolved or in the gaseous state, from the incidence of light rays, and from factors which damage the body. We know from various evidences that some animals perceive factors to which our own organs are not sensitive, but as far as we can know, the only stimulating factors are in these several groups.

Contact results in variable pressures to which organs of several kinds are sensitive. In vertebrates **tactile corpuscles** and other similar structures located in surface tissues may be classed as organs of touch. They are sensitive to simple pressure and give rise to images of form through the varying pressures due to uneven surfaces and gross contours. Since sound waves are due to rhythmic compression of the air, the ears and other **auditory organs** such as those of insects are also sensitive to pressures, but only to fluctuations of relatively high frequency (in man 30–30,000 per sec.). Between auditory organs and simple organs of touch are the **lateral line organs** of fishes and the **chordotonal organs** of insects, both related in some anatomical details to the auditory organs of the groups to which they belong. These organs are supposed to be sensitive to fluctuating pressures of lower than auditory frequency.

Tactile organs are also closely allied to sensory organs of insects which apparently enable them to avoid obstacles when flying. Supposedly these organs are sensitive to the changes of air pressure, often extremely delicate, resulting from approach to objects. They are located in the wings.

Dissolved substances stimulate organs of taste and gases or vapors act on organs of smell (**olfactory organs**). In the vertebrates the olfactory organs are

associated with the nasal passages or occupy a similar position; nasal structures of fishes are limited to the olfactory function. Vertebrate organs of taste are known as **taste buds** and are located in the oral cavity principally, although aquatic forms may have them also in the skin. Sensory organs of this class in the invertebrates are extremely varied. Some are known as **sensillae.** In addition to organs of taste and smell a general chemical sense is recognized. It is resident in various surface layers and is the least sensitive of the group. These sense organs are known collectively as chemoreceptors.

The varied integumentary sense organs of the human body are known to include some sensitive only to heat, cold, or pain. These organs may be the free nerve endings found in the skin. It has been suggested that pain may also result from overstimulation of other types of sense organs.

Sense organs that are stimulated by light are familiar to us in our own **eyes.** From this stage of complexity they range downward to simple light-sensitive cells. The transition includes organs capable of perceiving fluctuations of light, the direction from which it comes, and movements, as well as organs which form images in varying degrees of precision.

In contrast with sense organs of the kinds mentioned, which are classed as exteroceptors, the body contains others called interoceptors. They are the source of sensations of hunger, thirst, nausea, and pain. Other interoceptors in the muscles, joints, and tendons are associated with the maintenance of equilibrium and are classed as proprioceptors. They are probably subject to varying pressure due to tension of muscles and shifting of the weight of the body. The semicircular canals of the inner ear of vertebrates are also organs of equilibration.

Organs of many invertebrates, such as the **tentaculocysts** of jellyfishes, can be interpreted only by experimental evidence. By testing the animal with different stimuli definite conclusions can often be drawn from its reactions. In most cases there is evidence of functions like those of our own sense organs.

All sense organs consist of nerve endings associated with various specialized cells or tissues. The nerves are not limited to one type of stimulation but their response may be identical under various stimuli. Thus a mechanical shock to the eye produces a sensation of light. The nerve fibers leading from the sense organ toward the central system are sensory or afferent. (A.W.L.)

SENSILLAE. The sense organs of **insects.** The term is usually applied to the **integumentary** sense organs of the group but it is also extended to include the **scolophores** on which organs of hearing and chordotonal organs are based, and the **ommatidia** and **retinulae** of the eyes.

The sensillae of other kinds include some form of cuticular structure, often a projection, associated with a nerve ending and in some cases with gland cells. These organs include some of tactile function and chemoreceptors, both of taste and of smell. In form their external parts are classed as six types: 1. Placoid sensillae end in a thin porous plate or membrane covering a canal. 2. Trichoid sensillae end with a slender **seta.** 3. Basiconic sensillae have a conical protuberance. 4. Styloconic sensillae have a fixed conical base bearing subordinate projections. 5. Coeloconic sensillae end with a depression containing a conical projection. 6. Ampulliform sensillae end with a slender projection in an expanded chamber at the inner end of a long tubule.

Tactile sensillae are distributed over the entire body but are often much more abundant on the legs and sensory appendages such as antennae and palpi. Organs of smell are often abundant on the antennae and in some species appear to be limited to these appendages. There is some possibility that they may occur on other parts of the body. Organs of taste are undoubtedly associated with the mouth parts, but they are supposed to be present in aquatic insects on the outer surface of the body as well. (A.W.L.)

SENSITIVE PLANT. Movement in Plants.

SENSITIVITY, RECEIVER. This is defined as the signal input necessary for a **receiver** to produce a standard output. The amount of the output, the audio frequency used to modulate the input and the degree of modulation are all specified. The sensitivity of the usual receivers will vary from a few microvolts for highly sensitive ones to several hundred microvolts for smaller ones. (L.R.Q.)

SENSITIVITY DETERMINATION OF PHOTOGRAPHIC MATERIAL. Many different methods of measuring the speed of a plate or film have been proposed, but all may be divided into four groups.

1. The exposure producing the first visible density (**threshold speed**).
2. The exposure required to produce a certain density but greater than the **threshold density** (DIN, Weston speeds and General Electric speeds).
3. The exposure obtained by projecting the straight-line portion of the D log E curve to the log E axis (H & D speed).
4. The exposure at the lowest point on the D log E curve at which the density differences are sufficient to produce a good print (limiting gradient method, Kodak speeds, ASA speeds).

The best known method of speed measurement based on the threshold exposure is that due to Scheiner. The Scheiner speed number was obtained originally by exposing the plate or film in a rotating disk **sensitometer** producing an exposure range of 1:100 in 20 equal steps numbered from 1 to 20, developing under certain prescribed conditions and determining the last visible step. The number of this exposure step—from 1 to 20—became the Scheiner number expressing the speed of the sensitive material. While satisfactory as a means of indicating the speed of a film or plate in terms of the exposure required to produce a visible image, the Scheiner number fails to indicate speed in terms of the exposure required for a negative which will yield a good print. In the land of its origin, Germany, it has been superseded by the DIN speed; in other countries it is practically obsolete.

The DIN (German Industrial Standard) speed is determined from the exposure required to produce a density of 0.1 above the fog **density.** The sensitive material is exposed in a special sensitometer having an intensity scale of 30 steps, ranging in density from 0 to 3.0. The range of exposure is, therefore, 1:1000. The light source is a standardized 40-watt incandescent lamp with a daylight filter and the time of exposure is $\frac{1}{20}$ second.

After development, the step having a density of 0.1 above fog is determined by means of a special comparison **densitometer.** The density of the exposure step in the sensitometer producing the required density on the film or plate is multiplied by 10 to obtain the DIN speed number.

The DIN method is simple and direct, but has not found wide acceptance outside of Germany.

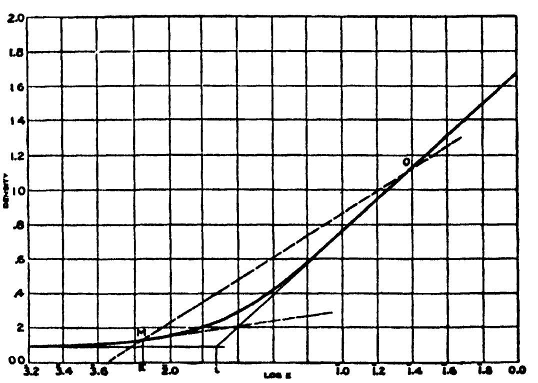
The speeds employed on the Weston and General Electric exposure meter are determined in the laboratories of the respective companies. After exposure in a continuous time-scale type sensitometer, the sensitive material is developed in the developer recommended by the manufacturer, the densities read and the D log E curve plotted in the usual way. The Weston speed is determined from the formula speed $= \frac{4}{E}$ and the Gen-

eral Electric speed from the formula speed $= \frac{5.2}{E}$. E, in both cases, is the exposure required for a density equal to the value of **gamma.**

For convenience in use, the actual laboratory speeds are not published; instead, the speed of the material is given in terms of the nearest speed number on the meter.

The H & D speed is based upon the *inertia* which was defined by Hurter and Driffield as the exposure at the point at which the straight-line portion of the D log E curve, when extended, intersects the log E axis. In recent years the practice has been to obtain the H & D speed from the formula speed $= \frac{10}{i}$ where i is the inertia as defined. The H & D method of determining speed is no longer used by the manufacturers of sensitized materials in this country, nor in England, and may now be considered obsolete.

In 1943 the American Standards Association gave its official sanction to a method of measuring speed which had been recommended by a committee representing the manufacturers of sensitized materials, the manufacturers of exposure meters, the Optical Society of America and the Photographic Society of America. Speeds determined by this method are designated ASA Speeds. The ASA speed is a value indicating the *minimum* camera exposure which the film must receive in order to produce a negative from which an excellent print may be obtained. This value is determined sensitometrically and is defined as the point on the D log E curve at which the gradient (slope) of the curve is 0.3 of the average slope over a log exposure range of 1.5. Thus, in the accompanying figure the slope or gradient of the D log E curve at M is 0.3 of the average



gradient between M and O representing a log exposure range of 1.5. The reciprocal of the exposure at E is the ASA speed. The ASA Speed Number for use on exposure meters and calculators is obtained by dividing the ASA speed by 4. The increased exposure indicated by the ASA speed number is designed to provide a margin of safety in practice sufficient to allow for uncertainties in processing, light conditions, accuracy of exposure meters, camera shutter variations, etc. (C.B.N.)

SENSITOMETRY AND SENSITOMETERS. Sensitometry, as the term implies, is concerned primarily with the measurement of photographic sensitivity; however, in the broader sense it is concerned with the measurement of the response of photographic materials upon exposure to light or other forms of radiant energy.

Photographic sensitometry involves:

1. The exposure of the sensitive material under measurable and reproducible conditions.
2. The standardization of development.
3. The establishment of standardized and reproducible methods of measuring the product of exposure and development (densitometry).
4. The interpretation of the result.

The instrument used in exposing sensitive materials for sensitometric investigations is known as a sensitometer. A sensitometer consists of (1) a standard light source, and (2) a means of regulating the exposure on the sensitive material in a quantitative manner. Sensitometers may be divided into two types: (1) illumination-scale instruments, and (2) time-scale instruments. In the former, the time of exposure is constant but the illumination on different parts of the sensitive material is varied; in the latter, the illumination is constant and the time of exposure is varied. (See **Density and Densitometers; Gamma; Sensitivity Determination of Photographic Material.**) (C.B.N.)

SEPALS. Flower.

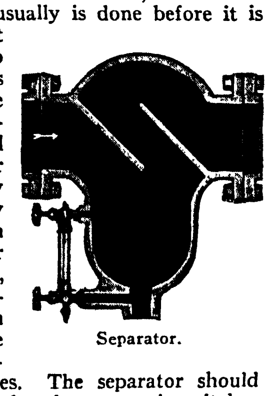
SEPARATING CALORIMETER. Steam Calorimeter.

SEPARATOR, CENTRIFUGAL. Centrifuge, Ultra Centrifuge.

SEPARATION OF SOLIDS. Classification, Filtration.

SEPARATOR, MAGNETIC. The separation of magnetic metals and ores from other non-magnetic material can be accomplished in many ways by varied use of magnets. Sometimes conveyor belts carrying bulk material are discharged over strongly magnetized pulleys which attract such iron or steel particles as bolts, nails and other tramp iron. The iron remains on the belt past the gravity dump point and is finally released by the weakened magnetic field caused by belt travel beyond the pulley. Internal damage to crushers and other machines in which the bulk material is to be processed can thus be prevented. Fine ferrous chips flushed by oil away from cutting operations can be recovered magnetically. In magnetic separation, strong magnetic fields are needed and electric magnets, rather than permanent magnets, must be used. (F.T.M.)

SEPARATOR, STEAM OR OIL. The steam separator is used to remove water from steam. Absolutely dry and saturated steam is a rarity. It is desirable in many cases to have saturated steam, as delivered by the boiler to the prime mover, as dry as possible. Wet steam may cause erosion and **steam engine** knocks. When accentuated by slugs of water from the **boiler,** or from pockets in the steam line, this trouble may be severe enough to knock out cylinder head blow-out plugs. In a **turbine** the damage is blade erosion, even more serious because the damage usually is done before it is suspected. Wet steam not only erodes blading, but also may deposit on it the solids which it has carried from the boiler water. The steam separator is installed to prevent all this. Even when the boiler normally produces a nearly dry steam the separator may be needed, because were high water accidentally carried, or foaming and priming started, the separator would be indispensable. The principles upon which separation is used are (1) reverse current, (2) centrifugal force, (3) wet baffles. The separator should provide for an enlarged path for the steam since it has been found that separation is more effective at lower steam velocities.



Separator.

Exhaust steam lines from engines and reciprocating steam pumps contain considerable oil as a result of the method of lubricating such equipment. If this steam is to be used in heating systems, to heat feed water, or for industrial processes, the oil content is objectionable. Therefore the oil separator, built much on the same principle as the steam separator, should form part of the exhaust line from such equipment. (F.T.M.)

SEPIOLITE. The mineral sepiolite or meerschaum is soft, white, light in weight, and occurs in clay-like masses. It is a complex, hydrous **magnesium silicate** corresponding to the formula $H_4Mg_2Si_3O_{10}$. It appears to be amorphous; hardness, 2–2.5; specific gravity, 2; color, white, grayish white, sometimes a yellowish- or bluish-green; opaque. It is capable of floating on water, hence the name meerschaum or sea foam. It occurs in Asia Minor associated with **serpentine** and **magnesite,** and may be derived from the latter. Other deposits are in Czechoslovakia, Morocco, and Spain; and in the United States in Pennsylvania and New Mexico. The name meerschaum is from the German. Sepiolite is from the Greek, meaning cuttlefish, referring to the similarity of the bone of that animal to the light, porous sepiolite. (E.S.C.S.)

SEPSIS. Septicemia.

SEPTARIAN STRUCTURE. Mineralized irregular polygonal joints or cracks in certain **concretions.** The structure resembles the pattern of cracks developed by desiccation of mud, and probably resulted from a similar cause—contraction due to desiccation of **colloidal** material. (R.M.F.)

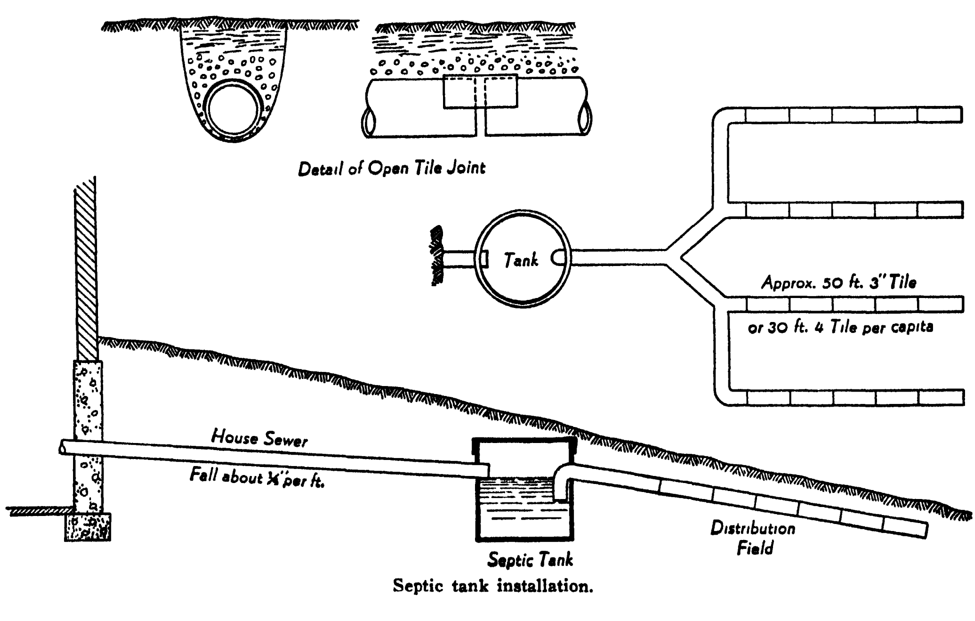
SEPTARIUM. Concretion.

SEPTIBRANCHIATA. Lamellibranchiata.

SEPTICEMIA. Septicemia or bacteremia is said to be present when bacteria are isolated from the blood stream. This is a serious complication of many acute infections, and often carries a grave prognostic significance. Infections caused by hemolytic **streptococci, staphylococci, pneumococci, meningococci,** and colon **bacilli** are most often associated with septicemia, although any organism can find its way from an area of infection into the blood stream. The usual portals of entry are the lungs, middle ear, mastoid process, the skin, and the genito-urinary tract. Although there are no constant signs of septicemia, the condition is suspected when during the course of an infection, a patient develops unusual fever, hemorrhages into the skin (**purpura**) or joints, signs of **endocarditis, jaundice,** or widespread **abscesses.** In **pneumonia,** meningococcus **meningitis, osteomyelitis,** puerperal or post-abortion infections, the physician is ever on the alert for the development of the signs of septicemia. Whenever the complication is suspected, a blood **culture** is made immediately to verify the diagnosis.

Since the advent of the **sulfonamides** and **penicillin** the mortality from septicemia has been greatly reduced. Although all bacteria are not susceptible to these drugs, fortunately the common ones associated with septicemia are. In addition to chemotherapy, **transfusions** and specific antiserums (see **Serum**) are sometimes useful. If the primary infection is one suitable for surgical drainage, this is carried out, but not until the blood stream is sterilized. (D.M.H.)

SEPTIC TANK. Septic tanks are water-tight compartments generally used for the disposal and purification of residential **sewage.** The tanks are made of concrete or steel. In the simplest form a septic tank is a circular steel tank of 200–600 gals. capacity, fitted with a lid, and with openings for sewage inlet and effluent outlet. The outlet will be baffled so that liquids are drawn from below the surface level to prevent floating solids entering the disposal field. The operation of a septic tank depends on the action of bacteria which convert the solids into liquids, and purify the liquid. The wastes of residences served by septic tanks are conducted to them by soil pipe buried in the ground. The septic tank is also buried; in fact, no part of the sewage system need appear above ground. The raw sewage enters the tank from the intake and settles to the bottom. A thick scum forms on the surface and effectively shuts off the contents from oxygen. **Anaerobic bacteria,** which live and thrive only when shut off from air, act upon the suspended matter and convert it into liquids and gases. The gases are discharged either from a septic tank vent or back through the sewer pipe to the house vent. The liquids overflow through the outlet into a disposal field, which is a branching pipe system of drain tile laid with open joints, so that the effluent may be leached into the soil.



Septic tank installation.

Aerobic bacteria act upon the effluent here to purify by a process of oxidation. The purification of sewage by this method is entirely automatic in character, and the system needs no attention beyond occasional cleaning of digested solids from the bottom of the tank. The septic tank is susceptible of more scientific design than is incorporated in the example just described, but the refinements are not generally considered warranted except for extremely large residences, institutions, or factories. However, where built, the large septic tank is usually of a 2-compartment type, in one of which the settling and anaerobic action take place, and from the other, the effluent is discharged intermittently by special siphons to the drainage field. The intermittent operation permitted by the siphon is much better from the standpoint of disposal of the effluent in a tile field, because when it discharges it floods the field and distributes to all portions, whereas the small outflow from a simple type septic tank is likely to be distributed mainly to one portion of the field, which is thereby liable to become clogged. The intermittent dosing of the disposal field, and the 2-compartment arrangement of the septic tank, permit more sewage to be handled for a given tank volume.

Some of the older municipal sewage disposal plants still make use of the septic tank, which is a horizontal rectangular tank through which the raw sewage is allowed to flow slowly. The solids settle to the bottom, where they are partially reduced to liquids and gases by anaerobic action similar to that which takes place in the residential septic tank. The liquid sewage is discharged at one end while the **sludge** is allowed to accumulate in the bottom of the tank. This sludge is removed periodically by completely emptying the flat-bottom type of septic tanks or by means of sludge discharge pipes in the case of hopper bottom tanks. Occasionally the effluent of septic tanks will contain as much suspended matter as the influent due to the disturbance of the sludge caused by septic action. The **Imhoff tank** is preferred for modern installations, since it eliminates this unsatisfactory condition. A still more recent improvement consists of plain sedimentation tanks, mechanical equipment for continuous sludge collection, and separate sludge digestion tanks. (F.T.M.)

SEPTUM. A thin wall or partition. The term is applied to the radiating plates on the foot of the coral **polyp**, to the transverse partitions which subdivide the body cavity of the **annelid** worms into chambers, and to the partitions between chambers of the shell of **Nautilus**, among the invertebrates. Its most familiar use among the vertebrates is to designate the nasal septum which separates the right and left nasal passages, although it applies also to the partition between the right and left chambers of the heart and to numerous other structures. (A.W.L.)

SEQUENTIAL TEST OF A STATISTICAL HYPOTHESIS. By a sequential test of a statistical hypothesis is meant any statistical test procedure which gives a specific rule, at any stage of the experiment for making one of the following three decisions: (1) to accept the hypothesis being tested (the null hypothesis), (2) to reject the null hypothesis, (3) to continue the experiment by making an additional observation. Such a test procedure is carried out sequentially. This definition and the general theory of sequential tests are due to A. Wald. (L.A.A.)

SEQUOIA. Paleobotany.

SEQUESTRUM. A piece of dead bone which separates from the sound bone. This frequently occurs in chronic infections of bone such as **osteomyelitis.** (R.S.M.)

SERIAL CORRELATION. Serial correlation is the study of **variables** which are ordered in time or space. Such variables occur in the study of time series. Given the **variates** x_i, $i = 1, 2, 3, \cdots, N$, as a measure of the dependence among them we define the serial correlation coefficient for lag L and N observations to be

$$_LR_N = \frac{_LC_N}{V_N} = \frac{x_1x_{L+1} + x_2x_{L+2} + \cdots + x_Nx_L - \dfrac{\left(\sum_{i=1}^{N} x_i\right)^2}{N}}{\sum_{i=1}^{N} x_i^2 - \dfrac{\left(\sum_{i=1}^{N} x_i\right)^2}{N}}$$

in which $x_{N+i} = x_i$. Clearly this is the ordinary **coefficient of correlation** between x_i and x_{L+i}. If we consider the case when x_i's are independently **normally distributed** about the same **mean** with unit **variance** then the distribution of $_LR_N$ has been given by R. L. Anderson. His results correspond to the hypothesis $_LR_N = 0$ in the **population.** Serial correlation has been used to find the lengths of periods in the analysis of cycles and may also be used to test the independence of the variates. Serial correlation has been extended to cases of more than one variable. (L.A.A.)

SERIAL DISTRIBUTION. A serial distribution is one in which the items have not been grouped. It always precedes the formation of a **frequency distribution.** (L.A.A.)

SERIAL TAP. Tapping.

SERIATE FABRIC. A geological term proposed by Cross, Iddings, Pirsson, and Washington in 1906 for the texture of an **igneous rock** whose granular crystals form a complete gradation in size. (R.M.F.)

SERICITE. Muscovite.

SERICITIZATION. Sericite.

SERIEMA. Aves, Gruiformes. *Cariama.* Peculiar South American birds (**Aves**) of several species. Their relationships are doubtful. They have long legs and moderately long necks, with a broad beak, slightly hooked. These birds live in open country and eat small animals and insects. (A.W.L.)

SERIES, BALL BEARING. Bearings.

SERIES, INFINITE. Infinite Series.

SERIES RESONANCE. Resonance.

SERINE. Aminoacids, Polypeptides, and Proteins.

SEROSA. 1. A thin membrane enveloping the developing **embryo** of terrestrial **vertebrates** (reptiles, birds, and mammals) and all of the other **extraembryonic membranes.** It is covered with ectoderm and lined with mesoderm, and in many species is formed simultaneously with the **amnion** as the outer layer of the amniotic folds. It becomes the outer component of the **chorion** and contributes to the formation of the **placenta** of mammals. 2. The lining membrane of any one of the great splanchnic or **lymph** cavities of the vertebrate body. (A.W.L.)

SEROTINE. Bat.

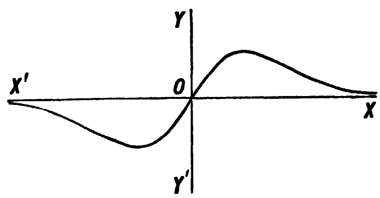
SEROUS GLAND. A gland that produces a watery secretion, in contrast with **mucous glands,** whose secretions are composed of or contain mucus. The term is

used in connection with the salivary **glands** of **vertebrates**, which are partly serous and partly mixed. The serous gland cells are distinguished in part by their more granular **cytoplasm** and rounded **nucleus**, located near the middle of the cell. (A.W.L.)

SEROW. Mammalia, Artiodactyla. *Capricornis.* The name of animals of several species peculiar to eastern and southeastern Asia. They occur in hilly or mountainous country, sometimes at an altitude of 12,000′, and are related to the gorals and goats. They are also called goat-antelopes. (A.W.L.)

SERPENT. Synonym of **snake.**

SERPENTINE. In mathematics, the serpentine is a plane cubic curve whose equation in **rectangular coordinates** is $x^2y + b^2y - a^2x = 0$.



Serpentine.

In mineralogy, serpentine is a hydrous **silicate of magnesium** corresponding to the formula $H_4Mg_3Si_2O_9$. It is a secondary mineral resulting from the alteration of magnesium-bearing silicates such as **enstatite, hypersthene, olivine,** etc., and possibly from the reaction between **feldspar** or other such silicates and waters bearing magnesium. Serpentine forms granular, fibrous, or **foliated** masses occurring as veins, or as rock masses, the latter often mixed with **calcite, dolomite,** or **magnesite** showing delicate clouded tints of green. This variety is known as verd antique or **ophicalcite,** and is used as an ornamental stone. Serpentine is found only as **pseudomorphs,** but with **monoclinic** crystalline structure. Its fracture is usually conchoidal, sometimes splintery; hardness, 2.5–4; specific gravity, 2.50–2.65; luster, greasy, pearly dull; color, usually dark green but may be reddish or yellowish-brown; translucent to opaque. Serpentine is very common and of world-wide distribution. There are many localities in Europe and North America. Decorative verd antique is obtained from Roxbury, Vermont. The name serpentine is derived from the twisting, serpentinous markings of the ophicalcite varieties. Besides the use of serpentine as an ornamental stone, much of this mineral is used in the manufacture of heat insulation materials.

Belts of serpentinized **peridotite** are intimately related to the geographical pattern, structure, and origin of island arcs such as the East and West Indies. Belts of serpentinized peridotites also occur in the deeply eroded roots of ancient mountain systems, indicating the pattern and date of the mountain building. (L.L.S., E.S.C.S., R.M.F.)

SERUM. The clear, slightly yellow liquid which is freed when blood is allowed to clot. The blood cells and fibrin are removed and the remaining fluid is serum. The composition of serum in the body shifts, varying with the cell metabolism. The chief constituents are: water; the **proteins, albumin,** and **globulin; hormones; enzymes;** sugar, **cholesterol** and other lipids; non-protein **nitrogen** waste materials; **amino acids;** organic acids; negatively charged **ions** (bicarbonate, **chloride, sulfate** and **phosphate**); and positively charged ions (**sodium, potassium, magnesium** and **calcium**).

The **antibodies,** which are important in protecting against disease, are contained in the globulin fraction of the serum. Various types of sera are therefore collected from individuals who have had a given disease (**convalescent sera**) to use prophylactically or therapeutically in other individuals exposed to, or ill with, the same disease. Effective antisera are also obtained by immunizing animals such as horses and rabbits, bleeding them, and preserving the serum. *Antitoxic* sera are obtained for use against disease caused by toxin-producing bacteria such as **diphtheria, tetanus, botulism, scarlet fever,** etc. *Anti-bacterial* sera are used against **pneumonia, meningitis** anthrax and other bacterial diseases. A *polyvalent* serum is one containing antibodies to several usually related organisms or toxins. (D.M.H.)

SERUM ACCIDENTS. Immediate shock-like reactions which may occur in man and certain animals on the administration of a foreign **protein.** Rarely, such a reaction is fatal.

Serum accidents occur as a result of protein sensitization. Since horse **serum** is the most common offender, individuals who are allergic and have **hay fever** or **asthma** when in contact with horses are the ones most apt to develop a serious reaction.

The symptoms follow the serum injection immediately. Several types occur: **urticaria, asthma, cyanosis** and choking; or chills and extremely high fever; or **shock** with pallor, weakness, rapid pulse, cold moist skin. The prevention of such reactions is accomplished by skin testing and desensitizing sensitive patients by repeated small doses of the serum to be used over 24 hours before giving it in therapeutic amounts. The treatment of the reaction is with **adrenaline** subcutaneously, repeated in a few minutes if necessary. (D.M.H.)

SERUM DISEASE. A delayed **allergic** reaction which occurs in sensitive individuals on the parenteral administration of foreign blood serum. This reaction in some form occurs in about 10% of those treated with small amounts of serum, and up to 90% in individuals receiving 100 cc. or more.

The symptoms begin 6–12 days after the injection of the serum. The onset is marked by intense itching and hives. The skin eruption may be varied and lasts from 1–3 days. The temperature may or may not be elevated; the lymph nodes are usually slightly enlarged. Arthritic symptoms are often present. **Edema** of the face, ankles, and hands may occur.

Serum sickness cannot be prevented and only symptomatic relief can be given when it occurs; fortunately the condition is not serious. (R.S.M., D.M.H.)

SERVAL. Mammalia, Carnivora. An African **cat,** *Felis serval.* The animal reaches a length of 5′ and is light tawny, spotted with black. (A.W.L.)

SERVOMECHANISMS. Probably the earliest recorded use of the word Servo was by a Frenchman, Joseph Farcot, who in 1872 gave the name Servo-Moteur (literally, Slave Motor) to an auxiliary motor on a speed governor for a steam engine. As the term is now used, a servomechanism is a device for automatically controlling some quantity such as position, direction, speed, or temperature, called the output, so that it maintains some desired relationship to another quantity called the input. This desired relationship is maintained by continuously comparing the output with the input, and using the difference between them—which is called the error—to change the output in a direction that tends to decrease the error. This correction of the output is accomplished by control of the servomotor which draws power from a source other than the input. Hence, a servomechanism usually gives over-all power amplification. Since the output may be at some distance from the input, a servomechanism often re-

quires the transmission of information for comparison, or correction, or both.

The input may be constant, as when a ship is steered on a fixed course, or a house is kept at a fixed temperature; or it may be variable, as when a searchlight is pointed at a moving target, or a cutting tool is made to reproduce the contours of a model. Also, the output quantity may be of the same kind as the input, as when the angular position of a repeater compass card is made the same as the angular position of the master compass card; or it may be quite different, as when the speed of a rolling mill is made proportional to a voltage on a controller potentiometer. There is no need to distinguish these various cases since the methods of analysis and dynamic design are the same for all.

In transmitting information to the output from the comparison point where the error is determined, or in transmitting information from the output to the comparison point, there may be delays due to the storage of energy in reactive elements such as mass, compliance, or thermal capacity. This may delay the application of corrective force and cause errors of the type known as lag, or it may delay the removal of corrective force and cause errors known as overshoot. If, in correcting one overshoot, an overshoot in the opposite direction is caused, **hunting** or oscillation may result.

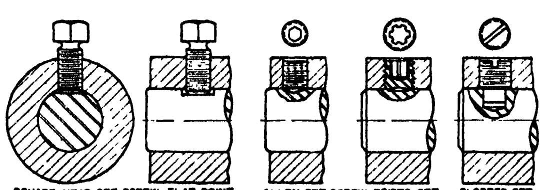
From the comparison point to the output and thence back to the comparison point, the control path is a closed loop, which is an essential characteristic of servomechanisms. In the general case, the input is varying as is, of course, the output, and since any quantity varying with time may, by Fourier analysis, be represented by a series of sinusoidal components of various frequencies, the closed loop of the servo actually carries a group of frequencies. These may be very low—1 cycle per sec. or even less—but they are still frequencies and are most conveniently treated as such.

One of the major difficulties of servo design is to select the arrangements either so that the various circulating frequencies do not add up in phase at the comparison point, or so that any frequencies that do add up in phase have sufficient attenuation in their path to prevent the steady oscillation that might otherwise occur. This problem of stability in servomechanisms is the same as that in negative-**feedback** amplifiers using vacuum tubes and other simple electrical arrangements. (E. B. FERRELL, Bell Telephone Laboratories.)

SESAME OIL. **Fixed Oils.**

SET. **Deformation.**

SET SCREWS. Set screws prevent relative motion by pressure exerted on their points. Several varieties are shown in the figure. Square head set screws have



SQUARE HEAD SET SCREW-FLAT POINT ALLEN SET SCREW CON. POINT BRISTO SET SCREW CUP POINT SLOTTED SET SCREW-DOG POINT

heads in which the distance across the flats is equal to the diameter of the screw, with a height equal to three-fourths the screw diameter. Safety or headless set screws may be set so that they do not project above the surfaces of the hub; Allen and Bristo screws require special wrenches, but can be seated more firmly than headless set screws with screwdriver slots. Any of the varieties of screws shown are obtainable commercially with all types of points shown. Cone and cup point set screws raise burrs on the shaft, and create difficulties in disassembly; shafts are usually made with a "flat," or "spotted" with the point of a drill, to provide a secure seat for the screw and to eliminate burring.

An equation for the size of a set screw is: $d = 0.25 + (D/8)$, where D is the shaft diameter, and d is the set screw diameter, in inches. The transmission capacity of cup point set screws is given by: $F = 2500d^{2.3}$, where F is the resisting force at the surface of the shaft. (H.C.H.)

SETA. Any slender bristle-like structure. The term is usually limited to the hairlike processes of the integument of invertebrates, of which the setae of **annelid** worms are a good illustration. These structures are formed of **chitin** secreted by cells of a pocket in which the base of the seta is lodged. They are also called chaetae. Setae gain high development among the **insects.** Here they are secreted by cells of the **hypodermis** and project from the surface of the cuticula. They vary in form from slender hair-like structures to broad flat scales like those of **butterflies** and **moths.** In some cases they are associated with sense organs or glands. (A.W.L.)

SETTING. This word is commonly used among **boiler** artisans to refer to the brick work which encloses the furnace and partially encloses the boiler itself. Originally this was probably derived from the fact that the **furnace** walls were built, and the boiler set on the brick work. The best modern practice in settings, however, attempts to eliminate boiler supports of that type in favor of independent suspensions because of the unequal rates of expansion of steel and masonry. The boiler setting consists chiefly of walls of a compound type, having **refractory** brick on the hot side, and common brick or steel casing on the exterior, or cool, side. Many types of setting walls are in use today. There are the solid masonry walls which range from a single homogeneous refractory section to one containing special **insulation** between the refractory lining and the exterior casing. This is a common type for steam generating units. Some setting walls are hollow. The air-cooled wall consists of a thin refractory section backed by an air space through which circulate currents of cooling air. Obviously an excellent feature of this construction is that the heat flow which cools the refractory lining may be returned to the furnace by using the cooling air for combustion. Often in settings of this type sections of the setting must be independently supported from a steel or iron skeleton, from which the bricks are hung. Many patented ingenious methods of doing this have appeared, and in the main this is the field of the proprietary setting. In some cases the setting has been partially protected from high temperature by covering a portion of it with water-bearing tubes. This tends to maintain the setting at a lower temperature.

In brick work settings it is necessary to provide for expansion, horizontally and vertically, with joints in the different layers overlapping so as to avoid cracks and infiltration of air. The setting often includes not only the enclosure of the furnace, but virtual enclosure of the boiler itself, which means that different parts of the setting work at widely different temperatures. The brick work is laid with thin joints in a refractory mortar. The exterior surface should be finished for a minimum of heat radiation from it, while the interior should be able to resist high temperature conditions, thermal expansion, spalling, and the action of slag and clinker. (F.T.M.)

SEVENTEEN-YEAR LOCUST. Insecta, Homoptera. A **cicada,** *Tibicina septendecim,* which requires seventeen years to complete its development from egg to adult. The eggs are deposited in slits cut deep into the wood of twigs. After hatching, the young drop to the ground and burrow, feeding on rootlets during their sub-

terranean life. When ready for their transformation into the adults, the **nymphs** leave the ground and climb some plant, where their dry skins can be found after the adults have emerged. The deposition of eggs weakens the twigs and sometimes causes heavy damage in young orchards. Although various broods occur which may overlap, the usual appearance of large numbers is infrequent. By consulting local entomologists the orchardist can learn when to plant trees to avoid trouble. Otherwise young trees can be protected by covering them with cheap cloth.

A variety whose life cycle is completed in 13 years occurs in the south. It is otherwise similar. (A.W.L.)

SEWAGE, SANITARY OR HOUSE. Sewage is a liquid composed of waste from such sources as domestic dwellings, commercial buildings, and factories, together with any ground or surface water which may enter the sewerage system. The average composition of sewage is over 99% water, the solid parts being composed of grease, fats, animal and vegetable matter, both dissolved and undissolved, and some inorganic matter. It is ordinarily swarming with **bacteria** which, in their ability to decompose dead organic matter, become active agents in the process of purification. Among the bacteria there may be some dangerous to human health, making it essential for the sake of general health to practice scientific disposition of the sewage. (E.W.S.)

SEWELLEL. Mammalia, Rodentia. The mountain beaver or **boomer.** A broad stout animal with short legs, found in mountain forests of the western states. It is a burrowing species which feeds on bark, twigs, and leaves. More closely related to the squirrels than to the beavers. (A.W.L.)

SEWEN. Pisces, Teleostei. A **trout** found in the rivers of Wales. (A.W.L.)

SEWERAGE SYSTEM. The term sewerage system refers to any system for the collection and/or disposal of sewage. A sewerage system usually consists of sewers and the necesary auxiliaries for the purification and disposal of the effluent. As sewage is a foul liquid, it must be carried in water-tight underground conduit systems known as sewers. A sanitary sewer is one devoted entirely to carrying sewage, and does not receive storm water which is usually carried by a storm sewer. In a municipality, where a central sewer system serves a large group of homes, industrial buildings, and business houses, the building sewer is connected to a lateral sewer which discharges into a street conduit, called the submain or main sewer. The latter discharges into an outfall sewer, which carries the sewage to the disposal plant. As the average per capita use of water is often assumed to be 100 gals. per day, the sewage load will be about 100 gals. per capita per day. The lateral and main sewers are composed of reinforced concrete or terra cotta pipe with tight joints. The outfall sewer, being larger, is often made of masonry. Sewerage works are plants which receive sewage and convert it into an effluent which may be disposed of without creating a nuisance or a focal point of infection.

A simple method of sewage disposal is described under the head of **septic tank,** but this system is not suitable for central sewerage works by virtue of its imperfect operation. Oxygen is a very important factor in converting sewage into a safe liquid. The oxidizing of sewage takes place either by the **dilution** process or by **aeration** or filtering. Often the discharge of a municipal sewerage works takes place into a nearby stream or river, in which case the dissolved oxygen in the water effects the oxidation required for complete breakdown of the solids. Disposal to a subsurface drainage field, which constitutes a crude form of filter, is illustrated by the tile disposal field, which is an essential part of the septic tank system. Aeration of sewage is illustrated by the activated sludge process. The principal equipment for sewerage works might be briefly enumerated as follows: screens, or racks, for the removal of floating matter, sedimentation tanks for the removal of solids by gravity, **Imhoff tanks,** and activated sludge chambers. In the last-mentioned system, the conversion of the solids in sewage is carried out by forced aeration. Aerobic bacteria are supplied in large quantities by recirculating to the incoming sewage a considerable amount of sludge, which contains large growths of these bacteria. This system is rather extensively used where dilution cannot be practiced, since the effluent is not foul. The operating costs of the activated sludge process may be rather high, because of the necessity for compressing the air for aeration and usage of other mechanical equipment. (E.W.S.)

SEX. The state of an individual as determined by its adaptations for a special part in biparental reproduction and modifications of the process. Also a category of individuals adapted for a special part in reproduction. The usual sexes are male and female. Neuter individuals exist among colonial invertebrates, including both sexless forms and abortive females whose limited reproductive powers are not exercised under normal conditions. Sex is also expressed in hermaphrodite animals which carry on the usual processes of sexual reproduction but have male and female organs in the same individual.

The differentiation of the sexes is associated with the development of two kinds of **gametes** in the process of sexual reproduction. Organs and ducts capable of producing the larger egg cells of the female and providing them with quantities of food material make up a **reproductive system** much different from that which produces the minute male spermatozoa and the seminal fluid in which they are discharged. The development of the external genitalia for internal insemination also results in conspicuous differences since the male has a projecting penis or other **intromittent organ** while the female has the terminal portion of the genital ducts specialized for the reception of this organ. In the mammals the **mammary glands** of the female also constitute a conspicuous sexual distinction. These organs may be classed as essential and accessory organs of reproduction, the former category including the **gonads** and ducts and the latter such parts as the external genitalia and the mammary glands.

Sexes also differ in more or less conspicuous **secondary sexual characters** such as the beard of man, which are definitely associated with sex but have no direct part in reproduction.

The sexes of most animals are specialized in behavior as well as in structure for the performance of reproductive acts, for accessory functions such as the building of nests, and for subsequent duties of parental care. All of these phases of sexual differentiation are intricately variable among the many species of animals. (A.W.L.)

SEX GLANDS. Ovaries or testes, the essential organs of the **reproductive system.** These organs are classed as cytogenic glands, or glands which produce cells (ova and spermatozoa); they also produce hormones and have endocrine functions. (R.S.M., D.M.H.)

SEX HORMONES. The hormones concerned with sexual function, the development of secondary sex characteristics, **menstruation,** and **pregnancy** may be classed as the sex hormones. These are produced by the gonads, the **ovaries** and **testes,** and by the anterior lobe of the **pituitary** gland.

The ovary produces two types of hormones, follicular

and luteal. Follicular hormone is associated with the presence in the ovary of a growing follicle, or egg, with its protective nutrient covering. (See figure page 629.) Since maturation of a follicle occurs each month as part of the menstrual cycle, this hormone undergoes cyclical variations. It is not a single substance but a group of closely related ones called, collectively, estrogens. The most active of the estrogens is estrone or theelin, which is responsible for the development of the sex organs at puberty, and for the development and maintenance of secondary sex characteristics such as the texture and distribution of the hair, the texture of the skin, the distribution of body fat, and the character of the voice. Luteal hormone, or progesterone, is necessary in the preparation and maintenance of the lining of the uterus for the implantation of the fertilized ovum, and the development of the embryo. It acts upon the **mammary gland** during pregnancy to prepare it for lactation, or the secretion of milk.

The estrogens and progesterone are secreted in sequence under the rhythmical stimulation of the anterior **pituitary** acting through its gonadotropic or gonad-stimulating hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The relationship of these two hormones and the ovarian hormones to the menstrual cycle and pregnancy is discussed under **Menstruation.**

Pharmaceutical preparations of estrogenic substances and progesterone are available for clinical use. A synthetic estrogen called stilbesterol has largely replaced estrone or theelin because it has the advantage of being inexpensive and active orally whereas the natural-occurring substance must be given by injection.

The estrogens are useful in the treatment of menopausal symptoms, senile vaginitis, and in conjunction with luteal hormone, in certain types of amenorrhea (absence of menstruation). In males suffering from inoperable cancer of the **prostate,** the estrogens are effective in controlling the symptoms and slowing the growth of the tumor (see **Prostate Gland**). Progesterone is valuable in the treatment of habitual **abortion,** where it acts by suppressing uterine motility.

The male sex hormones are known as the androgens. The testicular hormone, or testosterone, produced under stimulation by the gonadotropic hormone of the pituitary, is responsible for the development of the sex organs and the secondary sex characteristics at puberty. During adult life, the functions of the seminal vesicles, prostate, and epididymis (see **Reproductive System**) are dependent upon its presence. In the urine of the male a closely related hormone, androsterone, is found in minute quantities. This substance is thought to be testosterone which has been altered in the body. The male and female sex hormones are of strikingly similar chemical structure.

The therapeutic uses of the androgens are in castration syndromes, and in certain cases of cryptorchidism or undescended testicle. (D.M.H.)

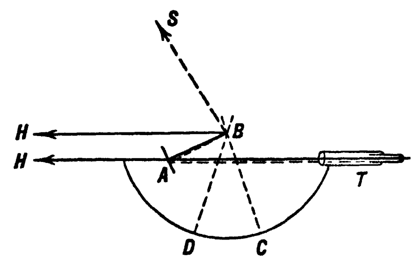
SEX LIMITATION. The conditioning of the expression of a hereditary character in the individual according to its sex. In many known cases exactly the same determining heritage according to Mendelian **heredity** may give different results in the two sexes. A good example is that of color in Ayrshire cattle. Males with determiners for the colors mahogany and red develop the former, while females develop the latter, although both colors may appear in both sexes under proper conditions of inheritance. (A.W.L.)

SEX LINKAGE. Heredity.

SEXAGESIMAL MEASURE OF ANGLES. Degree Measure of Angles.

SEXTANT. The sextant is a light, portable instrument designed for the purpose of measuring the angular distance between two objects. It represents the most recent stage in a succession of portable devices for angular measurement advancing from the **astrolabe** through the **cross-staff** down to the modern instrument. The immediate predecessor of the sextant was the quadrant (the "hog-yoke" of the sailing ship era), but the design of this instrument is very similar to that of the modern sextant. Since the sextant is universally used by navigators for the purpose of measuring the apparent **altitude** of celestial objects, the opinion is prevalent that it is purely a navigational instrument. Such is far from the case, and the instrument is of great value to explorers, surveyors, or any person who desires to measure angular distance.

The optical system of the sextant (and quadrant) is diagrammed in the accompanying figure. The mirror *A*



(called the horizon glass) is divided into two sections by a line parallel to the plane of the instrument. The upper section is unsilvered so that an observer looking through the telescope *T* can see directly through *A* to an object in the direction *H*. The mirror *B* (called the index mirror) may be rotated about an axis perpendicular to the plane of the instrument and coincident with the center of the graduated arc *CD*. Attached to the index mirror is a vernier arm which sweeps along the arc.

With the mirror *B* strictly parallel to *A* the observer will see two superimposed images of the object in the direction *H*. One of these is the direct image observed through the upper section of the horizon glass, the other is a reflected image with light traveling along the path *HBAT*. Under these conditions the index *C* should read zero; in case this is not so an "index correction" must be applied to all observations with the instrument.

In case the angular distance between an object in the direction *H* and another in the direction *S* (angle *SBH*) is desired, the observer moves the index arm along the arc until an image of *S* (light path *SBAT*) is superimposed on the direct image of *H*. Application of the laws of **reflection** of light will show that the angle *CBD* through which the mirror is turned is one-half the angle *SBH*. To obviate the necessity of dividing each reading of the instrument by two, the arc is so graduated that when *CBD* is actually 60° the index will read 120°.

To obtain the altitude of a celestial object at sea, the instrument is directed toward the visible **horizon** and the index arm moved until the desired object is in the field of view. Now the sextant is rotated back and forth about the optic axis of the telescope (the line *HAT* in the figure), and the image of the celestial object will apparently swing back and forth along a short arc. The index arm is now carefully adjusted until the celestial object is just tangent to the horizon at the lowest point of its apparent swing. Under these conditions the reading of the sextant will give the sextant altitude measured along the vertical circle through the object.

In case the sextant is to be used for measurement of altitude in a region where the sea horizon is not available, an artificial horizon must be used. This is a level reflecting surface, e.g., a basin of mercury. Simple geometric considerations will show that the angle between a line directly from a celestial object and the line from the image of that object reflected from the

level mirror, will be twice the altitude of the object. To measure the altitude with the sextant and artificial horizon, the instrument is pointed toward the level reflector, and the reflected image brought into the field of view directly through the horizon glass of the sextant. Next, the index arm is moved until the direct image of the celestial object (along path *SBAT* in the figure) is brought into the field of view. Now the sextant is rotated back and forth about the optic axis. In this motion the reflected image will remain stationary, but the direct image will apparently oscillate back and forth in a short arc. When the direct image passes through the reflected image at the bottom of its arc, the reading of the sextant will be twice the sextant altitude of the object.

On ships or airplanes the artificial horizon cannot be used. The visible horizon is always more or less ill-defined and serious errors are introduced when altitudes are measured from it. Over 50 years ago the so-called "bubble horizon" was invented in the attempt to remove the uncertainties of the visual horizon. The rapid expansion of aviation, where high altitude of flight frequently renders the use of the visible horizon impossible, has motivated the development of bubble instruments. In most of these instruments the arc is only 45° long, restricting measurement to 90° (the maximum altitude possible), and they are known as bubble octants to distinguish them from the older-type mariner's sextant. Many writers, however, use the term sextant to indicate any type of instrument used for measuring altitude for determination of position by methods of **celestial navigation.** The fundamental principle of all bubble octants is the same. The line of sight of the view telescope is so directed that, when the instrument is held in the proper position for observation of altitude, the image of the bubble of a spherical spirit **level** is in the field of view. A spherical spirit level differs from that used by mechanics in that the upper surface of the chamber containing the liquid is ground to the surface of a sphere so that, when the level is in the plane of the horizon, the bubble is at the "top" of the sphere. With the instrument held so that the bubble is centered in the field of the view telescope, a system of reflecting prisms is adjusted until the image of a selected celestial object is centered on the bubble. The reading of a scale gives the "sextant altitude" of the object. Most octants are so designed that the view telescope can be directed at the visible horizon, when it is available, and the instrument used as a mariner's sextant.

While the use of the bubble removes the uncertainties of the visible horizon, nevertheless other uncertainties are introduced which are of such magnitude that the sea horizon should be used whenever available. **Accelerations** produce a change of position of a level bubble, as may readily be demonstrated by moving a level about over a horizontal surface with anything other than constant velocity. The **Coriolis force** (or acceleration), due to the motion of the ship relative to the surface of the revolving earth, produces a displacement of the bubble of an octant which is proportional to the velocity of the ship and the latitude of the observer. A so-called Coriolis correction may be computed in terms of the speed of the ship, latitude of observation, and relative bearing of the observed object to the track of the ship. This factor is tabulated in the Air **Almanac** and a variety of other publications. However, the random accelerations, due to roughness of the sea or air, are unpredictable and cannot be corrected for. These are usually greater on seaborne ships than in the air, and may introduce errors in a single observation as great as 2° (120 miles in the position of the ship). These accelerations are, as the name implies, random and tend to average out if a number of settings are made in rapid succession. Most modern bubble octants are built with averaging devices so that a series of settings may be made and the average obtained without reading the scale for each setting.

Before the sextant altitude can be used for obtaining a celestial line of position, two types of corrections, instrumental and observational, must be applied. The instrumental corrections, which are common to both the sextant and the octant, are index correction and eccentricity of the arc. Observational corrections are (1) dip of the horizon, when the visible horizon is used, (2) Coriolis correction, if the bubble is used, (3) atmospheric **refraction,** (4) geocentric **parallax,** (5) **semidiameter,** with **augmentation** when necessary, if the altitude of a limb of an object of finite size (sun, moon, or large planet) is measured.

It is important to consider briefly the accuracy of angular measurements made with these portable instruments. If the instrument is mounted in a sextant holder and used to measure the angle between fixed points an accuracy of 20″ should be attained for a single setting. Such conditions are met in exploratory surveying or in measuring altitudes with an artificial horizon. Such accuracy cannot be expected in observations of altitude taken from a ship or plane. Under the best possible conditions of smooth sea and perfect visibility of the horizon and sky, the fix determined by celestial navigation may be accurate to within ¼ mile. However, under normal conditions an uncertainty of position of from 1 to 2 miles is to be expected. When the bubble is used, the random accelerations, even when a run of ten or more settings is averaged, always introduce an uncertainty of more than 1 mile in the fix, and when the sea or air is rough the error may be as great as twenty odd miles. (W.K.G.)

SHA. Mammalia, Artiodactyla. An Asiatic **sheep** with very wide range. It is found from Persia into India and northward through Tibet. The name more widely used is urial, sha applying to a large variety ranging from northern Tibet to Afghanistan. It is more common at high altitudes, up to 14,000′. (A.W.L.)

SHACKLE. A shackle is a piece used for connecting together two parts. The parts so connected can have some relative motion which is permitted by the shackle, but at the same time the extent of their freedom is limited by the restraining action of the shackle. The connections of the shackle to the part are not required to be as exacting a fit as a **bearing,** but often are of a type needing lubrication. A common example of shackle is the steel shackle employed to connect the ends of the suspension springs of an automotive vehicle to the frame. (F.T.M.)

SHAD. Pisces, Teleostei. A marine fish **(Pisces)** found along the Atlantic coast of the United States. It ascends the coastal rivers to spawn. This species belongs to the same genus as the herring and is ranked as one of our best food fishes. The roe is also regarded as a delicacy. (A.W.L.)

SHAFT. In mining, the term refers to a vertical excavation, sunk to permit access to the interior of the earth. An elevator shaft, used in building construction, refers to a vertical passage for passenger or freight elevators. In mechanical engineering, the term shaft denotes a rotating member used for transmitting power or motion. A spindle is a shaft that supports and drives either a cutting tool or work parts; a lathe spindle is an example of the first classification, and a milling machine spindle an example of the second. Shafts may be classified as transmission shafts and as machine shafts; the former are usually of uniform diameter, and range in size from $1\frac{5}{16}''$ diameter to $5\frac{7}{16}''$ diameter or larger. They are usually $\frac{1}{16}''$ under the conventionally accepted fractional sizes, such as $\frac{15}{16}''$ instead of 1″, $1\frac{7}{16}''$ instead of $1\frac{1}{2}''$, $1\frac{15}{16}''$ instead of

2″, etc. Machine shafts are usually, although not always, of non-uniform diameter, such as motor and generator shafts, gear transmission shafting, etc.

Transmission shafting is used for group driving, in which a lineshaft, coupled to and driven from an electric motor, is used to drive countershafts, which in turn drive individual machines. The drive is usually effected by belts and pulleys, although chain drives are sometimes employed. By using tight and loose pulleys between the lineshaft and each of the countershafts, one or more individual machines may be stopped without affecting the others. The drive from the countershaft to the machine may be effected by cone pulleys, to permit variations in the speeds of the individual machines while the lineshaft runs at a constant speed.

The stresses in a transmission shaft are due to the torsion caused by the transmitted power, and the flexure arising from the pulley weight and belt tension. The resultant shearing stress S in lbs. per sq. in., in a rotating shaft subjected to a torque T and a flexural moment M, in inch-lbs., is given by

$$S = \frac{16}{\pi D^3}\sqrt{(K_tT)^2 + (K_mM)^2}$$

where D is the shaft diameter, and K_t and K_m are torsional and flexural service factors. According to the A.S.M.E. Code for the Design of Transmission Shafting, K_t may vary from 1.0 to 3.0, and K_m from 1.5 to 3.0; the lower values are for gradually applied or steady loads, the higher for major shock loads. The permissible shearing stress S may be taken as 8000 lbs. per sq. in. for steels for which no physical properties are specified; where physical specification for the material is introduced, S may be taken as 30% of the tensile elastic limit, or 18% of the ultimate tensile strength, whichever is less. When keyways are cut in the shaft, only 75% of the aforesaid values may be employed. (H.C.H.)

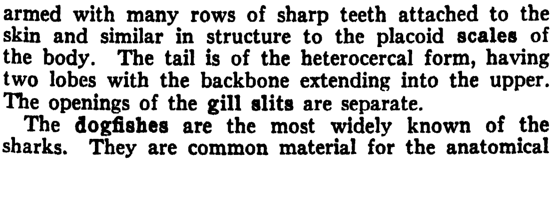
SHALE. Shale is a fine-grained sedimentary rock whose original constituents were clays or muds. It is characterized by thin laminae breaking with an irregular curving fracture, often splintery, and parallel to the often indistinguishable **bedding** planes. (R.M.F.)

SHAMA. Aves, Passeriformes. A jungle bird (**Aves**) of the Oriental region. The several species are found in the Malayan area, in the Philippines, in India, and on various Pacific islands. They are shy birds, but the Indian species is kept as a cage bird for its beautiful song. (A.W.L.)

SHANK. **Drilling; Rivet.**

SHAPER. **Woodworking; Planer.**

SHARK. Pisces, Plagiostomi. A carnivorous fish (**Pisces**) of the group with cartilaginous skeletons. The mouth opens on the ventral surface of the head and is



Shark.

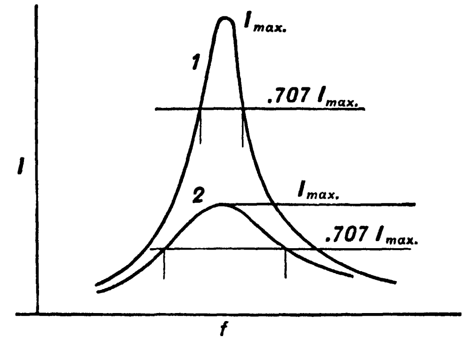
armed with many rows of sharp teeth attached to the skin and similar in structure to the placoid **scales** of the body. The tail is of the heterocercal form, having two lobes with the backbone extending into the upper. The openings of the **gill slits** are separate.

The **dogfishes** are the most widely known of the sharks. They are common material for the anatomical laboratory and are used to some extent as food. Some members of the group, notably the whale shark, *Rhinodon*, attain a length of 30′ or more, and others are large enough to be feared by divers. Although they are reputed to attack man freely, this tendency is also disputed by competent observers. There can be little doubt that under some conditions they do attack human beings.

Among the species whose common names do not indicate their association with this group are the thresher, *Alopias*, the **porbeagle**, the hounds, and the tope. The most peculiar species is the hammerhead, *Sphyrna*, whose head is transversely extended into two processes bearing the eyes at their tips. (A.W.L.)

SHARK SUCKER. **Remora.**

SHARPNESS OF RESONANCE. Since resonant circuits give a response which varies with frequency, reaching a maximum at the resonant frequency and dropping on either side, it is convenient to have some means of comparing different circuits. The usual purpose of such circuits is to select certain frequencies in preference to others so the common method of defining the sharpness of resonance is to specify the **frequency band** in which the response will exceed an arbitrary value. This arbitrary value is often taken as 70.7% of the maximum as this is the point where the power is half the value at **resonance.** The narrower the frequency band between these two points the sharper the



resonance, thus in the figure the circuit having the response curve 1 has much sharper resonance than that of curve 2. (L.R.Q.)

SHEAR. A force which lies in the plane of an area or a parallel plane is called a shearing **force.** It is the force which tends to cause the plane of the area to slide on the adjacent planes.

The vertical shear for any section of a simple beam is the magnitude of the **resultant** of the transverse loads on either side of the section. Transverse loads are those which are at right angles to the length of the beam. If the loads are inclined the vertical components, only, should be used in computing the vertical shear. The resisting shear at any section is the internal force which opposes the shearing action of the external loads. It is numerically equal to the external shear but in the opposite direction. Vertical shear, which is always accompanied by **bending moment** at a section of a beam, is numerically equal to the rate of change of this moment with respect to distance along the beam. This shear is arbitrarily assumed to be positive if the resultant of the vertical loads to the left of a section acts in an upward direction. In a symmetrically loaded simple beam the shear is equal to zero at the center of the beam. (See **Elasticity.**)

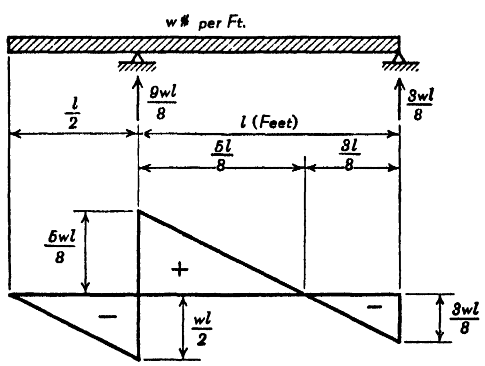
In addition to vertical shear in a beam there is always a horizontal shear which is a result of the difference in the flexural stresses (see **Flexure**) between any two

vertical planes. The tendency of adjacent horizontal planes to slide upon each other is caused by horizontal shear. The effect may be better understood by visualizing a beam composed of flat planks laid one on top of the other. As the beam bends, due to the applied loads, the bottom of one plank will slide upon the top surface of the one beneath it unless this effect is restrained by friction, nails, bolts, or other **fastenings.**

The unit stresses resulting from vertical shear are called vertical shearing stresses. At any point in a beam these stresses are numerically equal to the horizontal shearing stresses. The variation of the unit shearing stresses over the cross-section of a rectangular beam is parabolic, being equal to zero at the top and bottom surfaces and a maximum at the **neutral axis.** When horizontal and vertical shear, only, act at a point in a body, the body is said to be in a state of pure shear at the point.

Shear is not restricted to beams. It occurs wherever there is bending. The web members of **trusses** and web plates of **plate girders** are designed to carry the shear. Columns, which are subjected to bending caused by eccentric **loads,** or by inclined or **lateral** loads, must be designed to withstand the shearing stresses. **Rivets** and welds (see **Welding**) are also subjected to shear. If the riveted connection is made so that the shear occurs between two plates only, it is called a single shear. When the type of connection is such that the shearing force is opposed by resisting shears acting on two planes, as in the case of three plates riveted together, the condition is called double shear. (See **Rivet.**)

A shear diagram is a graphical representation of the variation of vertical shear on a beam. An illustration of a shear diagram is given below for an overhanging beam with a uniformly **distributed load** covering the



entire length of the beam. The points where the shear changes sign are points of maximum **bending moment.** The area of the shear diagram between any two points is equal to the change of bending moment between these points. (C.W.C.)

SHEAR CENTER. The point through which the external **shear** must act at any cross-section of a **beam** in order to eliminate **torsional stresses** is called the shear center of the particular cross-section in question. The shear center coincides with the **centroid** of the internal shearing forces on the cross-section. If the beam is to bend without twisting, the loads must be applied in such a manner that the external shear at any section will pass through the shear center. The shear center has no meaning for sections where **pure bending** occurs because there is no shear and, therefore, no torsional stress can exist under these conditions. (C.W.C.)

SHEAR RESISTANT. Tension-Field Theory of Beam Analysis.

SHEARING DEFORMATION. Deformation.

SHEARING LOAD. Load.

SHEARING STRESS. Stress.

SHEARWATER. Aves, Charadriiformes. **Puffins.** A group of marine birds (**Aves**) related to the auks, with large beaks, high at the base and strongly compressed. The name puffin is commonly applied to the Atlantic species and the name shearwater to those of the Pacific. Together they constitute the genus *Puffinus.* (A.W.L.)

SHEATHBILL. Aves, Charadriiformes. *Chionis.* A bird (**Aves**) related to the oyster-catchers. It is named from the horny sheath enclosing the base of the beak. Two species are known, both found in extreme southern latitudes and the Antarctic. (A.W.L.)

SHEAVE. A grooved pulley for use with vee-belts, rope drives, or round leather belts. Sheaves may have single or multiple grooves. Adjustable-diameter sheaves, for varying the diameter of the pulley, and consequently the speed ratio of the drive, are used in small and medium sized vee-belt drives. (See **Belting, Rope Drives.**) (H.C.H.)

SHEEP. Mammalia, Artiodactyla. Animals related to the oxen and goats but more sharply distinguished from the former by their smaller size and the usually spiral horns. They differ from goats in the absence of strong odor in the males and in the lack of a beard.

Aside from the many domestic breeds, *Ovis aries,* sheep are much more highly developed in the Old World. They are mountain animals, often found at high altitudes, and are represented by various species in the Old World, while in North America the mountain sheep or **bighorn,** *O. canadensis,* is the sole representative. Among the other species are the argalis, *O. ammon,* of Tibet, Mongolia, and Kamchatka, the urial or sha, *O. vignei,* the **mouflon,** the **bharal** or blue sheep of Tibet, and several known as the Armenian, Cyprian, and Barbary sheep. (A.W.L.)

SHEEP TICK. Insecta, Diptera. A wingless parasitic **fly,** *Melophagus ovinus,* resembling the true ticks only in its flattened body and leathery texture. Like the other flies it has sucking mouth parts, hence it draws blood from the skin of the host. It is especially harmful to lambs.

Control of the tick requires dipping, preferably twice, after shearing. The commercial preparations for dipping stock are effective against such pests. (A.W.L.)

SHEEPSHEAD. Pisces, Teleostei. 1. An excellent salt-water food fish (**Pisces**), *Archosargus probatocephalus,* related to the snappers. It ranges from Massachusetts to Texas. 2. A fresh-water species, *Aplodinotus grunniens,* one of the drums, found from the Great Lakes to the Gulf of Mexico. It is taken for food but must be regarded as inferior. The species bears several other names, among them white perch, croaker, and fresh-water drum. (A.W.L.)

SHEET. A thin flat-rolled metal product. In the case of steel, sheets and strip are under .25″ in thickness, heavier sections being classified as plates. Most sheets are actually rolled as coils on continuous strip mills and sheared to sheet sizes. (See **Sill.**) (R.H.H.)

SHEET METAL PROCESSES. Many manufactured articles are made from sheet metal. Such articles are usually lighter in weight and are often less expensive than castings or forgings. Such important parts as pipe, elbows, transitions, hoppers, and guards for gears, etc., may be made of sheet iron and steel, galvanized iron, copper, aluminum, or brass.

The shape to which the sheet material is cut while in the flat state is called the stretch-out or blank. The drawing which gives the size and shape of the blank is called the development. In many cases the blank is laid out directly by prick-punching through the corners of the development on the drawing; in other instances, where more than one blank is required, a pattern or template of sheet metal or thin wood is made from the development, and the outline of the blank is scribed on the sheet by following the outline of the pattern.

The blank is cut to the proper shape from the sheet material, and is folded, curved, or stretched until it assumes the desired form. The edges that meet are then joined by seaming, soldering, or riveting, or by a combination of these methods. Hand operations will probably always be necessary in sheet metal fabrication. Snips, which resemble large scissors, are universal and indispensable hand cutting tools. Straight snips may be used for straight or notching cuts; circle snips have curved jaws for cutting circular arcs and other curves. Bench shears are heavy-duty sheet metal cutting tools in which the jaws and handles are longer than in snips. Stakes are the anvils of the sheet metal worker. Such sheet metal operations as tube and taper forming, flanging, seaming, and riveting may be performed with their aid. Most stakes have squared shanks to fit holes in the work bench.

Ball peen, cross peen, and riveting hammers are used by sheet metal workers. Raising hammers have convex faces and are used for producing concave or convex formations in sheet metal by a series of blows. Soft-face hammers, such as plastic-tipped hammers, and hickory mallets are used when hard-faced hammers would deface the work.

A variety of standard machinery is used in sheet metal fabrication to facilitate production, secure a better product, and minimize fatigue of the operator. Foot- or power-actuated squaring shears are used to resquare plates that have been roughly cut on mill shears, and to shear plates into strips, trim edges, and cut square, rectangular, or other straight-sided blanks. Folders and brakes are machines used for bending or folding sheet metal to an angle or lock. Folders are employed for folds of limited width; brakes have unobstructed openings from front to back and are adapted to folds of unlimited width. Roll forming machines are used to curve flat sheets of metal into pipe or other cylindrical formations. The machine usually has three cylindrical rolls, *A*, *B*, and *C*, of which two rolls, *B* and *C*, are hand- or power-actuated. Roll *A* is adjustable vertically to clamp the sheet at the beginning of the bending operation; rear roll *C* is adjustable vertically to produce the required degree of curvature. In hand-operated machines, the sheet is placed between rolls *A* and *B* and roll *A* is adjusted to clamp the sheet. The sheet is then turned up in front in order to give it an initial curvature so that it will pass over the top of roll *C*. Rolls *B* and *C* are then rotated, causing *A* to roll with the sheet, which encircles the upper roll as it is formed. (H.C.H.)

SHEET PILE. Pile.

SHEET-STIFFENER COMBINATION. **Stressed Skin Constructon.**

SHELDRAKE. Aves, Anseriformes. 1. A **duck,** *Tadorna tadorna,* of the Old World, marked with green, bay, and white. It is a larger species than most of the ducks but has the characteristic broad beak of the group. 2. The American **merganser,** *Mergus merganser,* a fish-eating species found throughout North America, although it breeds chiefly north of the United States. (A.W.L.)

SHELL. A hard external covering secreted by folds of the body wall of many animals. The term applies properly to the shells of **Brachiopoda** and **Mollusca,** although it is sometimes used in reference to the hard exoskeleton of **crustaceans.** Also a hard covering of eggs.

Brachiopod shells consist of two valves, one upper and one lower. They have an outer layer of organic matter known as the periostracum, under it a thin layer of calcium carbonate, and a thick inner layer of mixed organic and calcareous matter, deposited in prismatic form. The valves are opened and closed by a complex system of muscles.

Molluscan shells are usually spiral in form, like many common snail shells, or bivalve like those of mussels and the oyster. The valves of such shells are lateral in position. A third rarer form is the shell of **nautilus,** which is spirally coiled in one plane. Internal shells of slugs, chitons, and some cephalopods are in the form of plates of calcareous matter.

The external shells of mollusks have an external horny layer, the periostracum, a smooth lining of nacre or mother-of-pearl, and a thick calcareous middle layer.

Because of their permanence and beauty the shells of many marine mollusks have attracted the attention of collectors, and many have received common names. Among them the spiral staircase or wentletrap, periwinkle, conch, finger shell, cowry, coffee-bean, appleseed, oyster drill, whelk, papal miter, cockle, gem, and others are to be found on the coasts of the United States.

The shells of eggs are calcareous or chitinous coverings secreted by a portion of the female reproductive ducts known as the shell gland. In the birds they are characteristically and often beautifully colored, and in the insects they may be beautifully sculptured They are sometimes perforated by a minute opening or group of openings called the micropyle for the entry of the sperm. The egg shell of insects is also called the chorion, a term not to be confused with the chorion of vertebrate embryos. (A.W.L.)

SHELL GLAND. A specialized region of the ducts of the female **reproductive system** which secretes a more or less rigid covering about the egg. (A.W.L.)

SHELL REAMER. **Reaming.**

SHELL SHOCK. A war neurosis or **psychoneurosis** which is seen in soldiers far removed from the field of battle as well as in men in combat. Like other psychoneuroses, shell shock has its origin in emotional conflict. The soldier facing battle is forced to repress an agonizing fear for his life. His code of honor and his sense of duty will not permit him to recognize this fear. But, subconsciously, his desire for escape is translated into a physical ill and expressed as a tremor, blindness, deafness or any other disability which renders him unfit for military duty. He thus escapes a dangerous and terrifying situation and at the same time is able to preserve his code of honor and his self-esteem. Shell shock is an hysterical type of psychoneurosis. If early treatment by means of psychotherapy is initiated, the prognosis for complete recovery is good. (D.M.H.)

SHELLAC. A secretion or excretion of the lac insect, *Coccus lacca,* found in the forests of Assam and Siam. Freed from wood it is called "seed lac." It is soluble in alkaline solutions such as ammonia, sodium borate, sodium carbonate and sodium hydroxide, and also in various organic chemicals. When dissolved in acetone or alcohol, shellac yields the familiar shellac varnish of superior gloss and hardness. Orange shellac is bleached with sodium hypochlorite solution to form white shellac. (R.K.S.)

SHEPPARD'S CORRECTION. Sheppard's corrections are applied to the **moments** of a **frequency distri-**

bution of more than 100 **variates** which is bell-shaped and whose frequencies taper off to zero gradually at both tails. The variates must be continuous. Then μ_2 corrected = μ_2 uncorrected $- 1/12$, where the results are in class interval units. Similarly μ_4 corrected = μ_4 uncorrected $- 1/2\mu_2$ uncorrected $+ 7/240$, where μ_4 is the fourth central moment and all moments are in class interval units. Similar corrections may be given for a **discrete variable.** Special correction formulae are needed for J-shaped and U-shaped frequency distributions.

Sheppard's corrections are corrections for grouping, and they aid in obtaining somewhat better results if the conditions underlying them are satisfied. (L.A.A.)

SHERARDIZING. Process for applying a thin adherent protective coating of zinc to steel parts by heating at 700° F. in contact with zinc dust in a rotating-drum container. (R.H.H.)

SHICHSHOKIAN DISTURBANCE. Devonian.

SHIELDING. In many circuits, particularly in the fields of communication and electronics where the currents and voltages are often very small it is necessary to protect from external disturbances. This may be largely accomplished by shielding. Disturbing voltages may be induced in a circuit or part of a circuit by electrostatic or electromagnetic (or both) induction. The first is relatively easy to shield against since it is only necessary to surround the circuit with a conducting surface which is grounded. This effectively prevents the electrostatic lines of force from reaching the circuit and thus inducing voltages in it. To shield from electromagnetic effects the magnetic lines of force must be prevented from linking the circuit. Since there are no effective magnetic insulators and no perfect conductors this is difficult to do. Fortunately, the number of lines of force which do get to the circuit may be reduced to a small value which will usually not cause trouble. At low frequencies (including the audio range) this is accomplished by surrounding the circuit by a material having high magnetic **permeability,** the higher the permeability the more perfect the shielding. At radio frequencies the effective permeabilities of all magnetic materials approach unity. At these frequencies the eddy currents induced in the shield serve to protect the circuit. As a consequence, the better the conductivity of the shielding the better its protection, aluminum and copper being the materials ordinarily used. (L.R.Q.)

SHINER. Pisces, Teleostei. A small fish (**Pisces**) found in streams east of the Rockies. It occurs in almost all of the states of this region and is sometimes very abundant in the smaller streams. Steel blue above and silvery on the sides. Also called the redfin and dace. The name is applied to other species of the same genus and to less closely related minnows. (A.W.L.)

SHIPWORM. Mollusca, Lamellibranchiata. A peculiar marine **mollusk** which bores into submerged wood and apparently is among the few animals that can digest cellulose and related materials. The shipworms belong to several genera of which *Teredo* is most often cited. All are slender worm-like creatures but they have the characteristic structures of the bivalves. The valves of the shell are small separate parts, located at the anterior end of the worm, and are used for excavating the burrow.

Shipworms do great damage to wooden hulls and marine piling, consequently they have been subject to detailed studies to determine methods of avoiding their destructive attacks. (A.W.L.)

SHOCK. This term is used loosely to describe all types of acute peripheral vascular collapse in which widespread dilatation of the blood vessels institutes a series of circulatory changes. Shock is most commonly associated with **hemorrhage,** severe **trauma, burns,** and **peritonitis.** It is also seen in acute **coronary occlusion.**

The mechanism of shock production is not completely understood. The three theories which explain the situation most satisfactorily are (1) that regional loss of blood and fluid into the involved areas causes reduced blood volume, reduced cardiac output, lowered blood pressure, and tissue **anoxia;** (2) that a toxic substance is released in the injured tissues and this, together with the rapid invasion by bacteria, initiates the shock syndrome; (3) that shock is neurogenic and vasodilation is due to reflex impulses which inhibit the normal constrictor tone of the blood vessels. The first theory is probably the most important and accounts for the majority of instances of traumatic shock.

The clinical features are similar regardless of the mechanism of production. In fully developed traumatic shock, for instance, the patient is apathetic, his skin is clammy and ashen grey in color, and he often feels nauseated and vomits. The pulse rate is rapid, the pulse volume small ("thready pulse"), and the blood pressure low. In burns or crush injuries hemoconcentration occurs, due to loss of plasma from the blood into the damaged tissues. Death due to severe irreversible shock is not uncommon in serious injuries or hemorrhage. Treatment varies somewhat with the type of shock. The general principles governing therapy are restoration of fluid balance, transfusions with whole blood and plasma, elevation of the foot of the bed to help maintain the blood pressure, conservation of body heat, hemostasis by tourniquet application if necessary, and relief of pain and apprehension by the administration of morphine. (D.M.H.)

SHOCK ABSORBER. A shock absorber is a device which absorbs energy of shock either by storage or dissipation. While there are many instances of the use of such equipment on machinery, the two outstanding uses of mechanical shock absorbers are found in the field of automotive and aeronautical engineering.

An automobile shock absorber is provided to absorb the shocks of road irregularity and prevent their transmission to the frame. Strictly speaking, pneumatic tires and springs are in the nature of shock absorbers, but, supplementing these, automobile manufacturers have added shock absorbers which prevent excessive rebound after unusually large spring deflections, or which set up forces aiding the spring in resisting deflection due to the tires passing over a severe bump. Many shock absorbers are simply snubbers, which tighten up when the spring is in its maximum deflected position, and gradually ease it out on the rebound, absorbing energy in mechanical or hydraulic friction, which might otherwise be used in throwing the vehicle.

Shock absorbers are used on **airplanes** to cushion the impact of landing. Although it is possible to land an airplane without impact, this type of landing is rarely accomplished, even by experts, and the usual landing is a **stall** from 3 or 4′ above the ground. Absorbers are installed to absorb the velocity of descent gradually, and prevent large impact stresses in the framework, as well as the unpleasant jarring of the occupants. They used to be of the type which merely stored this energy and then released it. Illustrative of this shock absorber is the type using rubber cords, in which the energy of shock is absorbed by the stretching of a number of loops of rubber shock cord. In their extended position, these cords contain energy which is liberated by a return to the unstretched position. The effect was frequently to throw the aircraft back in the air in a bounce, and such shock absorbers have been largely replaced today by a type in which the energy is dissipated in friction within the absorber.

The oleo shock absorber, used on aircraft, is essentially a smooth-fitting piston and cylinder. The cylin-

der is attached to the wheel, and the piston to a strut which extends to a fitting on the fuselage or vice versa. The energy is absorbed by compressing this member, thus moving the piston on the cylinder. The cylinder is filled with oil which flows through a small orifice when the strut is compressed. The energy is absorbed in the friction of the liquid flowing through that orifice. The resistance of such a shock absorber automatically adjusts itself to the degree of shock, being comparatively soft for a smooth landing, where the compression in the strut is low. On a hard landing the compression in the strut is greater, and the action of the absorber is harder, although the oil is of course flowing through the orifice faster under the greater pressure developed. For absorbing ground shocks while taxiing some absorbers support the piston on coil springs, others use compressed air.

SHOE. **Bearing.**

SHOE-BILL. Aves, Ciconiiformes. A large bird (**Aves**) of central Africa, *Balaeniceps rex,* noteworthy for its large beak. The organ is broad and moderately deep, and the upper **mandible** bears a strong hook at the tip. The species stands about 5′ high, has a moderately long neck and long legs, and is gray in color. Also called the whale-headed stork. (A.W.L.)

SHONKINITE. An **igneous rock** term proposed by Pirrson, in 1895, for a basic variety of **syenite** or **monzonite** containing both **orthoclase** and **plagioclase** and small amounts of accessory **nepheline.** (R.M.F.)

SHOOTING STAR. Shooting star is the popular term used to designate **meteors.** These objects bear little if any relation to the **stars** other than that they are seen as bright, rapidly moving objects against the dark sky and hence apparently among the stars. (W.K.G.)

SHOP SPLICE. Splice.

SHORE. **Underpinning.**

SHORING. **Underpinning.**

SHORT-CIRCUIT. An electrical circuit is considered to be shorted when the terminals are connected directly together with only the **impedance** of the short connecting leads between them, thus for all practical purposes there is no **resistance** between them, hence no voltage can exist between them. While shorting a circuit which does not contain and is not connected to any source of voltage will produce no harmful effects, shorting a set of terminals across which a voltage normally exists will produce in many instances disastrous current flows. In power circuits protection is often provided by **circuit breakers** or **fuses** which open the circuit under the high values of current which will flow on short-circuits. Even then the transient effects which result from short circuits may cause **generators** to arc over, etc. A short obviously puts the circuit out of use. (L.R.Q.)

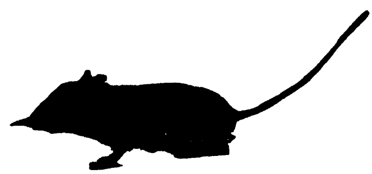
SHOT EFFECT. A troublesome phenomenon which gives rise to a sputtering or popping noise in **radio** and **amplifier** apparatus. It was called *Schroteffekt* (small shot effect) by Schottky, who first explained it as due to variations in the number of thermions per sec. emitted from the tube filament. This variation seems to be merely a statistical one, like the variations in the forces acting on particles exhibiting the **Brownian movement.** Its magnitude depends upon several factors, among which is the influence of the space charge (distribution of electrons) within the tube. A somewhat similar effect, produced by random variations in the velocities of the electrons, and depending upon the temperature of the filament, is manifest in what is called thermal noise, and is superposed on the shot noise. There is also a shot effect in the emission of photoelectrons, observable in the operation of **photoelectric cells.** (L.D.W.)

SHOU. **Deer.**

SHOVELLER. Aves, Anseriformes. A widely distributed **duck,** *Spatula clypeata,* of the northern hemisphere. The male has a dark green head and is beautifully marked with blue, white, chestnut and orange. The female is brownish but for the blue wing patch. The species is named from the greatly broadened beak. Also called the spoonbill. (A.W.L.)

SHOWER. Precipitation characterized by sudden starting and stopping and by rapid changes in intensity. Shower rain is usually associated with cumulonimbus type clouds and instability in the air. (P.E.K.)

SHREW. Mammalia, Insectivora. Small animals closely resembling the mice in general appearance. They are common in Europe, Asia, Africa and North America. Many species burrow and aquatic habits are not uncommon in the group. Another family, confined to Africa, is characterized by the great development of the hind legs; its members are known as the **jumping shrews.** The **tree shrews** or tupaias of the Oriental region constitute a third family of arboreal habits and somewhat squirrel-like appearance. All of these animals subsist on a diet of worms, insects, and some plant products. (A.W.L.)



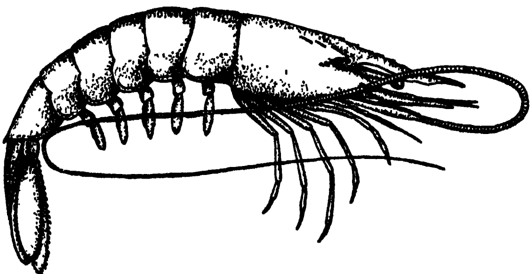
African jumping shrew. *(American Museum of Natural History.)*

SHRIKE. Aves, Passeriformes. *Lanius.* A bird (**Aves**) which is known chiefly for its habit of catching other birds and small animals and impaling uneaten remnants on thorns. Also known as the butcher bird. The beak is notched and in some species hooked. The numerous species occur on all continents but South America. (A.W.L.)

Shrike.

SHRIMP. Crustacea. 1. The edible shrimps of the order **Decapoda.** Closely related to the prawns and less closely related to the lobsters and crayfishes. The body is compressed, the antennae long and slender, and the chelate appendages small, although the related snapping shrimps have moderately large pinchers. A few species of shrimps and prawns are among the important edible crustaceans. They are found chiefly in warmer waters and are the basis of an important industry on the Gulf Coast of the United States. 2.

The **mantis shrimp**. The name is also applied in other combinations to many of the small crustaceans, including tadpole shrimps, skeleton shrimps, spiny shrimps, and fairy shrimps. (A.W.L.)

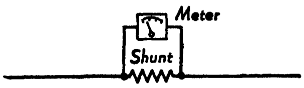


Shrimp.

SHRINKAGE. **Foundry Practice.**

SHRUBS. **Stem.**

SHUNT. The shunt is an electrical bypath so arranged that an **electric current** divides and flows partially through the shunt, and partially through the equipment that is shunted. See the accompanying diagram for connections. A shunt may be employed to

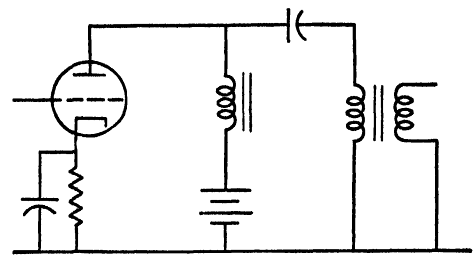


extend the range of currents measurable by an **ammeter,** since, when an ammeter is connected around a shunt, the currents flowing in the two branches, i.e., the shunt and the ammeter, are inversely proportional to the respective resistances. Thus, if the resistance of an ammeter is 5 ohms, and of the shunt, 1 ohm, the current through the shunt would be five times that through the ammeter. In such a case, the ammeter reading would have to be multiplied by 6, and 6 would be the multiplying power of this shunt. By the use of shunts of different resistances, a fixed-range ammeter may be adapted to a wide range of currents.

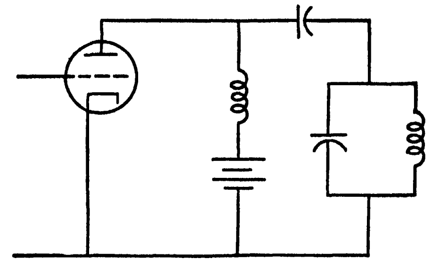
In the above illustration, the shunt has carried the main part of the current. In the shunt-wound **generator,** the field coils are shunted across the armature circuit, but in this case the shunt resistance is very high, and consequently only a very small portion of the current flows through the shunt winding. (F.T.M.)

SHUNT EXCITED. This is a method of exciting tower **antennae** which are not insulated from the **ground** at the base. The feeder is connected to a point about 1/6 of the way up the antenna, the exact location depending on many factors and usually involving some cut-and-try. For proper operation the feeder should slope up to the point of attachment from a point some distance from the base of the antenna, the slope being adjusted experimentally. The term is also applied to the method employed in providing field current for d-c **dynamos.** A shunt-excited machine is one in which the field windings are connected across the **armature** terminals. (L.R.Q.)

SHUNT FEED. In various vacuum-tube **amplifier** circuits the plate voltage may be applied to the **tube** in two ways, in series with the load **impedance** or in parallel (shunt) with it. In audio amplifiers employing transformer coupling the shunt feed circuit keeps direct current out of the transformer windings and also permits the resonating of the transformer inductance with the coupling capacitance. Both of these improve the low **frequency response.** In radio-frequency amplifiers used in **transmitters** shunt feed is often used to avoid the necessity of having **tank** condensers and inductances which will withstand the high d-c voltages in addition to the r-f voltages. Both types of circuits are shown with shunt feed. The **chokes** prevent the by-passing of



Audio Amplifier



Radio Frequency Amplifier

the useful a.c. through the supply voltage while the condensers block the d.c. from the output circuits and allow the passage of the a.c. (L.R.Q.)

SHUTTERS, PHOTOGRAPHIC. Modern photographic shutters may for all practical purposes be divided into three classes: (1) between-the-lens or diaphragm shutters, (2) focal-plane shutters, and (3) behind-the-lens shutters.

Between-the-lens shutters may be sub-divided into two types: (a) rotary, and (b) leaf shutters. The rotary shutter is found chiefly on inexpensive cameras where only one instantaneous speed is provided in addition to "time" and "bulb." One type of simple rotary shutter is shown in Fig. 1.

Fig. 1. Simple box camera shutter. *A*—Aperture admitting light to lens. *D*—Shutter disk. *C*—Spring that snaps disk around. *S*—Slot in shutter disk. *T*—Trigger or release lever. *E*—Capping disk, preventing double exposure as disk *D* returns after *T* is released. In diagram marked "Exposure," the dotted line shows the position of the shutter disk slot an instant before *T* reaches downward limit.

Leaf shutters are of more complex construction and may have a wide range of instantaneous speeds up to 1/600 second in addition to "time" and "bulb." A typical modern precision shutter of this type is shown in Fig. 2.

Presetting the shutter by moving lever (a) to the right sets up tension in spring (b); at 1/400 sec. an additional spring located under eccentric member (c) is brought into action. Shutter speeds are varied by engaged length of gear sector (d) of one member of the gear train retard mechanism (e) and the position of a small oscillating pallet relative to a ratchet wheel (f). Both of these variables are controlled by step-shaped cam shown as a dashed line (g and h). "T" and "B" are determined by position of levers (i), also controlled by a cam. All cams are part of speed-selecting ring (k). Release lever is marked (l) and socket for cable release (m). Moving self-timer lever (n) downward winds up a spring-actuated escapement mechanism (o) which, by means of an oscillating pallet and ratchet wheel (p), delays automatic tripping of shutter through extension of release lever (q) by 10 to 12 secs.

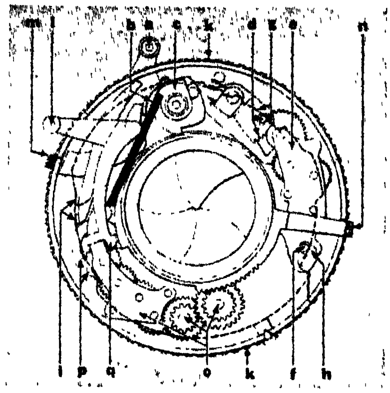


Fig. 2.

The focal-plane shutter is placed near the focal plane directly in front of the sensitive material. Shutters of this type are found on many miniature cameras, on hand cameras designed particularly for press photography, and on reflex cameras.

Single-curtain shutters contain a long curtain with apertures of various widths. To make an exposure this curtain is wound on a roller at the top, using the wind-key on the side, until the aperture of the desired width is in place. Upon releasing the exposure lever the curtain is freed and the tension on the lower roller causes it to revolve, winding the curtain on it so that the aperture is drawn past the sensitive material, thus making the exposure. A locking device stops the curtain after the aperture has reached the lower roller, so as to prevent a second exposure. The exposure is controlled (1) by the width of the aperture used and (2) by varying the tension which controls the speed at which the aperture is drawn past the film or plate. With this type of shutter it is necessary to cover the lens with a cap or insert the slide of the film or plate holder to prevent exposure of the sensitive material to light when setting the shutter.

This disadvantage is overcome in many cameras by the use of a shutter with two curtains. (See Fig. 3.)

A between-the-lens shutter exposes the entire picture area at one time; with a focal plane shutter, however, the exposure travels from one side of the image to the other as the aperture passes across the face of the sensitive material. This results in a distortion of the image of rapidly moving objects. If the direction of movement of the aperture and the image are the same, the image is elongated; if in opposite directions, the image is contracted; while if the movement of the aperture is at right angles to that of the object, the image is diagonally distorted.

The efficiency of a shutter may be defined as the ratio between the amount of light actually reaching the film for a given time of exposure and the maximum amount which could possibly reach the film for the same time interval. Thus, a between-the-lens shutter, whose blades opened instantaneously to full opening and remained open for the full exposure time and then closed instantaneously, would have an efficiency of 100%. However, since this is impossible, it is obvious that while the blades of the shutter are opening and closing, the amount of light reaching the film is reduced. The variation in illumination during the exposure with a between-the-lens shutter may therefore be represented by a diagram. (See Fig. 4.) The more rapid the opening and closing of the blades of the shutter, the higher its effi-

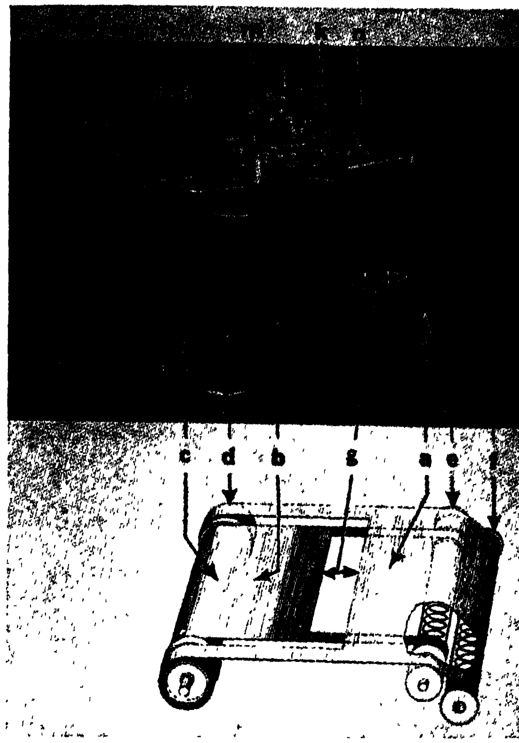

Fig. 3. Focal plane shutter. Operating lever on back of camera first brings edge of curtain (a) over edge of curtain (b), then winds them together across film aperture onto rollers (c and d) setting up spring tension in rollers (e and f). Shutter speeds of 1/50 to 1/1000 sec. determined by width of the curtain opening (g), regulated by knob (h) which turns roller (c) in relation to roller (d). Acceleration is compensated for by widening of slit as it travels across film plane due to difference in diameter of rollers (c and d). Speeds 1 to 1/25 sec. are selected with dial (i) and controlled by an escapement mechanism (k) which varies the delay of curtain (b) after curtain (a) has completed its run. At "B" setting curtain (a) moves across when shutter release button (l) is pressed down, and curtain (b) follows when button is released. Moving self-timer lever (m) in clockwise direction winds up a spring-actuated escapement mechanism (n) which delays automatic tripping of the shutter by 10 to 12 secs. (*Eastman Kodak Co.*)

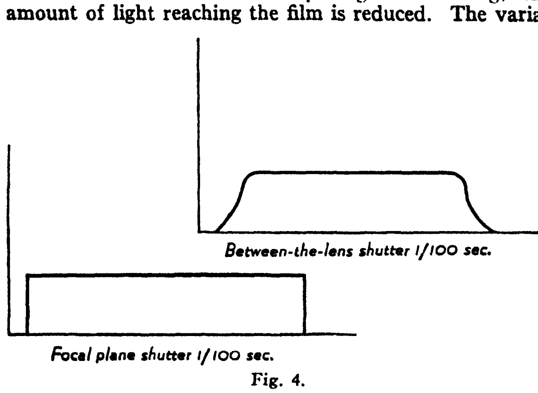

Fig. 4.

ciency. Also, the smaller the diaphragm used, the longer the time of exposure at full opening and the greater the efficiency.

The efficiency of a well-made focal-plane shutter is higher than that of a between-the-lens shutter, but becomes less as the width of the aperture is reduced and as the distance between the curtain and the surface of the film is increased. (C.B.N.)

SIAL. That portion of the crust of the earth which forms the continents and, possibly, some of the sub-oceanic **lithosphere.** Rocks predominant in silica (Si) and aluminum (Al). (R.M.F.)

SIALID. Insecta, Neuroptera. A member of the family Sialidae, usually applied only to the **alder flies** although the **dobson fly** and the **fish flies** also belong here. The alder flies are small insects whose larvae live in streams. The habit of the adults of perching on the alders lining the banks gives them their name. (A.W.L.)

SIAMANG. Mammalia, Primates. A species of **gibbon.** (A.W.L.)

SICHEL. Pisces, Teleostei. A fish (**Pisces**) of eastern Europe, related to the carps. It is of peculiar form, with the upper surface almost straight and the mouth directed upward. (A.W.L.)

SIDE BAND. **Modulation.**

SIDE CIRCUIT. **Phantom Circuit.**

SIDEREAL PERIOD. The sidereal period of any object is its period of revolution around its primary. In general, sidereal period may be defined as the time required for an object to move from a particular position among the stars back to the same longitude again, as seen from the sun. (W.K.G.)

SIDEREAL UNIVERSE. **Milky Way.**

SIDERIOLITE. **Meteor.**

SIDERITE or CHALYBITE. This mineral is a **carbonate** of iron, $FeCO_3$. It is **hexagonal** with **rhombohedral** crystals, and also occurs in various massive forms. It has a rhombohedral **cleavage**; uneven fracture; is brittle; hardness, 3.5–4; specific gravity, 3.83–3.88; luster, vitreous to pearly; color, gray, yellowish- or greenish-gray, green, reddish-brown and brown. Siderite is found as **concretionary** masses in the **sedimentary rocks**; as a replacement mineral from the action of iron solutions upon limestones; and in metalliferous veins as a **gangue** mineral. It is relatively common. Siderite is found in Austria, Saxony, Czechoslovakia, France, England, Italy, Greenland, Australia, Brazil and Bolivia. In the United States important localities are in Connecticut, Pennsylvania, New Jersey, Ohio and Washington. It is used as an iron ore. (E.S.C.S.)

SIDEWINDER. Reptilia, Sauria. A small **rattlesnake** of the southwestern deserts. It has a pair of hornlike projections between the eyes and progresses by a peculiar sidewise locomotion. (A.W.L.)

SIERRA NEVADA REVOLUTION. **Jurassic.**

SIEVE TUBES. A sieve tube is an elongate tube occurring only in **phloem.** It is made up of cells, each with a thin wall of **cellulose,** lined with the **protoplast,** and contains a large central **vacuole.** Through its walls there are many perforations, which are localized in those places known as sieve plates. The function of a sieve tube is the conduction of food.

For development, see **cambium.** (R.M.W., B.S.M.)

SIFAKA. Mammalia, Primates. A **lemur** of the genus **Propithecus.** The several species are found in Madagascar. They are related to the indri lemur but have long tails and shorter muzzles. (A.W.L.)

SIGILLARIA. **Paleobotany.**

SIGNAL-TO-NOISE RATIO. The usefulness of any communication system is limited by its ability to provide a useful signal which is strong enough to override any interfering noise. In passing through the various **amplifiers** associated with the modern systems both noise and desired signal are treated alike (except for freequency discrimination when they do not occupy the same frequency band) and so are amplified proportionately. It is necessary, then, that the input have a certain minimum ratio of signal to noise for the output to be satisfactory. This term is commonly applied to radio receiving systems. Various types of directional **antennae** will materially improve this ratio in many cases. (L.R.Q.)

SIGNIFICANT DIFFERENCE. Given two statistics θ_1' and θ_2' computed from **samples** of size N_1 and N_2, respectively, both consistent estimates of the **population parameters** θ_1 and θ_2, we wish to test the hypothesis $\theta_1 = \theta_2$ or possibly some other hypothesis. This test is based on the distribution of $\theta_1' - \theta_2'$ or in the general case on some function of θ_1' and θ_2'. If the test gives a point which falls in the critical region, we reject the hypothesis. If this happens, we say there exists a significant difference in θ_1 and θ_2, that is, $\theta_1 \neq \theta_2$. Significant differences may be found in **means, variances, coefficients of correlation,** and other measures. If a difference is shown to be significant statistically, this corresponds then to the statement that the two populations have different parameters. Two parameters may differ significantly in the statistical sense although from a practical point of view the difference may be very small. (L.A.A.)

SILENT CHAIN. **Chain.**

SILEX. **Flint.**

SILICATE. **Silicon.**

SILICATE BOND. A molded grinding wheel made from silicate of soda and abrasives, baked at a high temperature for several days. (H.C.H.)

SILICEOUS SINTER. **Geysers.**

SILICIC ACID. **Silicon.**

SILICON. Symbol: Si. Atomic number: 14. Atomic weight: 28.06. Density: 2.4. Hardness: 7. Melting point: 1420° C. Boiling point: 2600° C. Isotopes: 28 (89.6%), 29 (6.2%), 30 (4.2%).

Silicon is (1) a dark gray hard crystalline solid, (2) an amorphous brown powder. Both forms are unaffected by air at ordinary temperatures, but when heated in air to high temperatures a protective layer of oxide is formed; reacts with **nitrogen** at high temperatures to form nitride; with **chlorine** to form chloride; with several metals to form silicides. Crystalline silicon is unattacked by **hydrochloric** or **nitric** or **sulfuric acid,** but attacked by **hydrofluoric acid** to form silicon tetrafluoride gas; soluble in **sodium** hydroxide solution to form sodium silicate and hydrogen gas; reacts with dry chlorine to form silicon tetrachloride. Isolated by Berzelius in 1823.

Silicon occurs abundantly in all ordinary rocks except **limestone**, is second in abundance of the elements in the earth's crust (27.7% of the solid crust) and exceeded only by oxygen. Present in **igneous rocks** and clays as alumino-silicate; as the oxide (SiO_2) in the minerals **quartz**, sand, **flint**, and the gems **amethyst**, **jasper**, **chalcedony**, **agate**, **onyx**, **tridymite**, **opal**, **crystobalite**; as silicates, **zircon** (zirconium silicate $ZrSiO_4$), **willemite** (zinc silicate Zn_2SiO_4), **wollastinite** (calcium silicate, $CaSiO_3$), **serpentine** (magnesium silicate $Mg_3Si_2O_7$). Silicon is obtained from the oxide (1) by igniting with **aluminum** powder, (2) by reduction with **carbon** in the **electric furnace**, and is used to reduce many oxides. Silicon is chemically related to **aluminum**, **boron**, **titanium** and **carbon**. Silicon is an alloying element in **steel** and in **brass and bronze**.

Acids: Silicic acid (ortho H_4SiO_4 or $SiO_2 \cdot 2H_2O$; meta H_2SiO_3 or $SiO_2 \cdot H_2O$), white gelatinous precipitate, by reaction of solution of silicate and **hydrochloric**, **nitric** or **sulfuric** acid of proper concentrations, forms silicon oxide upon ignition, forms various silicates by fusion methods; hydrofluosilicic acid (H_2SiF_6), colorless solution, by reaction of silicon fluoride, forms fluosilicates by neutralization methods.

Aluminates: Many complex silico-aluminates or alumino-silicates are formed in nature. Of these, clay in more or less pure form (pure clay, kaolinite; **kaolin**, china clay, $H_4Si_2Al_2O_9$ or $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) is of great importance. Clay is formed by the weathering of igneous rocks, and is used in the manufacture of bricks, pottery, porcelain, Portland cement. (See **Ceramics**; **Cement, Portland**.) Sodium aluminosilicate is used in water purification to remove dissolved calcium compounds. (See **Calcium** aluminosilicates.)

Carbide: Silicon carbide (SiC), ("carborundum"), bluish-black iridescent crystals, very hard (hardness 9 Mohs scale), used as an **abrasive** and heat refractory material.

Chloride: Silicon chloride, silicon tetrachloride ($SiCl_4$), colorless fuming liquid, boiling point 58° C., by reaction of silicon, or silicon oxide plus **carbon**, heated in **chlorine**, fumes in moist air, and is used for producing white smoke in air.

Fluoride: Silicon fluoride, silicon tetrafluoride (SiF_4), colorless gas, by reaction of silicon oxide, **calcium** fluoride and hot concentrated **sulfuric acid**; reacts with water to form silicic acid plus hydrofluoric acid, and the latter, with excess silicon fluoride, forms hydrofluosilicic acid; combines with ammonia (e.g., $SiF_4 \cdot 2NH_3$).

Fluosilicate: Sodium fluosilicate (Na_2SiF_6), white solid slightly soluble; magnesium fluosilicate ($MgSiF_6$), white solid, soluble.

Hydrides: Silicon tetrahydride, silicon methane, silicane (SiH_4), colorless gas, boiling point 115° C., by reaction of magnesium silicide and **hydrochloric acid**, followed by purification of the gas, reacts with **silver** nitrate yielding silver plus silicon; silicoethane (Si_2H_6), colorless liquid, boiling point 52° C., by reaction of **lithium** silicide (Li_6Si_2) and concentrated hydrochloric acid.

Nitrides: Trisilicon tetranitride (Si_3N_4), by heating silicon oxide plus **carbon** to 1500° C. in a current of **nitrogen** gas.

Oxide: Silicon oxide, silicon dioxide, silica, **quartz**, **tridymite**, **crystobalite**, "vitreosil" (SiO_2), white to colorless solid. Ordinary quartz (alpha-quartz), density 2.65, melting point 1425° C., changes into beta-quartz at and above 575° C., these have different optical properties and etching marks with hydrofluoric acid. Beta-quartz is changed into tridymite, density 2.26, melting point 1670° C., at and above 870° C. When silica is maintained some time at the sintering temperature, crystobalite, density 2.32, melting point 1710° C., is formed. Different forms of silicon oxide differ in chemical activity, e.g., quartz is practically unreactive with **sodium** hydroxide solution, whereas amorphous silica, density 2.20, formed by heating silicic acid, is reactive. Silicon oxide reacts (1) with fused **sodium** carbonate, yielding sodium silicate glass, (2) with sodium and **calcium** carbonate to form ordinary glass, (3) with several metallic oxides to form various colored glasses, (4) with **hydrofluoric acid**, but not with other acids (except hot concentrated **phosphoric acid**). Quartz is commonly found as a mineral in rocks (second in abundance to feldspar among minerals of the earth's crust). Quartz softens gradually like glass when heated somewhat below its melting point, and in the plastic condition may be worked into various shapes like glass (such wares are called by various trade names, e.g., "vitreosil"). Various preparations of silica gel involve the dehydration of silicic acid to silica containing more or less combined water for special purposes of adsorption of gases and liquids.

Silicates: Sodium metasilicate, "water glass" (Na_2SiO_3), colorless (when pure) glass, soluble, melting point 1088° C., formed by reaction of silicon oxide and **sodium** carbonate at high temperature; solution reacts with **carbon dioxide** of the air, or with sodium carbonate solution or **ammonium** chloride solution, yielding silicic acid, gelatinous precipitate. Sodium silicate solution is used (1) in soaps, (2) for preserving eggs, (3) for treating wood against decay, (4) for rendering cloth, paper, wood non-inflammable, (5) in dyeing and printing textiles, (6) as an adhesive (e.g., for paper boxes) and cement. Various fused mixed silicates are used in glasses (sodium calcium silicates in common glass). Various colored silicates may be separated in solution by adding the colored soluble solid (e.g., cobalt nitrate) to sodium silicate solution. (See Aluminates above. See **Calcium** silicates.)

Silicones: Compounds containing Si and C and OH, made by reaction of $SiCl_4$ and RMgCl (**Grignard Reagent**) followed by hydrolysis to form $RSi(OH)_3$, $RSi(OH)_2$, RSi(OH). Of these, the first two types are used as baking enamels and resins, and the last two as greases. All show unique stability against heat and chemical action and are of high electrical resistance.

Sulfides: Silicon monosulfide (SiS), yellow solid, somewhat volatile, formed by heating to redness crystalline silicon in sulfur vapor, reactive with water; silicon disulfide (SiS_2), white crystals, formed by heating amorphous silicon and sulfur, and then subliming, reactive with water.

Organic compounds: Silicon tetramethyl ($Si(CH_3)_4$), liquid, boiling point 26° C.; silicon tetraethyl ($Si(C_2H_5)_4$), liquid, boiling point 152° C.; disilicon tetramethyl ($(CH_3)_2Si{:}Si(CH_3)_2$), boiling point 113° C.; silicon tetraphenyl ($Si(C_6H_5)_4$), solid, melting point 231° C.; methyl silicate, tetramethoxy silicon ($Si(OCH_3)_4$), boiling point 122° C.; ethyl silicate, tetraethoxy silicon ($Si(OC_2H_5)_4$), boiling point 165° C.

In the inorganic world of nature, the element silicon plays a role in the composition of rocks and minerals at least suggestive of the diversity shown by carbon in the organic world of plants and animals. (R.K.S.)

SILICONIZING. Also known as Ihrigizing after the inventor of the process. The surface of iron and steel objects is impregnated with silicon by treatment with silicon carbide and chlorine gas at temperatures between 1700° and 1850° F. A maximum silicon content of about 14% is obtained at the surface, giving the article excellent resistance to acid-corrosion and to scaling at elevated temperatures. (R.H.H.)

SILICOSIS. A chronic disease of the **lungs** seen chiefly in miners. It is caused by inhalation over long periods of time of air containing finely divided particles of **silicon**. Fibrous nodules develop in the alveolar divisions of the lung; after years of exposure, these occupy enough space to cut down seriously the functioning surface of the lung. Decreased vital capacity or possibly

total exchange of air with each respiration and **dyspnoea** result. Individuals with silicosis are prone to develop **tuberculosis.** (D.M.H.)

SILICIFICATION. An important geochemical process by which certain sedimentary rocks such as **limestones** and **dolomites,** or calcareous **fossils** are partially or entirely replaced by silica, SiO_2. (See also **Chert** and **Flint.**) (R.M.F.)

SILK. A material produced by many **insects** and **spiders** for the formation of cases in which the **larva** lives, cocoons in which pupation (**pupa**) takes place or eggs are deposited, and webs for the capture of prey. Some **caterpillars** form temporary defenses of silk and both caterpillars and spiders use it to lower themselves from elevated supports and sometimes to elevate themselves to such supports.

Silk is formed as a liquid secretion which hardens quickly on exposure to the air. It is spun by being forced through small apertures which mold it into a thread. When so discharged it is a clear, smooth, lustrous material of considerable strength, but spiders form opaque and adhesive threads as well.

The silk of commerce is produced by the silk worm, caterpillar of the **moth,** *Bombyx mori.* The fine threads of which the cocoon is composed are reeled and spun into threads large enough to be woven. Although the use of pure silk has been encroached upon by manufactured rayon and allied products, it is still produced in large quantities in the Orient and in the Mediterranean countries. Another product of the industry is catgut, produced by removing the silk gland of the worm and artificially drawing it into a thick thread. This product comes chiefly from Spain.

The silk of many other insects has been reeled and spun, and even that of spiders has been made into fabrics. The latter is too fine for practical purposes although the very fine filaments spun by the spider are used as cross-hairs in optical instruments. Pongee silk is the only commercial product of this kind that is derived from another moth than the true silkworm species. (For synthetic fibers such as rayon, see **Carbohydrates.**) (A.W.L.)

SILK GLAND. The gland from which **silk** is produced by the **insects** and **spiders.** Silk glands of most insects are modified salivary glands opening through the mouth parts in the **larvae** alone, but in the order Embiidina some observers report that the silk comes from glands in the front legs, whose ducts open through hairs on the tarsi.

The silk glands of spiders are located in the abdomen, opening through a group of special organs called spinnerets on the under surface near the tip of the body. They are of several forms. Ampulliform glands produce the strong radial lines of the orb webs and aggregate glands secrete the sticky spiral lines. Pyriform glands produce disks by which the anchoring lines of the web are attached to its supports. When prey is caught it is wrapped in fine silk produced from aciniform glands, and still another type, the tubuliform glands, form the silk of which the egg cocoon is made. The last occur only in the female. (A.W.L.)

SILKWORM. Insecta, Lepidoptera. The **caterpillar** of the **moth,** *Bombyx mori,* which produces the silk of commerce. Caterpillars of the family Saturniidae also spin cocoons of silk, and are known as the giant silkworms. This family includes the common luna, cecropia, and polyphemus moths of North America, as well as many other species. (A.W.L.)

SILL. A tabular mass of igneous rock that has been intruded laterally between layers of sedimentary rock, beds of volcanic lava or **ejectmenta,** or even along the direction of the **foliation** in metamorphic rocks. The term sill is synonymous with intrusive sheet. (R.M.F.)

SILLIMANITE. The mineral sillimanite is an **aluminum silicate,** the formula Al_2SiO_5 being like that of **andalusite** and **kyanite.** It is **orthorhombic,** usually in slender prisms, but may be fibrous or massive. Its hardness is 6–7; specific gravity, 3.23–3.24; luster, vitreous; color, various shades of gray, grayish-green, grayish-brown, etc.; transparent to translucent. It occurs in **granites** and **gneisses** as tiny prisms and aggregates, and is often associated with andalusite, **cordierite** and **corundum.** Sillimanite has been found in Bavaria, Czechoslovakia, France, India, Madagascar, Burma and Ceylon, the latter two localities furnishing transparent sapphire-blue gem stones. In the United States sillimanite has been found in Connecticut, New York, Pennsylvania, Delaware, North Carolina and California, where, in Inyo County is the largest deposit in the world. This mineral was named in honor of Benjamin Silliman for many years professor of chemistry and natural science at Yale University. Sillimanite is used in the manufacture of spark plug "porcelains" and laboratory ware. (E.S.C.S.)

SILTSTONE. A term signifying a **clastic** sedimentary rock in which the particles are of silt **grade.** (R.M.F.)

SILURIAN PERIOD. A major subdivision of the **Paleozoic Era.** Type locality, Wales and Shropshire, England. The formations of this system were first studied and described by R. I. Murchison in 1835. The Silurian Period began 380 million years ago and lasted for 50 million years. In Murchison's time, and for some time afterward, the Paleozoic Era, below the **Devonian,** was divided into the **Cambrian** and Silurian. This practice still holds in parts of Europe. The Silurian formations are well exposed in Eastern North America, especially in New York State, and the length of the **Appalachian geosyncline** where the sediments are principally red **sandstones** and **shales** of delta origin. There was little or no volcanic activity except in southeastern Maine. The Silurian is also well exposed in nearly all of Western Europe, Northern Siberia, Burma, Central Asia, Himalayas, Morocco, Australia, Peru and Bolivia. The system is characterized by all types of sediments, with evidence in certain areas of an arid climate, including thick deposits of salt and **gypsum.** The maximum thickness of sediments is 15,000′, in Britain. The principal types of fossils are **corals, bryozoans** (including primitive reefs), spire-bearing **brachiopods, graptolites, nautiloids, trilobites,** and **ostracods.** The first air-breather, a fossil scorpion, is reported from both Sweden and England. In North America the principal economic products of Silurian Age are rock salt, gypsum, iron ore, petroleum and natural gas. In western Europe the Silurian was brought to a close by a period of mountain building called the Caledonian Disturbance. (R.M.F.)

SILVER. Symbol: Ag (argentum). Atomic number: 47. Atomic weight: 107.880. Density: 10.5. Hardness: 2.5–2.7. Melting point: 960.5° C. Boiling point: 1950° C. Isotopes: 107 (52.5%), 109 (47.5%).

Silver is a white metal, softer than **copper** and harder than **gold;** when molten is luminescent and occludes **oxygen** (20 volumes) but the oxygen is released in solidification ("spitting"); the most malleable and ductile of the metals except gold; as a **conductor** of heat and electricity superior to all other metals; soluble in **nitric acid** containing a trace of nitrate; soluble in hot 80% **sulfuric acid;** reacts with **hydriodic acid** to yield **hydrogen;** insoluble in **hydrochloric** or **acetic acid;** tarnished by **hydrogen sulfide,** soluble sulfides and many sulfur-containing organic substances (e.g., **proteins**); not affected by air or water at ordinary

temperatures, but at 200° C. a slight film of silver oxide is formed; not affected by **alkalis**, either in solution or fused. Discovery prehistoric.

Silver is used (1) as an ornamental metal, either as silverware or silver-plated goods, and deposited on glass for mirrors, (2) in bearings for aircraft engines, (3) as an emergency substitute for copper for bus bars for electric power distribution, (4) in alloys, such as hard solder, and in coins (90% silver with 10% copper as a hardener).

Silver occurs native in Peru, but the chief ores are sulfides (argentite, Ag_2S) and it is frequently associated with gold, lead and copper ores. Silver is obtainable (1) as a by-product in the **electrolytic** refining of copper in the **anode** mud, (2) as a by-product in crude lead by its differential solubility in zinc metal when molten (silver is 3000 times more soluble in zinc than in lead), (3) by leaching the ore with **sodium** cyanide solution and recovery by electrolysis.

Acetate: Silver acetate ($AgC_2H_3O_2$), white solid, only slightly soluble in water.

Bromide: Silver bromide (AgBr), pale yellow precipitate by reaction of silver nitrate solution, and **potassium** bromide solution, insoluble in **nitric acid**, only slightly soluble in ammonium hydroxide, soluble in **sodium** thiosulfate solution, turns dark on exposure to light, melting point of silver bromide 434° C.

Chloride: Silver chloride (AgCl), white precipitate by reaction of silver nitrate solution and **potassium**, **ammonium**, or **sodium** chloride solution or by **hydrochloric acid**, insoluble in nitric acid, soluble in ammonium hydroxide, and in sodium thiosulfate solution, turns dark on exposure to light, melting point of silver chloride 455° C.

Cyanide: Silver cyanide (AgCN), white precipitate by reaction of silver nitrate solution and **potassium** cyanide solution; silver potassium cyanide ($KAg(CN)_2$), soluble, and recovered as white solid by crystallization.

Chromate: Silver chromate (Ag_2CrO_4), yellow to red to brown precipitate by reaction of silver nitrate solution and **potassium** chromate solution.

Dichromate: Silver dichromate ($Ag_2Cr_2O_7$), red precipitate by reaction of silver nitrate solution and **potassium** dichromate solution, changing to silver chromate upon boiling with water.

Iodide: Silver iodide (AgI), yellow precipitate by reaction of silver nitrate solution and **potassium** iodide solution, soluble in concentrated nitric acid, insoluble in ammonium hydroxide solution, and slightly soluble in sodium thiosulfate solution, turns dark on exposure to light, melting point of silver iodide 552° C. with decomposition.

Nitrate: Silver nitrate, lunar caustic ($AgNO_3$), white colorless crystals, soluble, the source of most insoluble and some soluble silver compounds, formed by the reaction of silver metal and **nitric acid** followed by crystallization, melting point of silver nitrate 212° C., and at 320° C. begins to decompose.

Oxides: Silver monoxide, silver oxide (Ag_2O), brown precipitate, by the reaction of silver nitrate solution and **sodium** or ammonium hydroxide, soluble in **ammonium** hydroxide (upon standing this solution forms a dangerous explosive), appreciably soluble (1 part in 300) in water, giving a solution that turns litmus blue, decomposes at 300° C. into silver metal and oxygen; silver dioxide, silver peroxide (Ag_2O_2), black precipitate by the reaction of silver nitrate solution and **ammonium** persulfate solution, an active oxidizing agent.

Phosphate: Silver phosphate (Ag_3PO_4), yellow precipitate, by reaction of silver nitrate solution and disodium hydrogen **phosphate** solution, soluble in nitric acid and in ammonium hydroxide, turns dark on exposure to light.

Sulfate: Silver sulfate (Ag_2SO_4), white precipitate, by the reaction of silver nitrate solution and **potassium**, **sodium** or **ammonium** sulfate solution or sulfuric acid, melting point of silver sulfate 652° C.

Sulfide: Silver sulfide (Ag_2S), black precipitate, by the reaction of silver nitrate solution and **hydrogen sulfide**.

Thiocyanate: Silver thiocyanate (AgCNS), white precipitate by reaction of silver nitrate solution and potassium thiocyanate solution, insoluble in nitric acid, soluble in warm ammonium hydroxide but re-precipitated on cooling.

Silver halides (**iodide, bromide, chloride**) on account of darkening on exposure to light, are applied in photography on the sensitized plate or film, and the solvent action of sodium thiosulfate on silver compounds is applied in the fixing process, the particles of metallic silver remain unattacked.

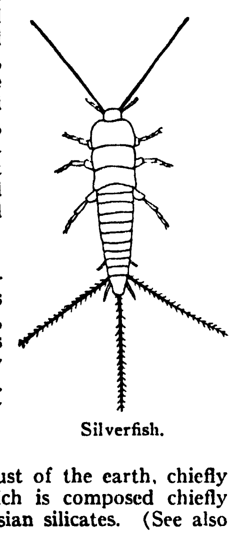
Colloidal silver and some of its insoluble compounds, are used in medicine for antiseptic and antibacterial action on mucous membranes. Silver nitrate is antibactericidal, astringent, and stimulating.

Silver forms more insoluble salts than any other metal (approached in number of salts by lead and mercury). (R.K.S.)

SILVER THAW. After a period of cold weather and below-freezing temperatures a mass of warm air passing over the region will cause frost or glaze to form on objects that are still at a low temperature. This condition is known as a silver thaw. A silver thaw usually lasts only a few hours as the warm air soon warms all exposed objects above 32° F. (P.E.K.)

SILVERFIN. Pisces, Teleostei. A small fish (**Pisces**), *Cyprinella whippli*, related to the shiners. Common in clear streams from New York to Alabama and west to Minnesota and Arkansas. It is silvery with a bluish tinge and the paired fins are pale whitish. (A.W.L.)

SILVERFISH. Insecta, Thysanura. *Lepisma*. One of the primitive wingless insects. It is about ½" long, broad in front and tapering behind, with two long slender antennae and three similar processes at the caudal end of the body. It is covered with lustrous grayish scales, whence the common name. The insect eats starchy materials and sometimes defaces book bindings, wall paper, and laundry, but as a rule it is not sufficiently abundant to be a pest. It is often found in damp buildings. Also called the fish moth. (A.W.L.)



Silverfish.

SILVERSIDES. Pisces, Teleostei. Small slender fishes (**Pisces**), of numerous species, found chiefly along the coasts of the warmer seas but in a few cases in ponds and streams. They make up the family Atherinidae. (A.W.L.)

SIMA. That portion of the crust of the earth, chiefly the sub-Pacific **lithosphere** which is composed chiefly of rocks rich in the ferro-magnesian silicates. (See also **Geosyncline.**) (R.M.F.)

SIMILITUDE. The analysis of an engineering structure may be made by means of mathematical equations or by the use of models. A model is a small-scale reproduction of the prototype in all features which are pertinent to the particular problem under investigation Model analysis is based on Newton's Law of Similarity. In general this law states that models must be geo-

metrically and dynamically similar to the structures which they represent. No restriction is placed on the size of the model. Consequently the scale and the material of the model may be varied to produce the particular action which is required.

Methods of analysis have been developed which reduce the essential elements for similarity to certain fundamental characteristics. The methods of analysis require a proportionality or scale ratio of the respective forces acting on the model and on the prototype. These forces, depending upon their nature or origin, are expressed in terms of one or several physical characteristics such as **mass**, length and time. The engineer does not always use these characteristics as such but may use **density, velocity, gravity, viscosity,** etc. Often it is impossible to satisfy all of the requirements for similitude simultaneously. In this event skill is required in designing the model in order to reduce the error, which is the result of ignoring some of these requirements, to a negligible value.

Models are used to determine the action of **bridges**, building frames, **airplane** structures and **hydraulic** structures under **load**. The action of some loaded structures is so complex that it is virtually impossible to make a mathematical solution which will have a practical application. Model analysis may then be used advantageously. (C.W.C.)

SIMPLE BEAM. A simple **beam** is one which rests on two end supports in such a manner that the ends of the beam are free to rotate on the supports. Since

riveted connections are elastic, the end restraint offered by this type of connection is not very reliable. Therefore, beams and girders which are riveted to supports are generally assumed to be simply supported unless a special type of moment connection is used. (C.W.C.)

SIMPLE CURVE. Circular Curve.

SIMPLEX TELEGRAPH. Telegraphy.

SIMPLY AND MULTIPLY CONNECTED REGIONS. By a simply connected region is meant a region such that no closed curve drawn in the region contains in its interior a boundary point of the region. All other regions are called multiply connected.

In a simply connected region, a curve between two points of the region may always be changed by continuous deformation into any other curve between those points, without passing outside the region.

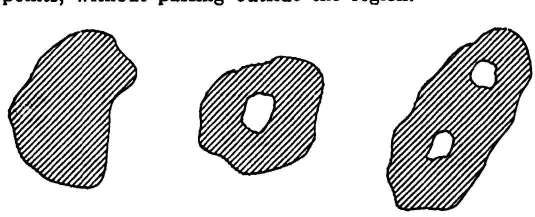


Fig. 1. Fig. 2. Fig. 3.
Simply and multiply connected regions.

A region bounded by a simple closed curve is a simply connected region (Fig. 1). A circular ring is an example of a doubly connected region (Fig. 2). A triply connected region is also shown (Fig 3). (L.L.S.)

SIMULTANEOUS EQUATIONS. Systems of Algebraic Equations.

SINANTHROPUS. Paleontology of Man.

SINE CURVE. Trigonometric Curves.

SINEW. A common term applied both to **tendons** and to **ligaments.** (A.W.L.)

SINGING. This is the term used by telephone engineers to designate the result of part of the output of a **repeater** being fed back into the input. This produces oscillations whose frequency is determined by the circuit constants. The frequency may vary over a wide range, but if it is in the audio range and is fed to a **speaker,** the output is a constant note or howl. (L.R.Q.)

SINGLE PHASE. Phase.

SINGLE SIDE-BAND TRANSMISSION. Modulation.

SINGLE SHEAR. Rivet; Shear.

SING-SING. Mammalia, Artiodactyla. An **antelope** of western and central Africa. It is a medium sized species with a white patch on the buttocks. (A.W.L.)

SINGULAR SOLUTION OF A DIFFERENTIAL EQUATION. Ordinary Differential Equations of First Order and Higher Degree than the First.

SINK OR SINK HOLE. Cave.

SINKING SPEED. The vertical component of the velocity of an airplane gliding without acceleration in power-off condition is the sinking speed. It is analagous to "rate of climb" of climbing flight. Methods exist for estimating sinking speed using other data of the airplane, to wit, air speed, altitude, weight, parasite area, wing span, and **airplane efficiency factor.** Gliding at minimum sinking speed should not be confused with the flattest glide. The latter occurs when parasite drag approximately equals induced drag, while for the former the parasite is three times the induced drag. (F.T.M.)

SINTER. The calcareous (see **Calcium**) or **siliceous** material deposited by mineral springs, usually thermal but not necessarily so, is known as sinter or tufa. Commonly the term sinter is used for the siliceous variety, tufa for the calcareous kind. Siliceous sinter is also known as **geyserite.** Rocks formed from calcareous tufa are known as travertine, and frequently used as decorative stones under the name of "**onyx marble.**" (E.S.C.S.)

SINUS. A pouch or cavity in any organ or tissue, or an abnormal cavity or passage formed by the destruction of tissue. The term is applied to a very large number of such structures in the human body, such as, a dilated portion of a **vein** containing venous blood; a chronically infected tract such as a **fistula;** the air cavities within the cranial bones, especially those located near the nose and connecting with it. They are called accessory sinuses of the nose. They extend from the nasal passages into bones of the skull, and are named according to the bones in which they lie as the frontal, ethmoidal, sphenoidal, and maxillary sinuses. The maxillary sinuses are also called antrums. The maxillary sinuses are found on either side of the nose. They are large in size, and lie between the floor of the eye socket above and the upper teeth below. The frontal sinuses lie in the forehead above the roof of the eye socket, one on either side of the midline of the forehead. The ethmoidal sinuses are three groups with numerous air cells, situated between the eyes in either side of the midline or septum of the nose. The sphenoi-

dal sinuses, two in number, are situated above and behind the nose proper. They are all lined with a delicate mucous membrane continuous with the nasal mucous membrane. When the sinuses become infected, **sinusitis** is said to be present. (A.W.L., R.S.M.)

SINUSITIS. Acute or chronic infection of the paranasal **sinuses.** Infection occurs most commonly during an acute **rhinitis** or common cold or as a complication of allergic rhinitis and hay fever. Infection of the roots of the teeth directly under the floor of the maxillary antra may extend upward and involve these sinuses.

The chief symptoms of sinusitis are pain and headache, usually limited to some portion of the face near the involved sinus. The symptoms are partly due to obstruction of the openings leading from the sinus cavities to the nose, thereby preventing the escape of infected secretion or the entrance of air into the involved sinus. In chronic sinusitis the symptoms are mild. Often an early morning postnasal discharge is the only sign.

The complications of sinusitis are inflammatory diseases of the eye, orbital cellulitis, and **abscess.**

Treatment is local and general, involving the establishment of correct drainage of involved sinuses and correction of any nasal or dental abnormality. **Penicillin** is effective in certain sinus infections. (D.M.H.)

SINUSOID. **Trigonometric Curves; Circulatory System.**

SIPHON. For the general use of this term in connection with the flow of fluids, see **Hydrokinetics.** In zoology, it refers more specifically to a passage between the **mantle** folds of **bivalve** mollusks through which water enters or leaves the mantle cavity. In some species these passages are developed into long muscular tubes and in others they are no more than poorly marked openings. They are two in number, a dorsal or excurrent siphon and a ventral or incurrent siphon. Water is taken in through the latter, passes through the **gills** to the chambers above them, and flows out through the dorsal siphon.

A part of the mantle border in some of the marine **gasteropods** also forms a tube through which water can be drawn into the mantle cavity. This tube is known as the siphon.

The term oral siphon is applied to the canal leading to the mouth of **ascidians** and the opening from the atrial cavity is sometimes known as the atrial siphon.

Unlike these organs, all of them associated with respiration, the siphon of sea urchins (**Echinoidea**) is a slender tube associated with the alimentary tract. (A.W.L.)

SIPHONAL CANAL. An extension of the lip of the shell surrounding the siphon of many **snails.** (A.W.L.)

SIPHONAPTERA. The fleas. An order of **insects** characterized by highly compressed bodies, sucking mouths, and complete metamorphosis. The eggs are dropped in the quarters occupied by the animals on which the fleas live and the larvae live on organic debris. The great majority of the known species live as adults on mammals but some are found on birds. Species found on the dog and cat are sometimes troublesome to man. (A.W.L.)

SIPHONOGLYPH. A ciliated (**Cilia**) groove in the angles of the **stomodaeum of sea anemones.** It conducts water currents into the enteric cavity for respiratory purposes and as a carrier of food particles, and also carries currents outward. In some species excurrent and incurrent siphonoglyphs occur and in others a single one serves both purposes by reversal of the effective beat of the cilia. (A.W.L.)

SIPHONOPHORA. **Hydrozoa.**

SIPHONOZOOID. A specialized **polyp** in the colonial **sea feathers, sea pens,** and related forms. It draws water into the enteric cavity of the colony. (A.W.L.)

SIPHUNCLE. A slender tube extending from the visceral hump of the **nautilus** through perforations in the septa of the shell along the entire spiral. The siphuncle contains blood vessels and its function is supposed to be the maintenance of the gas content of the closed chambers of the shell. By this contained gas the weight of the shell is offset to aid the animal in floating. (A.W.L.)

SIPUNCULIDA. **Gephyrea.**

SIREN. **Musical Sounds.**

SIRENIA. The **manatee** and **dugong,** constituting an order of mammals. They are marine animals with fore legs modified as flippers and hind legs lacking. The manatee is found on the east coast of Florida and southward and the dugong is found near Africa, Australia, and the islands of the Oriental region. (A.W.L.)

SIRIUS. Sirius (**α Canis Major**) is the brightest star in the sky and volumes have been written concerning its matchless brilliancy. Historically, it is undoubtedly the most interesting star in the heavens and references to it are found throughout all ancient literatures back to the earliest known writings. Aside from its surpassing brilliancy, the fact that it may be observed from every habitable portion of the earth has served to make it an object of veneration by all peoples. Sirius was worshiped in the valley of the Nile long before Rome was even heard of, and many ancient Egyptian temples were so arranged that the light from this star would penetrate to the inner altars.

Astronomically, Sirius is particularly interesting as being the typical, A, **spectral type.** The companion of Sirius is the first **white dwarf** discovered. (W.K.G.)

SISAL. **Agave.**

SISKIN. Aves, Passeriformes. A quietly colored **finch.** The numerous species are found throughout the temperate part of the northern hemisphere and in South America. The pine siskin of North America, *Spinus pinus,* also called the pine finch, is finely streaked with brownish on a lighter ground and has a few yellow marks on wings and tail. (A.W.L.)

SITITUNGA. Mammalia, Artiodactyla. An **antelope,** *Limnotragus spekei,* found in swampy ground in central Africa. It is grayish-brown in color and of medium size. Also called the nakong. (A.W.L.)

SIZING. **Press Working.**

SKARN. Used by **petrologists** to describe that process of contact metamorphism by which certain mineral silicates such as **amphibole, pyroxene** and **garnet** replace limestone and dolomite. (R.M.F.)

SKATE. Pisces, Plagiostomi. Cartilaginous fishes (**Pisces**) characterized by the broad flat body. The pectoral fins are extended at the sides and along the greater part of the head and body and are angled at the outer margin so that the general form is quadrangular. The tail is long and slender and is sometimes

armed with spines. The name is applied to the common rays, making up the family Rajidae. Several species are found off the coasts of the United States, including the common skate of the Atlantic coast which also bears the remarkable name, tobacco-box. The family is represented in most of the warm and temperate seas. (A.W.L.)

SKELETAL SYSTEM, SKELETON. An aggregation of rigid or semirigid structures that provide mechanical support for the body and usually a lever system on which the muscles act.

The simplest type of skeletal system is found in the sponges (Porifera) and some of the **coelenterates.** Sponges have scattered spicules of calcareous or siliceous matter among their loosely integrated tissues or are held together by a meshwork of fibers composed of the material spongin, so familiar in the sponges of commerce. The commercial sponge is, in fact, the skeleton freed of organic matter. Spicules are variously formed bodies, some straight rods, some with radiating axes from three to six in number, and some expanded at the ends. Approximately similar scattered bodies are found also in alcyonarians, and in some of these animals they are united to form a continuous mass in which the polyps are imbedded or a solid core surrounded by softer material. Rock **corals** lay down a calcareous deposit beneath the base to which each **polyp** of the colony adds.

In many invertebrates the body wall is the sole support of the animal. Even though it is soft, the incorporation of muscular layers in it provides for movement without rigid skeletal structures.

The **echinoderms** differ in having calcareous plates (ossicles) throughout the integument. In the sea urchins they are closely joined to form a shell and in the sea cucumbers they are small and scattered. Other groups show an intermediate condition with closely associated but movable ossicles. These structures in the sea urchin also illustrate lever action in the use of the spines for locomotion and in the peculiar chewing organ known as **Aristotle's lantern.**

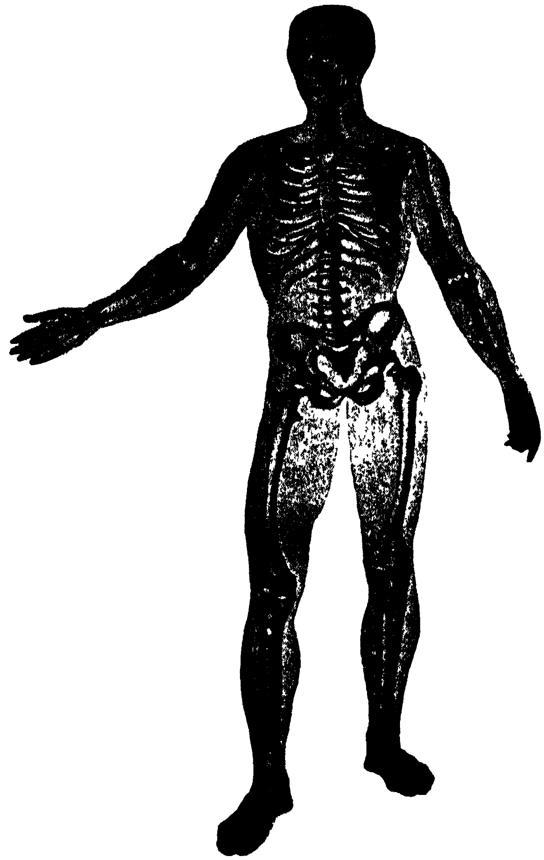
The **arthropods** and **vertebrates** differ in the presence of a complex skeletal system which supports the body and forms the foundation of the jointed appendages. In no other phyla are lever-like appendages found.

The arthropods have an exoskeleton made up of hard plates (sclerites) of **chitin** and calcareous matter, formed in circumscribed areas of the **cuticula.** They are separated by flexible zones which provide for freedom of movement, and are moved by muscles attached to their inner surfaces. The **appendages** are formed of rigid segments attached to each other and to the body by the flexible tissue of the joints. The skeleton forms a sheath enclosing the muscles in such appendages.

Among the half-million species of arthropods wide variation is inevitable. In general the exoskeleton of the head forms a compact capsule. The skeleton of the **thorax** also tends to become compact, although its segments are distinctly recognizable in many species. This portion of the exoskeleton also forms a shieldlike **carapace** in many species. The abdomen retains greater mobility, although its segments may be reduced in number and the exoskeleton of each may be consolidated to a ring surrounding the body. A moderately complex segment of the exoskeleton contains a dorsal, a ventral, and two lateral sclerites known respectively as the tergum or tergite, the sternum or sternite, and the pleura or pleurites. In many cases this plan is simplified by fusion or made more complex by subdivision of the sclerites.

An endoskeleton of limited extent in the arthropods is made up of internal projections from the exoskeleton known as apodemes. They serve as places of attachment for muscles.

One important result of exoskeletal support is the provision of wings in the insects as thin-walled sacs of the body wall. By the apposition of the upper and lower walls of these sacs they become thin membranous planes sufficiently strong and rigid to support the body in flight. Thus the jointed appendages are freed from participation in adaptation for flight.



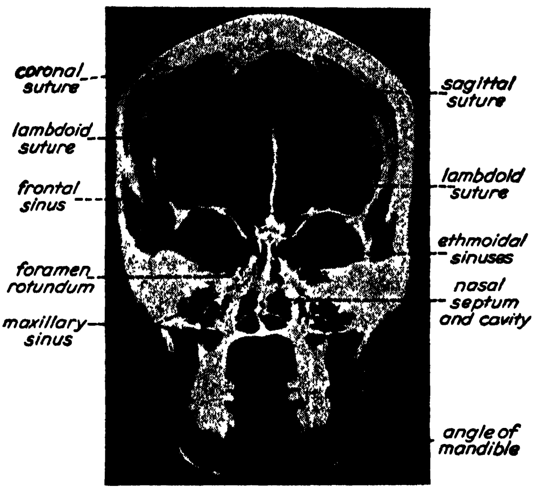
Skeletal system.

Exoskeletal structures also appear in the vertebrates but here they are merely hard parts without the usual supporting functions of the skeleton. They are derived from either or both layers of the skin. The category includes teeth and beaks, horns, claws, hoofs and nails, scales, feathers, and hair. Bony plates associated with scales, as in the alligator and armadillo, are also exoskeletal.

The supporting skeleton of the vertebrates is an endoskeleton composed of **bones** and **cartilage.** It is made up of two chief divisions, an axial skeleton consisting of a vertebral column, ribs, and skull, and an appendicular skeleton including pectoral and **pelvic girdles,** each bearing a pair of appendages. The pharyngeal wall of fishes is supported by the visceral skeleton which persists to a limited extent in the more advanced classes. In the elasmobranch fishes now living, the skeleton is composed entirely of cartilage. In most vertebrates it is made up very largely of bone.

The skull in the elasmobranch fishes consists of a mass of cartilage below, behind, and partially enclosing the brain. This structure is called the chondrocranium. In the bony fishes it is replaced by bones in the same position and is supplemented by superficial bony plates enclosing the remainder of the brain. The jaws of the elasmobranch are also supported by cartilages and in the bony fishes these cartilages are

supplemented by bones. Above the fishes a chondrocranium appears in the embryo and is replaced during development by the ethmoid bone and parts of the sphenoid, temporal, and occipital bones, taken in order from front to back. The remaining bones are not preformed in cartilage. They are more numerous in the lower forms than in man. In the human skull they are the pair of nasal bones in the bridge of the nose, the pair of lachrymals in the orbits, the vomer in the nasal septum, the large frontal bone of the forehead, the parietals in the top and sides of the skull, the



Antero-posterior radiography of a skull. (*Cunningham, Textbook of Anatomy, Oxford Press.*)

upper part of the occipital forming the lower back wall of the skull, and the temporals above the ears. The upper jaw is based on the maxillary bone from which the palatine extends into the hard palate. A slender rod, Meckel's cartilage, supports the lower jaw of the human fetus but the permanent lower jaw is the mandible, a dermal bone formed independently.

The vertebrae that make up the spinal column consist typically of a centrum bearing a neural arch above and a haemal arch below. The neural arch surrounds the spinal cord and is surmounted by a neural spine. In the fishes the haemal arch encloses the dorsal aorta and in the region of the body cavity open haemal arches form ribs known as fish ribs. In other classes and in a few fishes these ribs are replaced by similar slender bones known as true ribs. They develop between the segments of the body lateral to the fish ribs and above them, and articulate with processes of the vertebrae. These ribs join a median ventral structure, the sternum or breast bone, composed of bones and cartilages.

The vertebrae differ in various regions of the body. The first, with which the skull articulates, is the atlas. The second, the axis, is noteworthy for its odontoid process, a solid anterior extension of the centrum. This process is the centrum of the atlas. These two and the remainder of the series in the neck are called cervical vertebrae. The following series with which the ribs articulate are the thoracic vertebrae. The lumbar vertebrae extend to the articulation of the pelvic girdle, where one vertebra or a fused series constitute the sacrum. The following caudal vertebrae lie in the tail or, in the apes and man, are fused to form a mass called the os coccyx.

The pectoral and pelvic girdles are composed of three pairs of bones, two passing downward and toward the median line of the body from the articulations of the appendages and one upward. Of the more constant bones in the pectoral girdle, also called the shoulder girdle, the upper bone is the scapula (shoulder blade), the anterior of the lower bones is the clavicle (collar bone), and the posterior is the coracoid. These two pairs attach to the sternum. They are supplemented in amphibia and reptiles by other bones. The bones of each half of the pelvic girdle are the dorsal ilium, the anterior pubis, and the posterior ischium. This girdle in many forms is firmly attached to the sacrum.

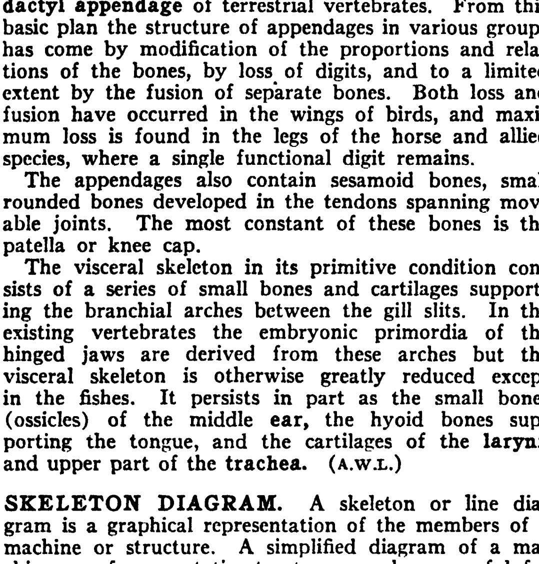
The girdles are modified in various ways. The principal tendency of the pectoral girdle is toward simplification by the loss of bones, so that in many species only the scapula and clavicle remain, as in man, the coracoid being reduced to a process on the scapula. In the hoofed mammals only the scapula persists. In the moles, however, the girdle is large and strong. The pelvic girdle, in correlation with the stresses that it bears in locomotion, becomes compact. The bones of each side tend to fuse and the pubic symphysis, at the ventral union of the two halves, is very firm. The name pelvis or pelvic bone is often applied to this composite structure.

The primitive appendages are the paired fins of the fishes. These structures are precursors of the **pentadactyl appendage** of terrestrial vertebrates. From this basic plan the structure of appendages in various groups has come by modification of the proportions and relations of the bones, by loss of digits, and to a limited extent by the fusion of separate bones. Both loss and fusion have occurred in the wings of birds, and maximum loss is found in the legs of the horse and allied species, where a single functional digit remains.

The appendages also contain sesamoid bones, small rounded bones developed in the tendons spanning movable joints. The most constant of these bones is the patella or knee cap.

The visceral skeleton in its primitive condition consists of a series of small bones and cartilages supporting the branchial arches between the gill slits. In the existing vertebrates the embryonic primordia of the hinged jaws are derived from these arches but the visceral skeleton is otherwise greatly reduced except in the fishes. It persists in part as the small bones (ossicles) of the middle **ear**, the hyoid bones supporting the tongue, and the cartilages of the **larynx** and upper part of the **trachea.** (A.W.L.)

SKELETON DIAGRAM. A skeleton or line diagram is a graphical representation of the members of a machine or structure. A simplified diagram of a machine or of some static structure, can be as useful for certain purposes as a complete drawing. In fact, a



Skeleton diagrams.

skeleton diagram is often more useful than a drawing of the actual equipment it represents, because of the elimination of unnecessary detail which might be confusing. Generally speaking, a skeleton for a static structure is a series of lines which might be thought of as being the center lines of the different structural members. In the case of a machine, a skeleton diagram could be one which would represent the machine kinematically (see **Mechanics**). Such diagrams are useful for study of motions and analysis of stresses. (F.T.M.)

SKEW BRIDGE. Bridge.

SKEW CURVES. Curves in Space.

SKEWNESS. Skewness is that property of a distribution involving its symmetry or asymmetry. As a measure of skewness we define $\alpha_{3:x} = \frac{\mu_{3\cdot x}}{\sigma_x^3}$, $\mu_{3.x}$ = *3rd*

central moment, σ_x = **standard deviation.** If the distribution is symmetrical $\alpha_{3:x} = 0$ (Fig. 1); if it possesses a tail to the right $\alpha_{3:x} > 0$ and the distribution is said to

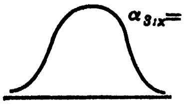


Fig. 1.

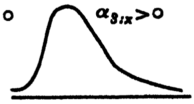

Fig. 2.

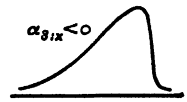

Fig. 3.

be positively skewed (Fig. 2); if it possesses a tail to the left, $\alpha_{3:x} < 0$ and the distribution is said to be negatively skewed (Fig. 3).

The J-shaped distributions are always skewed, and generally the bell-shaped curves are skewed. If in **Pearson's Type III** distribution, $\alpha_{3:x} > 0$, then more **variates** are below the **mean** than above the mean, but the variates above the mean are on the average farther from the mean than the variates below the mean. This is often the case with other skewed distributions. (L.A.A.)

SKIMMER. Aves, Charadriiformes. A bird (**Aves**) related to the terns and gulls but distinguished by its peculiar beak. The entire beak is long and compressed and the lower mandible is much longer than the upper. The bird dips this lower mandible into the water as it flies. Of the few species only one, the black skimmer, *Rhynchops nigra,* is North American. (A.W.L.)

SKIN. The covering of the body of **vertebrates.** It consists of two parts, an outer epidermis and an inner dermis or corium. The former develops in the embryo from the outer **germ layer,** the ectoderm, and the latter from the middle germ layer, the mesoderm.

The epidermis is composed of many layers of cells in two principal strata, the stratum corneum and the stratum germinativum. The flattened cells next the surface are hardened by deposits of pareleidin, a substance related to keratin, and are said to be keratinized. They make up the stratum corneum. Below them are several layers of thicker cells whose active proliferation gives rise to the cells of the stratum corneum. These layers constitute the stratum germinativum. In the outer cells of this stratum granules of keratohyalin appear as forerunners of the pareleidin of the stratum corneum, forming the thin stratum granulosum. A thin clear zone just outside of the granular layer, known as the stratum lucidum, is regarded as the basal layer of the stratum corneum. In its cells the granules of keratohyalin become a diffuse intermediate substance, eleidin.

The corium is a dense connective tissue layer extending from the fatty subcutaneous tissue. It is obscurely divided into an inner stratum reticulare and an outer stratum papillare which rises in papillae beneath the epidermis. Epidermal derivatives including hair follicles, sweat glands, and sebaceous glands extending into the corium and it contains nerve endings, tactile corpuscles, and blood vessels. Smooth muscle fibers attached to the hair follicles lie in it and in some parts of the skin it contains other muscle fibers. The voluntary muscles of the face by which expression is controlled end in it. (A.W.L.)

SKIN EFFECT. The current flowing in an a-c conductor is not uniformly distributed over the cross-section of the conductor but becomes denser the farther the cross-section being considered is from the center of the conductor. This effect, known as skin effect, is caused by the varying inductance of the different parts of the conductor. If we consider a circular conductor, to be specific, and imagine it composed of many elemental filaments in parallel we can readily see why the current flow is more dense as the distance from the center becomes greater. The current in each filament sets up a flux around it which links both it and any other filaments which may be within the lines of flux. It will be realized at once that the filaments in the center can be linked by many more lines than those on the outside, since the outer ones are beyond much of the flux of the inner ones. Thus the inductance of the inner filaments is greater than that of the outer ones and so the **reactance** of the inner ones is greater. This greater **impedance** of the inside causes more of the current to flow in the outer layers and gives rise to the skin effect. As the effective cross-section of the conductor is decreased by this, the **resistance** to a.c. is greater than the resistance to d.c. In certain cases, such as the induction **motor,** where the conductor is largely surrounded by iron, the skin effect is very much greater than in a conductor in free space. In this motor the effect is utilized to obtain high starting torque without serious impairment of the running characteristics. In the layout of a-c buses various arrangements such as hollow squares, channels, etc., are used to save material since the inner part would be of very little use. At radio frequencies the effect is very pronounced (it varies approximately as the square root of the frequency) so only a thin outer layer of the conductor is effective, thus greatly increasing the resistance. (See **High-Frequency Currents.**) (L.R.Q.)

SKINK. Reptilia, Sauria. A **lizard** of the family Scincidae. These animals vary greatly in structure but are usually small with short legs and long tails. The scales are underlaid with bony plates. The several species of the United States are widely distributed but are more common in the south. One of the most remarkable species of the family is the Australian stump-tailed lizard, a thick-bodied species with a very short blunt tail. (A.W.L.)

SKIP DISTANCE. As the frequency of a radio wave is increased the minimum angle of incidence at which the wave will be reflected from the **ionosphere** rather than pass on through becomes greater. This means that the higher the frequency the farther from the **transmitter** the reflected **sky wave** strikes the earth. This distance between the transmitter and the point closest to it at which the sky wave can be received is the skip distance. The **ground wave** is attenuated more rapidly the higher the frequency so that at high frequencies there may be a region in which the ground wave has become too weak for use and in which the sky wave cannot be received because of its skip. Above about 4 megacycles this effect becomes very noticeable, the dead region for higher frequencies running to a distance of a few hundred miles from the transmitter. (L.R.Q.)

SKIPJACK. Pisces, Teleostei. A common fresh-water fish, *Pomolobus chrysochloris,* of moderate size, related to the herring and shad. It is found throughout the Mississippi valley to the Gulf of Mexico and in Lake Erie and Michigan. The back is blue and the sides silvery. Of no value as a food fish. (A.W.L.)

SKIPPER. Insecta, Lepidoptera. An **insect** much like the butterflies but in many ways intermediate between the butterflies and moths. Most species are distinguished by their knobbed and hooked antennae. The few that lack the hook are less easily distinguished from the butterflies except by the veins of the wings or by other details of structure Most of the skippers of the temperate zones are of moderate size and modest colors but many tropical species are brilliant. They constitute the superfamily Hesperioidea.

The name skipper refers to the vigorous and often erratic flight of these insects. Their small wings and powerful muscles accompany rapid flight. Many species perch readily and make short darting flights from place to place. (A.W.L.)

SKUA. Aves, Charadriiformes. *Catharcta.* Marine birds (**Aves**) related to the gulls. The few species are widely distributed in both hemispheres. (A.W.L.)

SKULL. **Skeletal System.**

SKUNK. Mammalia, Carnivora. Animals of the Americas, widely known for their foul odor. All of the species are black and white, with a long bushy tail under which are the two glands that produce the defensive secretion.

The skunks of North America have been divided into fifteen species and a number of varieties. These species are grouped as the striped or common skunks and the small spotted skunks, belonging respectively to the two genera, *Mephitis* and *Spilogale.* Both genera are widely distributed.

The fur, especially of the larger striped skunks, is commercially desirable. (A.W.L.)

SKUNK CABBAGE. **Aroids.**

SKY CONDITION. The state of the sky is also known as the sky condition. In terms of tenths of sky covered, airways' observers in the U.S. recognize four sky conditions.

1. Clear sky is less than $1/10$ cover of clouds.
2. Scattered clouds is $1/10$ to $5/10$ cover.
3. Broken clouds is more than $5/10$ but not more than $9/10$ cover.
4. Overcast is more than $9/10$ cover.

International practice and observations made for synoptic charts in North America recognize 10 states of the sky. They are indicated by code numbers.

0	no clouds
1 . .	less than $1/10$
2	$1/10$
3 .	$2/10$ to $3/10$
4	$4/10$ to $6/10$
5	$7/10$ to $8/10$
6 . . .	$9/10$
7	more than $9/10$ but with openings
8	$10/10$
9	sky obscured by fog, dust, snow, etc.

Sky condition is also qualified by such remarks as "ugly, threatening sky," "water spout," "tornado to NW," "signs of tropical storm," etc. (P.E.K.)

SKY WAVE. The sky wave is that part of the energy radiated from an **antenna** which does not travel along the surface of the earth but goes upward. This wave does not suffer attenuation by the earth as does the **ground wave.** At the **ionosphere** it passes into the ionized regions and is refracted. If the frequency of the **radiation** is low enough the refraction becomes so great the wave is bent back towards the earth and thus the radio signals are returned and make possible reception great distances from the **transmitter.** As the frequency is increased the wave penetrates successive layers of the ionosphere and if high enough the wave will penetrate all layers and not return to the earth. While the returning sky wave gives reception at distances where the ground wave has died out, it does cause undesirable effects such as **fading,** interference with other signals, etc. (L.R.Q.)

SKYROCKET. **Rockets.**

SLAG. Slag is a fused product occurring in connection with metallurgical and **combustion** processes. It is composed of the **oxidized** impurities in a metal, and of a fluxing substance, and of ash. In the steel industry, slag is the neutralized product of anhydrous compounds entering into the process. Slag is of great importance to the operator of a steel **furnace** or a cupola, in that, through the slag, impurities are separated and removed from the metal. By floating as a molten covering on the pool of metal, slag protects it from oxidation and serves to keep it clean. By controlling the character of slag, and continuous observation, the metallurgist insures that the metal is of the quality desired.

Molten ash is one of the products of **combustion** of coal in certain high-capacity boiler furnaces. It is also called slag. In some plants, the ash is removed from the furnace in this fluid form. Such furnaces are known as slag tap furnaces. Slag has some commercial value as **ballast,** coarse **aggregate** for **concrete,** road metal, etc. (F.T.M.)

SLAKED LIME. **Calcium** (Hydroxide).

SLATE. A fine-grained homogeneous sedimentary rock composed of **clay** or volcanic ash which has been metamorphosed (foliated) so as to develop a high degree of fissility or **slaty cleavage** which is usually at a high angle to the planes of stratification. This high degree of fissility makes the better grades of slates an extremely useful roofing material which, however, has been somewhat replaced in recent years by synthetic and manufactured substitutes. The finest slates in the world come from Wales, Britain. (R.M.F.)

SLATY CLEAVAGE. That type of **foliation** in fine-grained metamorphosed sedimentary rocks which produces a high degree of fissility. (See **Slate.**) (R.M.F.)

SLEEPER. **Dormouse.**

SLEEPING SICKNESS. **Trypanosomiasis.**

SLEET. When raindrops enter a layer of intensely cold air, they become supercooled, that is, cooled below the freezing point but without freezing. In this state they are highly unstable, and upon coming in contact with any object, even a speck of dust, they suddenly freeze into white, spherical pellets of sleet. Larger objects such as twigs or telephone wires, when touched by these supercooled drops, receive a coating of ice, which may result in a landscape of marvelous beauty when the sun appears, but which often proves very destructive if the ice is heavy. Sleet is quite commonly mixed with snow or with rain; but it is always a cold-weather product, and is not, as many suppose, a small form of **hail.** (See **Hydrometeors.**) (L.D.W.)

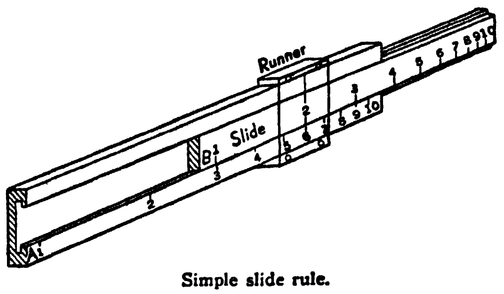
SLEEVE COUPLING. **Coupling.**

SLEEVE VALVE. **Otto Engine.**

SLIDE RULE. The slide rule is an instrument for multiplying, dividing, extracting roots, and obtaining powers of numbers mechanically by logarithmic means. In construction, the simple slide rule consists of two adjacent logarithmic scales which may be so set that a reading on one is added to a reading on another. This represents the addition of logarithms when multiplying numbers. The slide rule for general use is found in several different forms, and there are many special slide rules such as stadia rules, electrical rules, hydraulic computing rules, etc.

The accompanying figure illustrates the principle of multiplication by the slide rule. Two logarithmic scales, A and B, are arranged on a slide rule so that they may be mechanically added. In the illustration given, the process of multiplying three by two is shown. The end of the B scale is aligned over the 3 on the A scale, so that to 3 on the A scale may be added 2 on the B scale. Now if these scales were uniformly divided, the result, of course, would be five units on the A scale,

but since they are logarithmically divided, the result on the A scale is the product rather than the sum. Thus, under the 2 on the B scale, one reads the prod-



Simple slide rule.

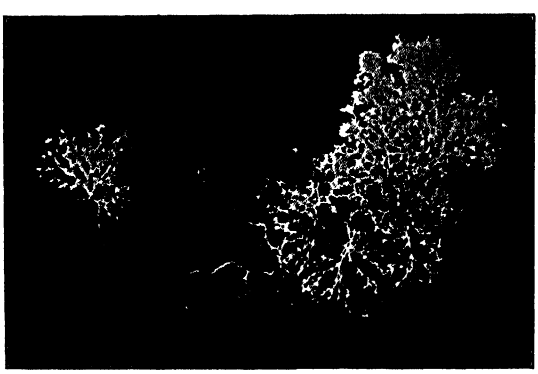
uct of $3 \times 2 = 6$ on the A scale. A glass runner is provided so that the alignment of the numbers of the two scales may be facilitated. By halving the divisions, two complete scales could be placed on the rule. Using a full scale, such as A of the figure, and a double scale, one can extract square roots. A triple scale can be used for cube roots. Other scales contained on the ordinary slide rule are a uniform division scale for logarithms, and scales for reading the value of the trigonometric functions of an angle, known as the sine and tangent. (F.T.M.)

SLIDE TOOL. Turret Lathe.

SLIDER. Reptilia. Chelonia. **Turtles** related to the painted turtles and land tortoises. The several species are brownish or greenish, marked with yellow and in some cases also with red. They constitute the genus *Pseudemys*. Most of the species are confined to the southern states but one, known as the red-bellied terrapin, is found near coastal rivers from Florida to Cape Cod and another lives in the Mississippi valley as far north as Iowa. Both of these species are edible. Also called cooters. (A.W.L.)

SLIME MOLDS. Myxomycetes. Slime molds are **saprophytes** found growing on wood, on rocks, or on grass, or wherever there is sufficient moisture to prevent them from drying up. There are some 300 species.

Claimed and rejected by both botanists and zoölogists, this group of organisms occupies a doubtful position in either kingdom. They are simple organisms which have certain characteristics which place them in

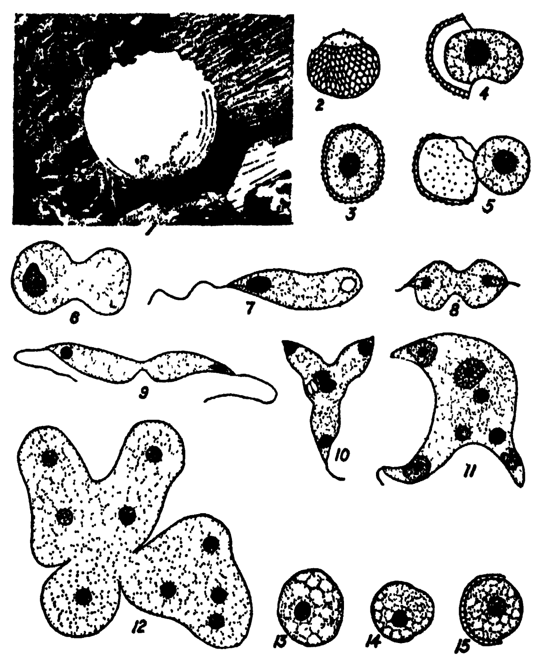


A slime-mold (Myxomycete), *Fuligo septica*, growing on the inner surface of a glass jar. About natural size. (*Gager, General Botany, P. Blakiston's Son & Co.*)

the plant kingdom and others which make them animals. Perhaps they are best treated as organisms which are in a separate classification from both plants and animals.

The vegetative phase of the life history of a typical slime mold starts with the germination of the **spores**. The spores are unicellular non-motile bodies. When sufficient moisture is available the wall of the spore bursts and the **protoplast** escapes. It becomes a uninucleate bit of naked **protoplasm** which moves about in an amoeboid (see **Amoeba**) manner. Soon it forms a single **cilium** at one end and by means of this moves more rapidly in the water. It is now known as a swarm spore. After a time the cilium is lost and it becomes once more like an amoeba, crawling about by forming extensions of its protoplasm, called pseudopodia, and "flowing" into them. In this stage it is called a myxamoeba. Both swarm spores and myxamoebae can increase by simple division.

After a time the myxamoebae move together and coalesce in pairs, forming **zygotes**. Coalescence continues until considerable masses are formed. In these nuclear divisions occur repeatedly, forming a multinucleate mass of naked protoplasm which is not separated into cells. This mass of protoplasm is usually colorless, but sometimes white or yellow or brownish. It has a consistency very similar to that of raw egg white. It is called a plasmodium. The plasmodium is a formless mass which creeps or flows about over the substratum.



Reticularia Lycoperdon. 1, mature fruiting body on a log; 2, spore, external view; 3, spore, internal view; 4, spore germinating; 5, protoplast which has escaped from spore wall; 6, simple myxamoeba; 7, zoospore; 8, dividing zoospore; 9, fusion of two gametes; 10, 11, three zygotes uniting to form a plasmodium; 12, portion of protoplasm dividing by cleavage to form spores; 13, young spore before wall is formed; 14, spore with young wall; 15, nearly mature spore. (*Malcolm Wilson, Transactions of the Royal Society of Edinburgh, Volume 55.*)

This movement is not a slow regular progress but a series of surges. As it moves about, the plasmodium engulfs food substances such as bacteria, spores of fungi and other organic substances, which are digested in the plasmodium. In some slime molds the plasmodium is replaced by a pseudo-plasmodium consisting of many myxamoebae.

In time the plasmodium, or pseudo-plasmodium, is ready to reproduce. At this time it changes its reactions and turns toward the light. It heaps itself up in certain places. These heaps become the **sporangia**. In some species a long slender stalk is formed by the plas-

modium and at the top of the stalk the sporangium is formed. A membrane is formed around the heaped-up mass of protoplasm. The protoplasm and wall form a sporangium. Within this wall the protoplasm becomes separated into numerous small units, each containing a single nucleus. Spores result when walls are formed around each bit of protoplasm. Dispersed among the spores are many slender threads called elaters which may be simple or branched in different species. The aggregate of elaters is called a capillitium. They give strength to the sporangium and also because of their reaction to changes in humidity, which causes them alternately to coil and straighten out, they aid in loosening the spores and pushing them from the sporangium. The spores are capable of resisting prolonged

Fruiting bodies of different kinds of Myxomycetes. (*Kerner's Natural History of Plants, Blackie & Son.*)

desiccation, as well as low and high temperatures. Eventually the spores germinate and the life cycle is repeated.

The sporangia of slime molds show a variety of forms. In some species they are small brown balls appearing singly or in clumps on rotten wood. In other species they are long-stalked structures of great beauty and delicacy. Some resemble small mazes of irregular shape. A few suggest spots of thick brown grease deposited on leaves and stems. The size of the sporangia varies from coarse fusiform bodies 1½–2″ long and 1″ thick, to minute objects scarcely a mm. in diameter.

Slime molds are of no importance to man. (R.M.W., B.S.M.)

SLING PSYCHROMETER. **Meteorological Instruments.**

SLIP. For the meaning of slip in geology, see **Fault.**

Slip is a characteristic of the induction **motor. Alternating current** is used in the field windings of an a-c motor to produce a revolving field. The speed of this revolving field is the synchronous speed, and depends on the frequency of the system. The rotor of the induction type of a-c motor revolves at a speed less than synchronous. The percentage by which the rotor speed falls below synchronous speed is called the slip, and this varies from practically zero at no-load up to maximum at the stalling torque.

The slip of a propeller is the difference between its actual forward motion and that which it would have if it were revolving in a solid medium analagous to a bolt in a nut. The slip of water propellers is less than that of air propellers, because of the relative densities of the two media in which these propellers rotate.

The slip of a pump arises in the following way: A positive displacement type **pump,** such as a piston or plunger pump, should, theoretically, discharge a volume of liquid equal to the piston displacement. Leaky valves, defective piston rings, and other faults, can cause the delivery to be less than the piston displacement. This difference, stated as a percentage, is called slip, and may have a value of about 5% when the pump is in good condition.

In the early stages of the plastic deformation of **metals and alloys** the internal deformation of individual crystals takes place by slip along planes of atoms. The total deformation of a given crystal is the sum of many small lateral displacements in parallel crystallographic planes of a given family. Each slip plane becomes more resistant to further deformation than the remaining potential slip planes; in fact, the crystal as a whole is strengthened by deformation in a manner which has not been adequately explained, thus the theory of hardening metals by **cold working** is not fully developed. (See also **Metallography.**) (F.T.M., R.H.H.)

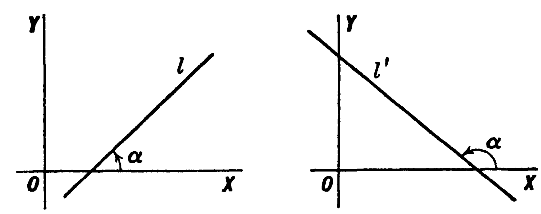
SLIP FUNCTION. **Propeller, Air, Characteristics.**

SLIP RINGS. These are conducting rings attached to a rotating part of an electrical machine to make connection through **brushes** with the stationary part of the circuit. They are used where it is not necessary to commutate the current being conducted (see **Commutation**). (L.R.Q.)

SLOPE OF A CURVE. **Derivative of a Function of One Variable.**

SLOPE OF A LINE. The inclination of a straight line is the least positive angle α from the X-axis to the given line.

The slope of a straight line is the tangent of the inclination angle α of the line: $m = \tan \alpha$.



The slope of a horizontal line is 0, but a vertical line has no slope.

If a line rises from left to right, its slope is positive, but if the line falls from left to right, its slope is negative.

The slope of the line through the points (x_1, y_1) and (x_2, y_2) is given by the formula

$$m = \frac{y_2 - y_1}{x_2 - x_1}$$

when **rectangular coordinates** are used.

If two lines are parallel, their slopes are equal. If the lines are perpendicular to each other, their slopes are negative **reciprocals** of each other. (L.L.S.)

SLOPE STAKE. **Earthwork.**

SLOT, AIRFOIL. **High Lift Devices.**

SLOTH. Mammalia, Edentata. Animals of Central and South America, highly specialized for arboreal life. Their claws are large hooks by which they suspend themselves from branches, and they are so thoroughly adapted to this inverted position that the hair runs from belly to back, opposite to its direction in animals of the usual position. They eat the foliage of cecropia

trees by preference. Apparently in coordination with the total lack of competition and risk in their lives, these strange creatures are extremely dull-witted.

The sloths are of two forms: 2-toed and 3-toed, each including several species. The 2-toed sloths, *Choloepus*, are also called unaus, and the native name for the 3-toed species, *Bradypus*, is ai. (A.W.L.)

SLOTTER. **Planer.**

SLOW-WORM. **Blind-Worm.**

SLUDGE. When fresh sewage is admitted to settling tanks a certain amount of the solid matter in suspension will settle out, 50% more or less for sedimentation periods of an hour and a half or so. This collection of solids is known as fresh sludge. Such sludge will become actively putrescent in a short time and in modern treatment plants must be passed on from the sedimentation tank before this stage is reached. This may be done in two common ways. The fresh sludge may be passed through the slot in an **Imhoff Tank** to the lower story or digestion chamber. Here decomposition by anaerobic bacteria takes place with considerable liquefaction and reduction in volume. After the decomposition process has run its course (in 6–9 months) the resulting sludge is called "digested" sludge and is relatively inoffensive in character. It may be disposed of by drying on sludge drying beds and spreading on the land. It has little, if any, fertilizing value, being in the nature of humus. The sludge digestion chamber is operated on a periodic schedule of sludge withdrawals.

Alternatively, plain sedimentation basins with mechanical equipment for continuous collection of the fresh sludge may be used. The fresh sludge, so collected, is discharged into separate sludge digestion tanks which operate on the principle of the lower story of the Imhoff Tank except that by means of higher and better temperature control the digestion cycle is much more rapid and efficient than for the Imhoff Tank. (E.W.S.)

SLUG. Mollusca, Gasteropoda. **Mollusks** of the family Limacidae, related to the land snails but without an external shell. The name also appears in the term sea slug, applied to members of the marine group, Nudibranchiata, which are also without external shells. (A.W.L.)

SLUICE. A channel through which water issues is, in some cases, called a sluice. A sluice may be a pressure conduit, or it may be an open flume. For instance, the word may be applied to an artificial channel to lead water from one point to another, especially a temporary wooden channel. Sluices are often incorporated in dam structures. A sluice through a **dam** is a conduit cast in the concrete and equipped with controls called sluice gates. The purpose of the sluice is to empty the reservoir if necessary, to control the water level, and to aid in passing floods. (F.T.M.)

SLURRY. **Filtration.**

SMALL-AREA PLOTTING SHEET. A small-area plotting sheet is an approximation to a **mercator** plotting sheet, and may be used for solving problems in **dead reckoning** and for plotting **lines of position.**

In constructing the **graticule** for the sheet, the fundamental assumption is made that, within the limit of errors inherent in the problems to be solved, the distance between successive parallels of **latitude,** separated by 1°, is constant all over the sheet. This is equivalent to assuming that the same scale of distance may be used all over the sheet. The ratio between the linear distance, X, between successive **meridians** and the linear distance, Y, between successive parallels, is that of **middle-latitude sailing:** $X = Y \cos L_m$, in which L_m is the average latitude of the region covered by the sheet.

Two types of small-area plotting sheet are in common use: (1) the fixed meridian type, and (2) the fixed parallel type. The method for completing the graticules and plotting a point is shown in Figs. 1 and 2 re-

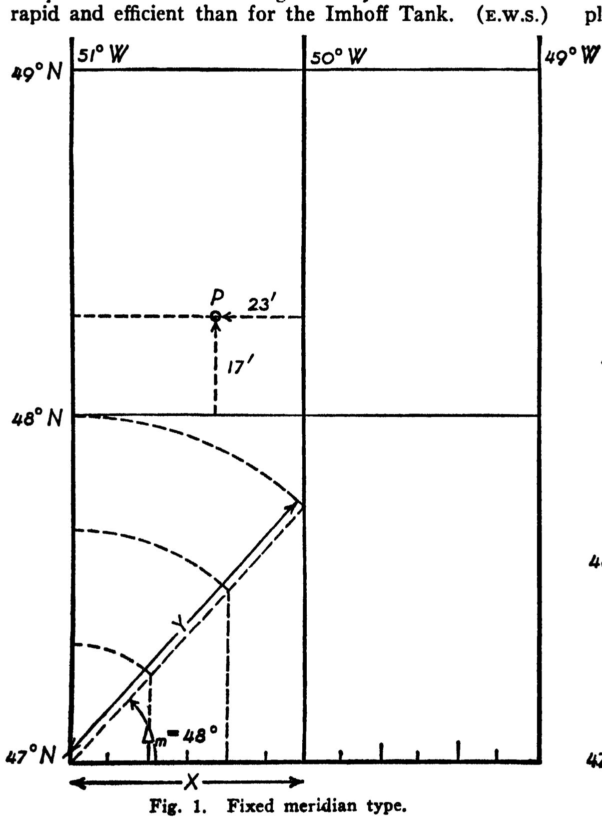


Fig. 1. Fixed meridian type.

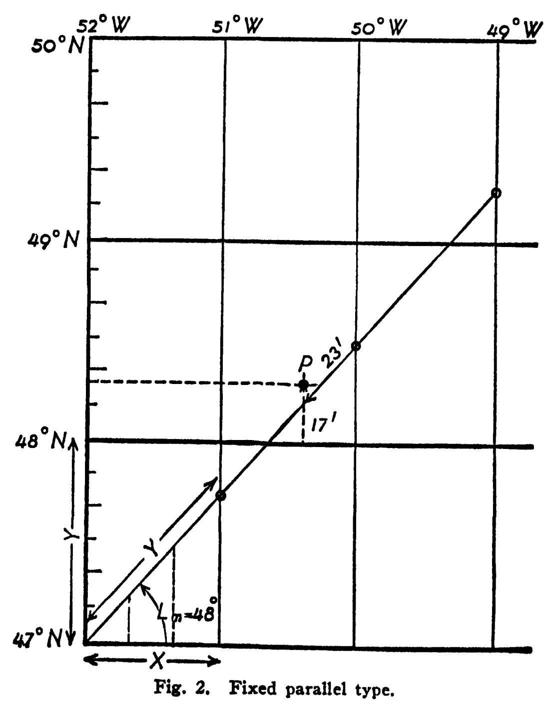

Fig. 2. Fixed parallel type.

spectively. In the figures the heavy lines are those printed on the published forms, and the light lines are those drawn to complete the graticule. Dotted lines in the figure are construction lines which need not appear on the completed sheet. The sheets in the figure are completed for $L_m = 48°$ and the point, P, is in latitude 48° 17′N and longitude 50° 23′ W.

In the older or fixed meridian type, Fig. 1, a diagonal line is drawn making an angle L_m with the base line. The distance, X, is that between the fixed meridians, and the distance, Y, is the length of the diagonal, measured between the meridians. Elementary trigonometry shows that $X = Y \cos L_m$. This distance, Y, is then transferred to one of the fixed meridians and becomes 1° of latitude for the small-area plotting sheet. This length, Y, is also equivalent to 60 nautical miles and is used as a scale of distance all over the sheet. The central parallel on the sheet is that of L_m. The central meridian is that of the middle of the region covered by the particular problem to be solved. With this type of sheet the longitude scale is constant, no matter for what region the sheet is drawn. The latitude spacing, and hence the scale of distance, is different for different sheets.

In the more modern, and far more frequently used, fixed parallel type, Fig. 2, the diagonal line making an angle of L_m with the base, is drawn. Distances equal to that between the fixed parallels are laid off along this diagonal and lines are drawn through these points parallel to the latitude scale of the sheet. These become the successive meridians. It will be seen that, as above, $X = Y \cos L_m$. However, on this style of sheet the distance Y is fixed, no matter for what region the sheet is prepared, and a scale for distance ruled on celluloid, or other permanent material, may be used on all sheets. Furthermore, this same scale may be used for measurement of longitude by placing it along the diagonal and then projecting the desired value, parallel to the latitude scale, to the proper latitude.

Plotting sheets of both types and for various scales are published by the U. S. Hydrographic Office, and by several publishing firms. Most of the forms have a **compass** rose at the center of the sheet so that parallel rulers and dividers may be used, instead of protractor and scale, if the user prefers. However, printed forms are by no means necessary, for the graticule can quickly be drawn on blank paper with the aid of a protractor and scale. Using a blank sheet requires about one minute to obtain the completed graticule, while with the printed forms this time is cut in half.

Either type sheet can be used, without introducing errors greater than those inherent in the problems for which they are designed, for any mid-latitude between the equator and 60° and for areas of about 300 miles sq. For low latitudes the area can be correspondingly increased. (W.K.G.)

SMALL ERRORS. **Differentials.**

SMALLPOX. (Variola). An acute contagious disease caused by a filtrable **virus**. The disease is characterized by severe constitutional symptoms and a distinctive skin eruption which leaves scarring upon healing. Smallpox has been known since antiquity and lesions have been seen on the skin of an Egyptian mummy of the 20th dynasty. The disease originally spread from India and Central Asia to Europe and became especially prevalent at the time of the Crusades in the 11th century. It was first introduced in America by a Negro slave of Cortez in 1520, producing an epidemic that killed several million people. One century later it appeared in New England. It was first called smallpox in Europe, to differentiate it from grand-pox (**syphilis** of the skin). The discovery of vaccination by Jenner in 1798 is one of the landmarks in the development of medical science.

Since only a small percentage of people have natural immunity, the incidence of smallpox varies with the per cent of the population vaccinated. In the United States, where vaccination is not compulsory, the incidence is relatively high. Permanent immunity usually develops after an attack of smallpox. Epidemics vary greatly in severity. In recent years the disease has been of a mild type.

The incubation period averages between 8–12 days in the majority of cases. The onset of the disease is usually sudden and may begin with a chill. The temperature soon becomes high and headache, generalized pain and vomiting are frequently all present. The patient is prostrated. Delirium, convulsions, and coma occur, primarily in children.

As the skin eruption appears the symptoms and fever abate and the patient feels more comfortable. The eruption first appears as reddish spots which become elevated. After a few days the elevated area is capped by a small blister, which grows bigger and on the 7th or 8th day contains pus. During this period, secondary fever develops, gradually disappearing as healing and desquamation, or peeling, progress. This begins around the 12th or 14th day.

Black or hemorrhagic smallpox is a virulent fulminating type of the disease which invariably causes death in 2–6 days.

Smallpox occurring in those who have been vaccinated is called varioloid, and is usually a mild form.

The deaths in smallpox are often due to complications which are usually infections following secondary invasion by **staphylococci** and **streptococci**. The most common complications are **abscesses**, **pneumonia**, **septicemia**, **nephritis**, and ulcers on the cornea of the eye.

There is no specific treatment for smallpox, and the general treatment is similar to that of any severe acute infection. (R.S.M., D.M.H.)

SMALTITE-CHLOANTHITE. The mineral smaltite-chloanthite is an **isomorphous** mixture of **cobalt diarsenide**, $CoAs_2$ (smaltite), and **nickel** diarsenide, $NiAs_2$, (chloanthite), the proportions varying widely. It occurs in tin-white **isometric** crystals, but is also found massive. It is brittle; hardness, 5.5–6; specific gravity, 6.4–6.6; luster, metallic; color, tin-white to steel gray; streak, nearly black; opaque. It is associated with other nickel and cobalt minerals as well as with **silver** and **copper** ores. It is found in Bohemia, Saxony, Baden, Alsace, Spain, England and New South Wales. In the United States it has been found in Connecticut, New Jersey; and in Canada at Cobalt, Province of Ontario. It is used as an ore of both metals. (E.S.C.S.)

SMEAR METAL. The heat generated by metal cutting is often very great, and may cause a decided change in the nature of the metal adjacent to the cut surface. Under the influence of heat, some of the loose metal particles, and the serrated edges caused by metal cutting, may be welded or combined into an amorphous metal substance known as smear metal. Smear metal has little or no resistance to wear and must therefore be removed from surfaces that are subject to heavy pressures, particularly in bearings. Such processes as **lapping** and **superfinishing** are usually employed for this purpose. (H.C.H.)

SMELL. A chemical sense by which the animal perceives substances in the gaseous state and sometimes in exceedingly small quantities. It is valuable to the individual because the rapid transmission of many volatile substances over long distances permits the recognition of foods or enemies prior to close meeting with them. The sense is resident in **olfactory organs**. (A.W.L.)

SMELT. Pisces, Teleostei. The small fishes (**Pisces**) of the family Osmeridae, including the **candlefish** and the common smelt, *Osmerus eperalnus*, of the Atlantic. Both of these species are marine, ascending the streams to spawn, and both are important food fishes. (A.W.L.)

SMELTING. The process of heating ores to a high temperature in the presence of a **reducing** agent, such as **carbon** (coke), and of a **fluxing** agent to remove the accompanying rock gangue is termed smelting. Iron ore is the most abundantly smelted ore. It contains about 20% gangue (clay and sand). The ore is heated in an air **blast furnace** with coke and **limestone** (fluxing agent) at a temperature above the melting point of iron and **slag** (fusion mixture of impurities and flux). The molten iron (the more dense material) and molten slag (the less dense material) are removed separately from the furnace. (R.K.S.)

SMEW. Aves, Anseriformes. A European name for a small **merganser,** *Mergellus albellus.* Sometimes also applied to widgeons and pochards, and said to be used for the pintail duck, although pintail is by far the more common name. (A.W.L.)

SMILAX. Asparagus; Sarsaparilla.

SMILODON. Pleistocene.

SMITHSONITE. Smithsonite is **zinc** carbonate, $ZnCO_3$, a **hexagonal** mineral with a **rhombohedral** cleavage. It is a brittle mineral; hardness, 5; specific gravity, 4.3–4.5; luster, vitreous to dull; color, usually white, but may be colored yellowish or brownish or perhaps blue or green due to impurities. It is translucent to opaque. Smithsonite is a secondary mineral after **sphalerite** or may replace **limestone** or **dolomite.** It is sometimes called calamine (but true calamine is a **zinc silicate**) and often associated with it. Smithsonite occurs in Siberia, Greece, Rumania, Austria, Sardinia, Cumberland and Derbyshire, England; New South Wales, South West Africa, and Mexico. In the United States it is found in Pennsylvania, Wisconsin, Missouri, Arkansas, and Utah. This mineral was named in honor of James Smithson, whose generous legacy founded the Smithsonian Institution at Washington, D. C. (E.S.C.S.)

SMOKE. Smoke is the colored product of incomplete combustion, consisting chiefly of particles of unburned carbon. The discharge of smoke to the atmosphere can be considered nothing but an evil—and an unnecessary evil at that. The evil effects of smoke may be considered under three headings, viz., (1) effect on health, (2) financial loss due to incomplete combustion, deleterious effect on plant growth, and begriming of buildings, (3) effect on standard of living.

The smoke nuisance is at its worst, of course, in metropolitan districts. The smoke is produced from both industrial and domestic fires. Smoke abatement workers have found it much easier to render the former class smokeless than the latter.

There has been no definite coordination discovered between diseases of the respiratory tract and smoke density; however, common sense would say that a smoky atmosphere was bound to be less healthful than air alone. Chronic sinus and nose troubles seem to be prevalent in extremely smoky atmospheres. It is a well-known fact that the effect of smoke is deadly to vegetation. One unit of sulfur in the coal gives about three units of **sulfuric acid,** a substance most poisonous to plant life; indeed, the sulfur dioxide content of flue gas has caused more than one large lawsuit to be brought against central station operators. Sulfuric acid plus rain has a detrimental effect upon the limestone of buildings. Smoke corrodes metals, darkens paints, and in many other ways creates a tremendous economic loss other than that due to loss of heating value of fuel. It is well known by those who have lived in smoky cities that a much lower standard of cleanliness is prevalent. Neither building interiors nor exteriors, clothing, hangings, furniture, etc., can be kept clean.

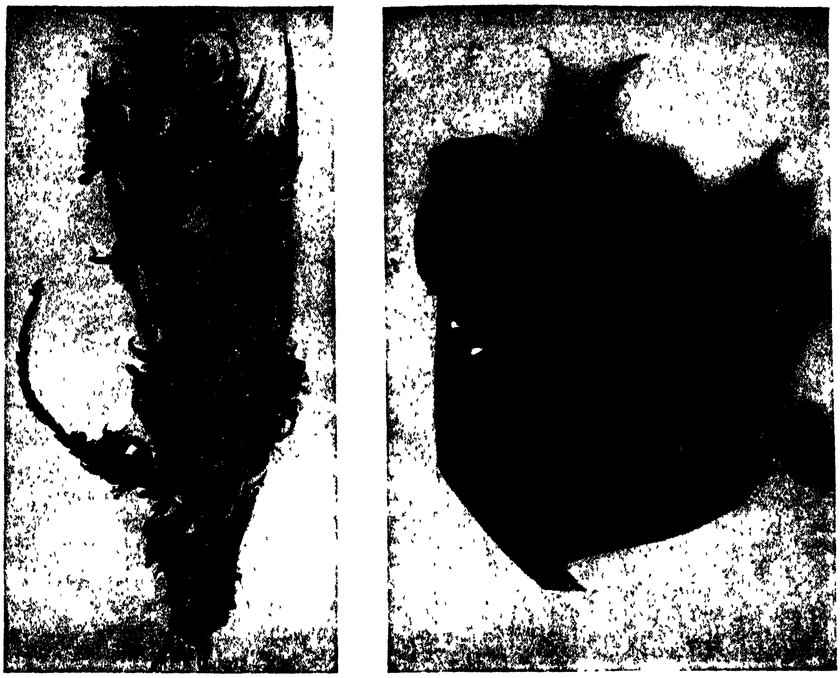
One of the oldest methods of gauging the smoke emitted by a chimney involves use of the Ringleman smoke comparison chart.

The Ringleman chart is composed of four sets of gratings. When these are placed about 25 ft. from the observer the gratings merge to a solid color ranging from light gray to a dense black. The chart enables a smoke inspector to rate the character of smoke emission from a chimney by comparison. Smoke ordinances are often based on the Ringleman chart, as, for instance, prohibiting the emission of smoke to exceed "No. 2 Ringleman" more than a certain period of time, say, one minute.

Smoke and fog often combine to form a "smog" or fog-smoke mixture. Concentration of smoke particles depends mainly on three factors: 1. The intensity of output at the source. 2. The depth to which smoke is distributed. 3. The strength of winds which carry smoke from the source. Of these three, the second has the greatest bearing on visibility. When air is stable, vertical currents are suppressed; smoke particles, therefore, remain near the ground. Ground inversions preclude any vertical distribution of smoke and these are very common during early morning hours. As the sun rises, the ground inversion or stability is destroyed and air is mixed to a greater vertical depth; smoke is thinned in proportion to the depth of mixing, and visibility improves. On overcast days when stable air lies adjacent to the ground all day, smoke does not thin, and visibility remains considerably reduced. In extreme cases twilight dimness may prevail throughout the day. (F.T.M., P.E.K.)

SMOOTH-HEAD. Pisces, Teleostei. A fish (**Pisces**) related to the salmons. The head is entirely without scales and the median fins, both dorsal and ventral, are located just before the tail. All of the species live in the deep sea. (A.W.L.)

SMUTS. Ustilaginales. Smuts are parasitic **Basidiomycetes** which are so named because of the conspicuous masses of sooty black spores which they form externally on the host plant. Infection by smuts is seldom fatal to the host plant but does seriously reduce its size and may even prevent seed formation completely. The fungus grows as a septate **mycelium** which penetrates between the cells of the host plant; into these cells it sends **haustoria,** which obtain nourishment therefrom. Presently this septate mycelium gives rise to immense numbers of **spores.** Often the presence of the mycelium causes the host tissue to enlarge tremendously, producing irregular tumor-like growths. These are particularly conspicuous in Corn Smut. The spores are thick-walled unicellular objects capable of surviving for some time under unfavorable conditions. On germinating, each spore develops a short germ tube, or promycelium, which becomes from 1–4 cells long. Each of these cells produces a spore. The promycelium becomes a basidium; and the spores, basidiospores. These spores are capable of infecting new host plants, producing therein a mycelium. Conjugation between cells of the mycelium occurs so that each cell comes to have two nuclei. As growth continues, the two nuclei of any cell divide simultaneously so that every cell continues to have two nuclei. When spore formation occurs, the two nuclei fuse, dividing again when the spore germinates. Many variations of this process are found; in many smuts the promycelium buds off from its apex many cells. Often fusion between two of these cells occurs immediately, even before they are separated from the promycelium.

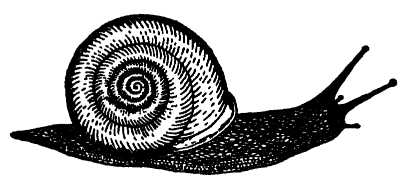


Corn smut. Left, smutted tassel; right, smutted ear.

Because of the rapidity with which smuts may spread and the great reduction of seed production which their presence may cause, smuts are of great economic importance. One species, Corn Smut, *Ustilago zeae,* causes the loss of millions of bushels of corn yearly. Oat smut, *Ustilago avenae,* may cause a 30% reduction in yield, while other smuts are equally important. Control of the parasites may be obtained by rotating crops; but due to the resistant nature of the spores, at least three years should elapse before replanting an infected field to the same crop. Other methods of control consist of soaking seeds in various solutions, such a formaldehyde (see **Aldehyde**) solution in water, or dusting infected seeds with copper compounds. (R.M.W.)

Smutted oat head. Left, smutted plant; right, healthy plant.

SNAIL. Mollusca, Gasteropoda. A name properly applied to most members of this class but usually given onlv to the small fresh-water and terrestrial species with



Snail.

coiled shells. The term does not correspond with any part of the scientific classification of mollusks beyond this general application.

Snails are eaten in several countries of Europe, where they are regarded as a delicacy. (A.W.L.)

SNAKE. Reptilia, Sauria. A slender elongate reptile with no trace of external appendages and only in a few species with vestiges of the appendicular skeleton. The snakes differ from the lizards also in the large scales of the ventral surface. They are widely distributed and many species are poisonous.

Among the large number of snakes that bear distinctive names are the adders, racers, **vipers** and **pit vipers**, constrictors, including the **python**, **boa**, and **anaconda**, **cobras**, **craits**, **asp**, **bushmaster**, **fer-de-lance** and many others. The poisonous North American species, aside from the relatively unimportant coral snake of the southeast, are the **copperhead**, the **moccasin**, and the **rattlesnakes**. (See also **Fossil Reptiles.**) (A.W.L.)

SNAKE FLY. Insecta, Neuroptera. A peculiar insect found only in the far West. It has four membranous wings and the body is prolonged at the anterior end.

They are insect eaters and are found commonly on the bark and foliage of trees. (A.W.L.)

SNAKE VENOM POISONING. Snake venom is a mixture of **protein** substance, cellular debris, fatty matter, and salts such as **calcium** chloride and phosphate, **ammonium** and **magnesium**. The venom of most snakes contains several toxic elements, including a hemotoxin and neurotoxin. The hemotoxin causes damage to the blood vessels with extravasation of blood into the tissues and extensive swelling and discoloration of the soft parts. The neurotoxin attacks nerve centers, causing **paralysis**. Other components are the anti-coagulating factor, which prevents blood **coagulation** and predisposes to hemorrhage; the hemolysin, which causes the red blood cells to dissolve; the agglutinin component which produces agglutination of both red and white blood cells; and other less well established cell poisons.

Various venoms differ in the relative amounts of each of these toxins and in their strength. In the American tropics the **fer-de-lance**, the *mapepire balsayn*, and the *barba amarilla* and the **jararaca** all have a venom that contains a powerful hemotoxin which may cause rapid death in untreated cases. The venom of the cobra of India consists for the most part of the neurotoxin, and death results from paralysis of respiration. The North American snakes, such as **rattlesnakes, copperheads, moccasins**, inject a venom which contains a considerable amount of the hematoxin and hemolysin but it is not as rapid in its action as that of some of the tropical snakes.

Venom is injected through fangs which are a type of highly specialized tooth, and resemble in construction a hypodermic needle.

The mortality from snake bite is very high. In India the annual mortality is around 20,000. Anti-venom serum has been prepared and is easily accessible for use in many countries. In Brazil the Institute at São Paulo, under the auspices of the Government, has made a study of the various venoms, and anti-venom serums are widely distributed. Thus the mortality from snake bites has been reduced from several thousand to less than 50. The annual mortality from this source in the United States is around 150.

In the treatment of snake bite, prompt measures designed to keep the venom from getting into the circulation offer the best method of attack. Proper treatment consists of application of a tourniquet or ligature about the site of the bite. Deep incisions at the site of the fang punctures with the use of some suction device will remove a good deal of venom. Venom is absorbed very rapidly and if several hours elapse before this procedure is carried out the results may be poor. Anti-venom serum should be injected as soon as possible to neutralize the poison. Transfusion and other supportive measures are also important. (R.S.M., D.M.H.)

SNAP GAUGE. **Measurement.**

SNAPDRAGON. **Figwort.**

SNEDECOR'S F DISTRIBUTION. Let $F = \frac{s_1^2}{s_2^2}$ where s_1^2 is the estimated **variance** with n_1 **degrees of freedom** and s_2^2 is the estimated variance with n_2 degrees of freedom when the **variates** are **normally distributed** with a common **population** variance of σ_P^2. The distribution of F is given by

$$P_F dF = \frac{n_1^{\frac{n_1}{2}} n_2^{\frac{n_2}{2}}}{B\left(\frac{n_1}{2}, \frac{n_2}{2}\right)} \frac{F^{\frac{n_1}{2}-1}}{(n_1 F + n_2)^{\frac{n_1+n_2}{2}}} dF, \quad 0 \leqq F < \infty.$$

Let $\int_{F_\alpha(n_1, n_2)}^{\infty} P_F dF = \alpha$. The value of $F_\alpha(n_1, n_2)$ is given by tables. It should be noted $F_{1-\alpha}(n_1, n_2) = \frac{1}{F_\alpha(n_2, n_1)}$. Tables for $F_\alpha(n_1, n_2)$ have been constructed. Snedecor's F is related to Fisher's z by $F = e^{2z}$. The F distribution occurs in the **analysis of variance.** We may interpret F as the quotient $\frac{n_2 \chi_1^2}{n_1 \chi_2^2}$, where χ_1^2 is distributed in a χ^2 distribution with n_1 **degrees of freedom** and χ_2^2 is distributed as χ^2 with n_2 degrees of freedom. The F distribution may be transformed into **Fisher's z distribution,** into an **incomplete Beta function,** and, as special cases, includes the **normal probability function, Student's t distribution** and the χ^2 distribution. In the limit as n_1 and n_2 approach infinity in any manner whatever, the F distribution approaches the **normal curve** with mean 1 and variance $2\left(\frac{1}{n_1} + \frac{1}{n_2}\right)$. The approach to normality, however, is very slow. (L.A.A.)

SNELL'S LAW. **Refraction.**

SNIPE. Aves, Charadriiformes. Long-legged and long-beaked wading birds (**Aves**) related to the sandpipers and woodcock. They are found in marshy ground and occur on all continents. North America has one species, the Wilson snipe, *Capella delicata*, or jack snipe, which is regarded to a limited extent as a game bird. Certainly its erratic flight makes it a severe test of marksmanship. This species breeds from the northern states northward and migrates to South America. (A.W.L.)

SNIPE FLY. Insecta, Diptera. Two-winged flies with long legs and a conical abdomen. They belong to the family Rhagionidae, sometimes called Leptidae. Some of the species suck blood and in the western mountains are very annoying to human beings. They receive the name **deer fly** in the west, a term applied to a small horse fly in the east. (A.W.L.)

SNOW. Snow crystals when freshly formed are often almost perfect and exhibit an endless variety of detail. They are commonly flat, 6-sided polygons, stars, or spangles, often of very complicated and beautiful design, but always with the 60° and 120° angles characteristic of the hexagonal system. Sometimes they are needle-like, resembling miniature 6-sided lead pencils, or needle-like with a hexagonal head, like a pin. The finer spicules are sometimes suspended high in the atmosphere, and are the cause of **halos**. Snow differs from **frost** chiefly in being formed in the air instead of upon solid objects near the ground, the crystallization nuclei being particles of dust. Partly melted crystals often cling together to form snowflakes of varying size, and may melt into raindrops before reaching the ground. Snow appears white only because of the multitude of reflecting surfaces; the individual crystals are of transparent ice. In the United States, a heavy snowfall is commonly followed by intense cold, partly because of the low absorptivity of snow for solar radiation, and partly because of the cyclonic character of the snowstorm, which brings a change of wind to the north on the westward or following side of the storm. (See **Hydrometeors.**) (L.D.W.)

SNOW LEOPARD. **Ounce.**

SOAP. **Esters; Surface-Active Compounds.**

SOAPSTONE. **Talc.**

SOCIETY. A group of individuals of the same **species** living together for mutual benefit, with some division of labor. The society is a high expression of colonial organization in the animal kingdom, and is not sharply separated from simpler forms of colonies.

In the simplest type of colony, as found among the 1-celled animals, the associated individuals are similar and each is capable of complete existence in itself. In

the same group a slight division of labor appears, accompanied by structural differentiation of the individuals for different tasks. This form of organization persists in the **coelenterates, bryozoans,** and **ascidians,** with varying degrees of structural continuity in the colony and varying degrees of differentiation and division of labor.

Among the more highly organized animals the possibility of association of individuals in a complex society involving division of labor is expressed only among the social insects and man. The insect society, or colony as it is often called, continues the associated principle of structural specialization of the individual for its particular duties, with the resulting castes exemplified in a simple form by the queen, drone, and worker honeybees. Among the **termites** and **ants** the differentiation is much more extreme and complex. To a moderate degree the **honey-bee** colony also shows specialization of behavior among the workers, which may engage in various activities within their powers according to the requirements of the colony at different times.

The human society differs from that of insects in the restriction of inherent fitness for special duties to less evident details of organization. While inherent fitness undoubtedly exists among men, they are structurally of approximately the same form and their specialization is largely a result of training. In other words, specialization of the individual in human society is conspicuously a specialization of behavior. Lack of structural specialization is compensated by the use of tools.

In all cases the society is an extension of the prevailing biological principle that biological units of any degree of complexity can be associated together as component parts of a larger coordinated unit. (A.W.L.)

SOCKET WRENCH. Wrench.

SODA. Term applied to **sodium** compounds.. Soda ash, sodium carbonate; washing soda, sal soda, sodium carbonate decahydrate; baking soda, sodium hydrogen carbonate; caustic soda, sodium hydroxide. Percentage of soda expressed in analyses of chemicals is for sodium oxide (Na_2O). (R.K.S.)

SODA NITRE. The mineral soda nitre or Chile saltpeter is naturally occurring **sodium nitrate,** $NaNO_3$. Its **hexagonal** crystals are rare, this mineral usually being found in crystalline aggregates, crusts or masses. It is soft; hardness, 1.5–2; specific gravity, 2.24–2.29; vitreous luster; colorless or white to yellow or gray; transparent to opaque. Soda nitre is a most important mineral commercially, being used in the manufacture of nitric acid, other nitrates and fertilizers. The chief soda nitre deposits of the world are those found in the Atacama and Tarapaca deserts of northern Chile, although others exist in the Argentine and Bolivia. Some small deposits have been found in California, New Mexico and Nevada. The origin of these **nitrate** deposits is far from being well understood. They have been regarded as nitrates formed originally by oxidation of organic matter and subsequently leached out. Guano, the excrement of birds, might be the original source of the nitrates. Ground water and ancient marine deposits have been suggested as well as the possibility of derivation from nitric acid produced in the atmosphere during electrical storms. Some invesigators have felt that the nitrates may have come from volcanic sources. (E.S.C.S.)

SODALITE. An **isometric** mineral, a **sodium aluminum silicate** containing **sodium chloride,** with the chemical composition $3NaAlSiO_4 \cdot NaCl$, **potassium** sometimes replacing a small amount of sodium. It is commonly found as **dodecahedrons** or simply massive. When observed sodalite has a dodecahedral **cleavage;** conchoidal to uneven fracture; brittle; hardness, 5.5–6; specific gravity, 2.14–2.30; luster, vitreous to greasy; color grayish to greenish or yellowish, may be white. It is often a beautiful blue and may sometimes be red. It is transparent to translucent; streak, white. Sodalite is found in **igneous rocks** of **nephelite-syenite** type which have been produced from soda rich **magmas.** It has also been found in the lavas of Vesuvius. Common minerals associated with it are **nephelite** and **cancrinite.** It occurs in the Ilmen Mts. of Russia; at Vesuvius and Monte Somma, Italy; in Norway and Greeland. In Canada, in British Columbia and in Ontario, beautiful blue sodalite is found; and in the United States similar material comes from Kennebec County, Maine. It derives its name from the fact of its soda content. Attempts have been made to use this mineral for ornamental purposes. (E.S.C.S.)

SODIUM. Symbol: Na (natrium). Atomic number: 11. Atomic weight: 22.997. Density: 0.97. Hardness: 0.4. Melting point: 97.5° C. Boiling point: 880° C. No isotope, but of single atomic form: 23.

Sodium is a silvery-white metal, can be readily molded and cut by knife, oxidizes instantly on exposure to air, and reacts with water violently, yielding sodium hydroxide and hydrogen gas, consequently is preserved under kerosene, burns in air at a red heat with yellow flame. Discovered by Davy in 1807.

Sodium occurs as sodium chloride in the ocean (1.14% Na), in salt deposits (salt, **halite,** NaCl), e.g., in Michigan, New York, Lousiana, in Great Britain, in Germany, in salt lakes, e.g., the Dead Sea (3% Na), Great Salt Lake; in common rocks (average of the solid shell of the earth 2.75% Na) as sodium nitrate (Chile saltpeter, $NaNO_3$) in Chile; as sodium borate (**rasorite, kernite,** $Na_2B_4O_7 \cdot 4H_2O$, in California; **tinkal,** $Na_2B_4O_7 \cdot 10H_2O$, in Tibet); as sodium carbonate (Na_2CO_3) and sulfate (Na_2SO_4) in certain salt lake areas.

Sodium metal is obtained by **electrolysis** of fused sodium chloride or hydroxide out of contact with air. Its uses are limited in extent, but important in particular cases, as in the liberation of a metal from its chloride by reaction of sodium to form sodium chloride, and in certain reactions of organic chemistry.

Acetate: Sodium acetate ($NaC_2H_3O_2 \cdot 3H_2O$), white solid, soluble, formed (1) by reaction of sodium carbonate or hydroxide and **acetic acid,** and then evaporating, (2) by precipitation of **calcium** acetate solution and sodium carbonate solution, followed by filtration, and evaporation of the filtrate. Used (1) as a source of acetate, (2) in the dye industry. Reacts (1) with sulfuric acid, upon heating, yielding sodium hydrogen sulfate non-volatile and acetic acid volatile and condensable, (2) with sodium hydroxide solid, upon heating, yielding sodium carbonate and methane.

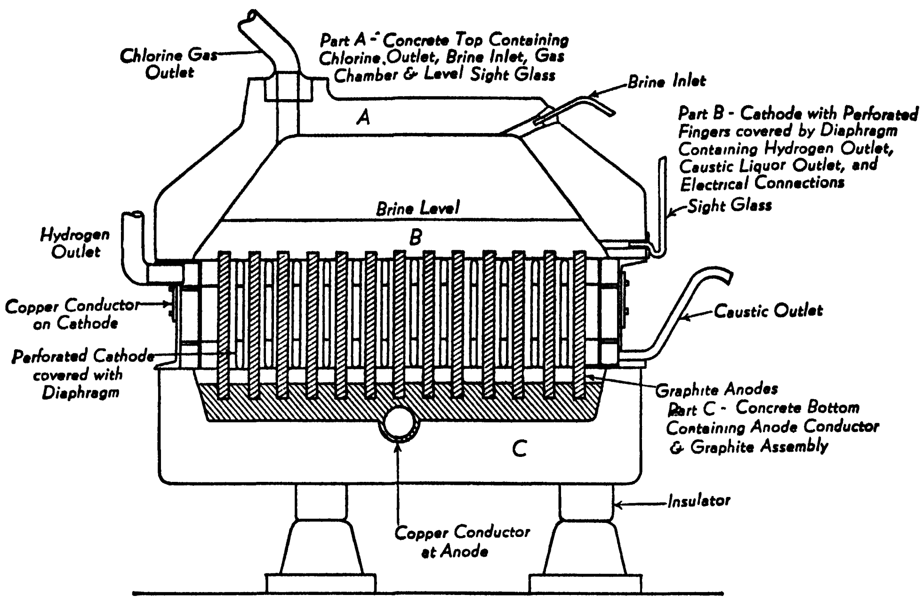
Alum: Soda alums are those alums such as **aluminum** sodium sulfate ($Al_2(SO_4)_3 \cdot Na_2SO_4 \cdot 24H_2O$) where sodium sulfate is used instead of the more common potassium or ammonium sulfate.

Aluminate: Sodium aluminate ($NaAlO_2$), white solid, (1) by reaction of **aluminum** hydroxide and sodium hydroxide solution, (2) by fusion of aluminum oxide and sodium carbonate, the solution reacts with carbon dioxide to form aluminum hydroxide. Used as a mordant, and in water purification.

Aluminosilicate: Sodium aluminosilicate is used as a water softener ("Permutite") for the removal of dissolved calcium compounds.

Amide: Sodamide, sodamine ($NaNH_2$), white solid, formed by reaction of sodium metal and dry **ammonia** gas at 350° C. Reacts with **carbon** upon heating, to form sodium cyanide, and with nitrous oxide to form sodium azide (NaN_3).

Arsenate: Sodium arsenate ($Na_3AsO_4 \cdot 12H_2O$), white solid, soluble, formed by oxidation of sodium arsenite. Used (1) as a source of arsenate, (2) as a mordant in dyeing and printing, (3) as an insecticide.



Cross-section of Hooker cell.

Arsenite: Sodium arsenite ($NaAsO_2$), white solid, soluble, formed by reaction of **arsenic** trioxide and sodium hydroxide or carbonate solution, and boiling. Used (1) as an antiseptic, insecticide, weed-killer, hide preservative, and (2) in dyeing.

Benzoate: Sodium benzoate ($NaC_7H_5O_2$), white solid, soluble, formed by reaction of **benzoic acid** and sodium carbonate solution, and then evaporating. Used as a food preservative to a limited extent, an antiseptic, in pharmacy, and in dyeing.

Borate: Sodium borate, sodium tetraborate, borax ($Na_2B_4O_7 \cdot 10H_2O$), white solid, soluble, formed (1) by reaction of sodium carbonate or hydroxide and **boric acid**, (2) by reaction of sodium carbonate and **calcium** borate (**colemanite**), followed by filtration, and then evaporating the filtrate, or (3) by use or purification of the mineral. Used as a flux in soldering, in ceramics, in textiles and tanning, in laundering and soaps, as a food preservative to a limited extent, and in medicine.

Bromide: Sodium bromide (NaBr), white solid, soluble, melting point 755° C. Used in photography and in medicine.

Carbonates: Sodium carbonate (anhydrous), soda ash (Na_2CO_3), sodium carbonate decahydrate, washing soda, sal soda ($Na_2CO_3 \cdot 10H_2O$), white solid, soluble, melting point 851° C., formed by heating sodium hydrogen carbonate, either dry or in solution. Commonly bought and sold in quantity on the basis of oxide (Na_2O) determined by analysis (58.5% Na_2O equivalent to 100.0% Na_2CO_3). Used (1) as a source of carbonate, (2) in laundering, dish-washing, cleansing, and soaps, (3) in water purification for the precipitation of dissolved **calcium** compounds, as for boiler water supplies, (4) in the preparation of sodium salts (a) in solution, (b) upon fusing, at high temperature, for the manufacture of salts, such as sodium silicate from silicon oxide, sodium chromate from chromite, sodium manganate from **manganese** dioxide; sodium hydrogen carbonate, sodium bicarbonate, sodium acid carbonate, baking soda ($NaHCO_3$), white solid, soluble, when heated, dry or in solution, yields sodium carbonate; formed (1) by precipitation of sodium chloride and **ammonium** hydrogen carbonate cold concentrated solutions, and then filtering (ammonia soda process), (2) by reaction of sodium hydroxide or carbonate solution and excess **carbon dioxide**. Used (1) as a **leavening agent** (with an acid material) for carbon dioxide in baking, (2) in **baking powder**, (3) in effervescent beverages (with an acid material), (4) in fire extinguishers (with **sulfuric acid**), (5) in medicine as an antiacid. Both sodium carbonate and sodium hydrogen carbonate are relatively cheap and satisfactory mild alkalis. (See **Glass**.)

Chlorate: Sodium chlorate, chlorate of soda ($NaClO_3$), white solid, soluble, melting point 260° C., powerful oxidizing agent and consequently a fire hazard with dry organic materials, such as clothes, and with sulfur; upon heating oxygen is liberated and the residue is sodium chloride; formed by electrolysis of sodium chloride solution under proper conditions. Used (1) as a weed-killer (above hazard), (2) in matches, and explosives, (3) in the textile and leather industries.

Chloride: Sodium chloride, common salt, rock salt, halite (NaCl), white solid, soluble, melting point 804° C. Source in nature is widely distributed. Formed by reaction of sodium carbonate or hydroxide and **hydrochloric acid**. Used (1) in foods for man and animals, (2) as the original source of most sodium-containing substances, and of chlorine and **hydrogen chloride** (therefore, of most chlorine-containing substances).

Chlorite: (See **Chlorous Acid**).

Chromate: Sodium chromate ($Na_2CrO_4 \cdot 10H_2O$), yellow solid, soluble, formed by reaction of sodium carbonate and **chromite** at high temperatures in a current of air, and then extracting with water and evaporating the solution. Used (1) as a source of chromate, (2) in leather tanning, (3) in textile dyeing, (4) in inks.

Citrate: Sodium citrate ($Na_3C_6H_5O_7 \cdot 5\frac{1}{2}H_2O$) white solid, soluble, formed (1) by reaction of sodium carbonate or hydroxide and **citric acid**, (2) by reaction of **calcium** citrate and sodium sulfate or carbonate solution, and then filtering and evaporating the filtrate. Used in soft drinks and in medicine.

Cyanide: Sodium cyanide (NaCN), white solid, soluble, very poisonous, formed (1) by reaction of sodamide and **carbon** at high temperature, (2) by reaction of calcium **cyanamide** and sodium chloride at high temperature, reacts in dilute solution in air with gold or silver to form soluble sodium gold or silver cyanide, and used for this purpose in the cyanide process for recovery of gold. The percentage of available cyanide is greater than in potassium cyanide previously used. Used as a source of cyanide, and for **hydrocyanic acid**.

Dichromate: Sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$), red solid, soluble, powerful oxidizing agent, and conse-

quently a fire hazard with dry carbonaceous materials Formed by acidifying sodium chromate solution, and then evaporating. Used (1) in matches and pyrotechnics, (2) in leather tanning and in the textile industry, (3) as a source of chromate, cheaper than potassium dichromate.

Dithionate: Sodium dithionate, "sodium hyposulfate" ($Na_2S_2O_6 \cdot 2H_2O$), white solid, soluble, formed from **manganese** dithionate solution and sodium carbonate solution, and then filtering and evaporating the filtrate.

Ferricyanide: Sodium **ferricyanide,** red prussiate of soda ($Na_3Fe(CN)_6 \cdot H_2O$), red solid, soluble, formed by reaction of sodium **ferrocyanide** solution and chlorine, and then evaporating.

Ferrocyanide: Sodium ferrocyanide, yellow prussiate of soda ($Na_4Fe(CN)_6 \cdot 12H_2O$), yellow solid, soluble, formed by treating "spent oxide" of coal gas works with **calcium** hydroxide to extract ferrous cyanide as soluble calcium ferrocyanide, and then treating with sodium carbonate, filtering, and evaporating the filtrate. Used (1) as a source of ferrocyanide, (2) in **blue print** paper, (3) in tanning, (4) in tempering steel.

Fluorides: Sodium fluoride (NaF), white solid, soluble, formed by reaction of sodium carbonate and **hydrofluoric acid,** and then evaporating. Used (1) as an antiseptic and antifermentative in alcohol distilleries, (2) as a food preservative, (3) as a poison for rats and roaches, (4) as a constituent of ceramic enamels and fluxes; sodium hydrogen fluoride, sodium difluoride, sodium acid fluoride ($NaHF_2$), white solid, soluble, formed by reaction of sodium carbonate and excess hydrofluoric acid, and then evaporating. Used (1) as an antiseptic, (2) for etching glass, (3) as a food preservative, (4) for preserving zoological specimens.

Fluosilicate: Sodium fluosilicate (Na_2SiF_6), white solid, very slightly soluble in cold water, formed by reaction of sodium carbonate and **hydrofluosilicic** acid. Used (1) in ceramic glazes and opal glass, (2) in laundering, (3) as an antiseptic.

Formate: Sodium formate ($NaCHO_2$), white solid, soluble, formed by reaction of sodium hydroxide and **carbon monoxide** under pressure at about 200° C. Used (1) as a source of formate and **formic acid,** (2) as a reducing agent in organic chemistry, (3) as a mordant in dyeing, (4) in medicine.

Hydride: Sodium hydride (NaH), white solid, reactive with water yielding **hydrogen** gas and sodium hydroxide solution, formed by reaction of sodium and hydrogen at about 360° C. Used as a powerful reducing agent.

Hydroxide: Sodium hydroxide, caustic soda, sodium hydrate, "lye" (NaOH), white solid, soluble, melting point 318° C., an important strong alkali, not as cheap as **calcium** oxide (a strong alkali) nor sodium carbonate (a mild alkali), but of wide use. Formed (1) by reaction of sodium carbonate and calcium hydroxide in water, and then separation of the solution and evaporation, (2) by **electrolysis** of sodium chloride solution under the proper conditions, and evaporation. Commonly bought and sold in quantity on the basis of oxide (Na_2O) determined by analysis (77.5% Na_2O equivalent to 100.0% NaOH). Used (1) in the manufacture of soap, rayon, paper ("soda process"), (2) in petroleum and vegetable oil refining, (3) in the rubber industry, in the textile and tanning industries, (4) in the preparation of sodium salts, (a) in solution, (b) upon fusion.

Hypochlorite: Sodium **hypochlorite** (NaOCl), commonly in solution by (1) electrolysis of sodium chloride solution under proper conditions, (2) reaction of **calcium** hypochlorite suspension in water and sodium carbonate solution, and then filtering. Used (1) as a bleaching agent for textiles and paper pulp, (2) as a disinfectant, especially for water, (3) as an oxidizing reagent.

Hypophosphite: Sodium hypophosphite ($NaH_2PO_2 \cdot H_2O$), white solid, soluble, formed (1) by reaction of **hypophosphorous acid** and sodium carbonate solution, and then evaporating, (2) by reaction of sodium hydroxide solution and phosphorus on heating (poisonous phosphine gas evolved).

Hyposulfite: Sodium hyposulfite, sodium hydrosulfite (not sodium thiosulfate) ($Na_2S_2O_4$), white solid, soluble, formed by reaction of sodium hydrogen sulfite and **zinc** metal powder, and then precipitating sodium hyposulfite by sodium chloride in concentrated solution. Used as an important reducing agent in the textile industry, e.g., bleaching, color discharge.

Iodide: Sodium iodide (NaI), white solid, soluble, melting point 651° C., formed by reaction of sodium carbonate or hydroxide and **hydriodic acid,** and then evaporating. Used in photography, in medicine and as a source of iodide.

Manganate: Sodium manganate (Na_2MnO_4), green solid, soluble, permanent in alkali, formed by heating to high temperature **manganese** dioxide and sodium carbonate, and then extracting with water and evaporating the solution. The first step in the preparation of sodium permanganate from **pyrolusite.**

Nitrate: Sodium nitrate, nitrate of soda, Chile saltpeter, "caliche" ($NaNO_3$), white solid, soluble, melting point 308° C., source in nature is Chile, in the fixation of atmospheric **nitrogen** nitric acid is frequently transformed by sodium carbonate into sodium nitrate, and the solution evaporated. Used (1) as an important nitrogenous fertilizer, (2) as a source of nitrate and nitric acid, (3) in pyrotechnics, (4) in fluxes.

Nitroprusside: Sodium nitroprusside ($Na_2Fe(CN)_5NO \cdot 2H_2O$), red solid, soluble. Used in testing soluble sulfides.

Nitrite: Sodium nitrite ($NaNO_2$), yellowish-white solid, soluble, formed (1) by reaction of nitric oxide plus **nitrogen** dioxide and sodium carbonate or hydroxide, and then evaporating, (2) by heating sodium nitrate and **lead** to a high temperature, and then extracting the soluble portion (lead monoxide insoluble) with water and evaporating. Used as an important reagent (diazotizing) in organic chemistry.

Oleate: Sodium oleate ($NaC_{18}H_{33}O_2$), white solid, soluble, froth or foam upon shaking the water solution (soap), formed by reaction of sodium hydroxide and **oleic acid** (in alcoholic solution) and evaporating. Used as a source of oleate.

Oxalates: Sodium oxalate ($Na_2C_2O_4$), white solid, moderately soluble, formed (1) by reaction of sodium carbonate or hydroxide and **oxalic acid,** and then evaporating, (2) by heating sodium formate rapidly, with loss of hydrogen. Used as a source of oxalate; sodium hydrogen oxalate, sodium binoxalate, sodium acid oxalate ($NaHC_2O_4 \cdot H_2O$), white solid, moderately soluble.

Oxides: Sodium oxide, sodium monoxide (Na_2O), white solid, reactive with water to form sodium hydroxide, formed by reaction of sodium hydroxide or peroxide and the requisite amount of sodium metal upon heating; sodium peroxide (Na_2O_2), yellowish-white solid, soluble in water with some evolution of **oxygen** at 30–40° C., complete at 100° C. Reacts (1) as an oxidizing agent, e.g., nitric oxide converted to sodium nitrate, (2) as a reducing agent, e.g., salt solutions of silver or mercury converted to silver or mercury metal, and oxygen. Formed by heating sodium metal and dry air at 300° C. Used as an important bleaching and oxidizing agent for various materials, e.g., wool, straw, wood pulp, and as a source of oxygen.

Palmitate: Sodium palmitate ($NaC_{16}H_{31}O_2$), white solid, soluble, froth or foam upon shaking the water solution (soap), formed by reaction of sodium hydroxide and **palmitic acid** (in alcoholic solution) and evaporating. Used as a source of palmitate.

Perborate: Sodium perborate ($NaBO_3 \cdot 4H_2O$) white solid, soluble, stable in air, but in water solution loses oxygen, formed (1) by the **electrolysis** of sodium borate solution (in the presence of sodium carbonate), (2) by reaction of sodium borate solution, in the presence of sodium hydroxide and excess hydrogen peroxide.

Permanganate: Sodium permanganate, permanganate of soda ($NaMnO_4$), purple solid, soluble, formed by oxidation of acidified sodium manganate solution with chlorine, and then evaporating. Used (1) as disinfectant and bactericide, (2) in medicine.

Phenate: Sodium phenate, sodium phenoxide, sodium phenolate ($NaOC_6H_5$), white solid, soluble, formed by reaction of sodium hydroxide (not carbonate) solution and **phenol**, and then evaporating. Used in the preparation of sodium salicylate.

Phosphates: Trisodium phosphate, tribasic sodium phosphate ($Na_3PO_4 \cdot 12H_2O$), white solid, soluble, formed (1) by reaction of sodium hydroxide and the requisite amount of **phosphoric acid**, and then evaporating, (2) by reaction of disodium hydrogen phosphate plus sodium hydroxide, and then evaporating. Used (1) as a cleansing and laundering agent, (2) as a water softener, (3) in photography, (4) in tanning, (5) in the purification of sugar solutions; disodium hydrogen phosphate, dibasic sodium phosphate ($Na_2HPO_4 \cdot 12H_2O$), white solid, soluble, formed (1) by reaction of dicalcium hydrogen phosphate and sodium carbonate solution, and then evaporating the solution, (2) by reaction of sodium carbonate and the requisite amount of phosphoric acid, and then evaporating. Used (1) in weighting silk, (2) in dyeing and printing textiles, (3) in fireproofing wood, paper, fabrics, (4) in ceramic glazes, (5) in baking powders, (6) to prepare sodium pyrophosphate; sodium dihydrogen phosphate, monobasic sodium phosphate ($NaH_2PO_4 \cdot H_2O$), white solid, soluble, formed (1) by reaction of sodium carbonate and the requisite amount of phosphoric acid, and then evaporating, (2) by reaction of **calcium** monohydrogen phosphate and sodium carbonate solution, and then evaporating the solution. Used (1) in baking powders, (2) in medicine, (3) to prepare sodium metaphosphate; sodium pyrophosphate ($Na_4P_2O_7 \cdot 10H_2O$), white solid, soluble, melting point about 900° C., formed by heating disodium hydrogen phosphate to complete loss of water, followed by crystallization from water solution. Used (1) in electroanalysis; sodium metaphosphate ($NaPO_3$), white solid, soluble, melting point 617° C., formed by heating sodium dihydrogen phosphate or sodium ammonium phosphate to complete loss of water, is an easily fusible phosphate forming colored phosphates with many metallic oxides, e.g., **cobalt** oxide. The hexametaphosphate $(NaPO_3)_6$ is an important water-conditioning agent forming soluble complex compounds with many cations, e.g., Ca^{++}, Mg^{++}.

Phosphites: Disodium hydrogen phosphite ($Na_2HPO_3 \cdot 5H_2O$), white solid, soluble, formed by reaction of **phosphorous acid** and sodium carbonate, and then evaporating at a low temperature, melting point of anhydrous salt is 53° C., at higher temperatures yields sodium phosphate and **phosphine** gas; sodium dihydrogen phosphite ($NaH_2PO_3 \cdot 2\frac{1}{2}H_2O$), white solid, soluble, formed by reaction of phosphorous acid and sodium hydroxide cooled to −23° C. when the crystalline salt separates.

Salicylate: Sodium salicylate ($NaC_7H_5O_3$), white solid, soluble, formed by reaction of sodium phenate and **carbon dioxide** under pressure. Used as a source of salicylate and for **salicylic acid**.

Silicate: Sodium silicate, sodium metasilicate, "water glass" (Na_2SiO_3), colorless (when pure) glass, soluble, melting point 1088° C., formed by reaction of **silicon** oxide and sodium carbonate at high temperature; solution reacts with carbon dioxide of the air, or with sodium carbonate solution or **ammonium** chloride solution, yielding silicic acid, gelatinous precipitate. Sodium silicate solution is used (1) in soaps, (2) for preserving eggs, (3) for treating wood against decay, (4) for rendering cloth, paper, wood non-inflammable, (5) in dyeing and printing textiles, (6) as an adhesive (e.g., for paper boxes) and cement. Sold as granular, crystals, or 40° Baumé solution.

Silicoaluminate: (See aluminosilicate, above.)

Silicofluoride: (See fluosilicate, above.)

Stearate: Sodium stearate ($NaC_{18}H_{35}O_2$), white solid, soluble, froth or foam upon shaking the water solution (soap), formed by reaction of sodium hydroxide and **stearic acid** (in alcoholic solution) and evaporating. Used as a source of stearate.

Sulfates: Sodium sulfate (anhydrous), "salt cake" (Na_2SO_4), sodium sulfate, decahydrate, "Glauber's salt" $Na_2SO_4 \cdot 10H_2O$), white solid, soluble, formed by reaction of sodium chloride and **sulfuric acid** upon heating with evolution of hydrogen chloride gas. Used (1) in dyeing, (2) along with **carbon** in the manufacture of glass, (3) as a source of sulfate, (4) to prepare sodium sulfide; sodium hydrogen sulfate, sodium bisulfate, sodium acid sulfate, "nitre cake" ($NaHSO_4$), white solid, soluble, formed by reaction of sodium nitrate and sulfuric acid, upon heating, with evolution of nitric acid. Used (1) as a cheap substitute for sulfuric acid, (2) in dyeing, (3) as a flux in metallurgy; sodium pyrosulfate ($Na_2S_2O_7$), white solid, soluble, formed by heating sodium hydrogen sulfate to complete loss of water.

Sulfides: Sodium sulfide (Na_2S), yellowish to reddish solid, soluble, formed (1) by heating sodium sulfate and **carbon** to a high temperature. Used (1) as the cooking liquor reagent (along with sodium hydroxide) in the "sulfate" or "kraft" process of converting wood into **paper** pulp, (2) as a depilatory, (3) in sheep dips, (4) in photography, engraving and lithography, (5) in organic reactions, (6) as a source of sulfide, (7) as a reducing agent; sodium hydrogen sulfide, sodium bisulfide, sodium acid sulfide ($NaHS$), formed in solution by reaction of sodium hydroxide or carbonate solution and excess hydrogen sulfide.

Sulfites: Sodium sulfite (Na_2SO_3), white solid, soluble, dilute solution readily oxidized in air, but retarded by mannitol (**carbohydrates**), formed by reaction of sodium carbonate or hydroxide solution and the requisite amount of **sulfur** dioxide, at high temperature yields sodium sulfate and sodium sulfide. Used (1) as a source of sulfite, (2) as a reducing agent, (3) to prepare sodium thiosulfate, (4) as a food preservative, (5) as a photographic developer, (6) as a bleaching agent and antichlor in the textile industry; sodium hydrogen sulfite, sodium bisulfite, sodium acid sulfite ($NaHSO_3$), white solid, soluble, formed by reaction of sodium carbonate solution and excess sulfurous acid. Uses similar to those of sodium sulfite.

Tartrate: Sodium tartrate ($Na_2C_4H_4O_6 \cdot 2H_2O$), white solid, soluble, formed by reaction of sodium carbonate solution and **tartaric acid**. Used in medicine; sodium potassium tartrate, Rochelle salt ($NaKC_4H_4O_6 \cdot 4H_2O$), white solid, soluble. Used (1) in medicine, (2) as a source of tartrate.

Thiosulfate: Sodium thiosulfate, "Hypo" ($Na_2S_2O_3 \cdot 5H_2O$), white solid, soluble, formed by reaction of sodium sulfite and **sulfur** upon boiling, and then evaporating. Used (1) in photography as fixing agent to dissolve unchanged silver salt, (2) as a reducing agent and antichlor.

Tungstate: Sodium tungstate ($Na_2WO_4 \cdot 2H_2O$), white solid, soluble, by reaction of sodium hydroxide solution and **tungsten** trioxide upon boiling, and then evaporating. Used (1) in fireproofing fabrics, (2) as a source of tungsten for chemical reactions.

Uranate: Sodium uranate, **uranium** yellow (Na_2UO_4), yellow solid, insoluble, formed by reaction of soluble uranyl salt solution and excess sodium carbonate solution. Used (1) in the manufacture of yellowish-green fluorescent glass, (2) in ceramic enamels, (3) as a source of uranium for chemical reactions.

Vanadate: Sodium vanadate, sodium orthovanadate (Na_3VO_4), white solid, soluble, formed by fusion of **vanadium** pentoxide and sodium carbonate. Used (1) in inks, (2) in photography, (3) in dyeing of furs, (4) in inoculation of plant life.

All sodium-containing substances impart a characteristic yellow color to the bunsen flame. (R.K.S.)

SOFTENER, WATER. An apparatus devised to remove from water the dissolved salts producing hardness is known as a softener. Hardness of water is due to dissolved salts that make it difficult to obtain soapsuds in the water. Hardness of water is also indicative of the scale-forming quality of that water as a boiler feed. Consequently, in the power generation field, in the laundry trade, and in many industries making use of water in one way or another, raw water needs to be softened. Water softeners are of two types—precipitation and base exchange. There are several commercial types, but practically all are included in the following classification:

1. Precipitation softeners.
   a. Cold lime and soda.
      (1) Intermittent.
      (2) Continuous.
   b. Continuous hot lime and soda.
   c. Lime and barium (cold).
      (1) Intermittent.
      (2) Continuous.
   d. Lime and sodium aluminate.
2. Base exchange (artificial and natural zeolites).

A precipitation softener embodies the principle of using calculated quantities of soluble reagents to react with the hardness in raw water.

A base exchange softener removes the hardness by a simple filtration of the water through a bed of active material which exchanges its sodium base for the magnesium and calcium in the water. Natural and artificial zeolites are used as the active material. When its softening characteristics are nearly exhausted the zeolite is regenerated by backwashing it with a brine solution. The base exchange softener is simple and effective in that no proportioning of chemicals is required and practically zero hardness is obtained. Base exchange softening may give dangerously high alkalinity when the raw water itself contains large amounts of sodium bicarbonate in addition to calcium and magnesium salts. (F.T.M.)

SOIL. A complex sediment, exceedingly variable as to texture, inorganic and organic composition. Difficult to define except in terms of practical fertility or mode of origin. From the purely geologic point of view, soil is usually the relatively thin upper layer of the unconsolidated mantle of disintegrated and decomposed rock material or regolith which overlies the consolidated bedrock. The upper portion of the regolith is divided into topsoil and subsoil. The topsoil is usually a relatively thin zone of the more highly decomposed mineral constituents of the regolith and contains a varying proportion of organic material called humus. This soil zone is the habitat of the shallow rooted plants, such as most grasses and cereals. The topsoil usually passes gradationally into the subsoil which supplies some of the moisture and food for the deeply rooted plants and trees. The subsoil may or may not pass gradationally into the underlying bedrock. It is important to note that the topsoil is easily destroyed by erosion, when not protected by a mantle of vegetation. Classification of soils founded entirely on the origin of the regolith has been found to be impractical. Since the important topsoils are primarily the result of the interaction of rainfall, temperature and organisms with the regolith, the soil specialist recognizes over 7500 types of soils, irrespective of textural differences, and with particular reference to age and to the climatic and other physical conditions under which each soil has been developed. Soils are therefore usually classified as follows: 1. Young Soils. These usually show their relationship to the parent material and are typical flood plain and hilly land deposits, when the soil surfaces are constantly being replenished or disturbed. 2. Mature Soils. These usually cover relatively flat lands where there are good drainage conditions but relatively little erosion. The development of these soils has gone so far in some cases, particularly in semi-arid regions, that little relation is shown to the parent material and their nature has therefore been principally determined by climatic and organic factors. 3. Old Soils. These usually cover old flat surfaces which have not been disturbed by erosion or sedimentation for a long time. Such soils, due to the dominance of climatic factors in their formation, have lost many of their original characteristics and have, therefore, developed abnormal features. When soils are intensively cultivated their mineral and organic constituents are rapidly depleted and must be replenished by rotation of crops and the application of natural fertilizers. The method of allowing the land to remain fallow is now known to be inefficient. The complete removal of the vegetable cover, such as may result from over-grazing, deforestation, or dry farming, exposes the soil to rapid erosion and destruction. It has been estimated that already 35 million acres of good soil have already been destroyed in the United States, and that 225 million acres will soon be destroyed if immediate and adequate steps are not taken to conserve them. (R.M.F.)

SOLANINE. Alkaloids.

SOLAR CONSTANT. The rate at which the earth is receiving energy from the sun is known as the solar constant. Technically defined the solar constant is the quantity of **energy** that falls in unit time on a unit area placed perpendicular to the direction of the sun at the mean distance of the earth from the sun. It is usually expressed in units of **heat** energy and many hundreds of observations give a mean value of 1.938 **calories** per sq. cm. per min. Converted into more familiar units this amounts to 1.8 hp. falling upon each sq. meter of the earth, neglecting the effects of atmospheric absorption. If this solar energy had to be paid for at the extremely low rate of one cent per kilowatt hour, it would cost the earth about 478,000,000 dollars each second.

Observations of the solar constant are made by means of the **pyrheliometer** and, of necessity, must be made from the surface of the earth. Corrections must be made to all determinations to allow for variations in the distance of the earth from the sun, due to the **eccentricity** of the earth's **orbit**, and also for the effects of the earth's **atmosphere**. The Smithsonian Institution has established, under the direction of Dr. C. G. Abbot, a number of stations scattered over the northern and southern hemispheres, at which daily observations of the solar constant are made. The determination of the absorptive effects of the earth's atmosphere have been very carefully investigated in a number of painstaking researches.

The results of a long series of observations by Abbot and his associates have shown that the value of the solar contant fluctuates by several per cent. These fluctuations are correlated with the sun-spot number and the solar constant is 2 or 3% higher when the number of sun spots is at a maximum. This variation has been further studied by Pettit at Mount Wilson and he has found that the ratio of the amount of solar radiation in the violet to that in the green varies by as much as 50%, with the intensity of the ultra-violet being greatest at the time of sun-spot maximum. The effects of these variations on the general climate of the earth are under investigation. Some correlations have been definitely established but the whole problem is in too confused a state to warrant definite conclusions. (See **Sun Spots.**) (W.K.G.)

SOLAR MOTION. We know that the so-called fixed stars are actually moving in space and in many cases the **space velocity** has been determined. By 1783, the **proper motions** of thirteen stars had been determined and Sir William Herschel noticed that they seemed to have a preferential character. In the direction of the constellation of **Hercules** he noticed that the stars seemed

to be moving apart, while in the opposite direction they appeared to be closing in. He interpreted this phenomenon not as a characteristic of the sidereal system as a whole, but rather a perspective effect caused by the actual motion of the sun in the direction of the constellation of Hercules. During the next 50 years the proper motions of many more stars were determined, and in 1837 Argelander discussed the results statistically and confirmed Herschel's determination. With the rapidly increasing number of proper motion determinations during the past century, numerous statistical discussions of proper motions have been made and all have yielded the same conclusion.

With the application of the **Doppler-Fizeau principle** to the determination of the **radial velocities** of the stars a method for determining the solar motion independently from the proper motions became available. With increasing number of radial velocity determinations, it is found that stars in the general direction of the constellation of Hercules seemed to have a preferential motion toward the sun, while in the opposite part of the sky the preferential motion was one of recession.

Since all methods for the determination of solar motion are purely statistical in character, it must not be expected that results from different methods will agree exactly. The point toward which the sun is apparently moving is known as the solar apex, while the opposite point on the celestial sphere is known as the solar antapex. Results of statistical analysis of proper motions give the position of the solar apex as **right ascension** 18 hr. 03.1m and declination $+27°.0$; while an independent discussion from radial velocities yields 18 hr. 02.4m and $+29°.2$. The value of the velocity with which the sun is moving toward this point in the constellation of Hercules is 19.65 kilometers per sec. (12.3 miles per sec.).

Up to the present time there is no conclusive evidence other than that the sun is moving toward the solar apex in a straight line. Many attempts have been made to employ the solar motion for the determination of the distances of the stars. The complete discussion of the problem is far too complex for discussion here but the results which have been obtained, while not of great accuracy for individual stars, are, nevertheless, of great importance for statistical investigations in problems concerned with the discussions of the structure of the **galactic** system. (W.K.G.)

SOLAR PARALLAX. The mean distance of the earth from the sun is one of the most important constants in astronomical measurement. Known as the **astronomical unit**, it forms the standard of measurement throughout the **solar system**; it is also the base line for the determination of **stellar parallax**. To measure the distance from the earth to the sun directly is obviously impossible and some indirect method must be used. The most common method for the determination of this distance is to determine the angle subtended by an equatorial radius of the earth at the mean distance of the earth from the sun, and this angle is known as the solar parallax.

To measure the solar parallax directly is a very difficult problem for a variety of reasons: the sun is very large and very bright, and, furthermore, when the sun is visible there are no stars visible with reference to which the position of the sun can be measured. Even with these difficulties overcome there remains the smallness of the solar parallax (8″.80) which is practically impossible to determine directly with great accuracy.

The most common method for the determination of the solar parallax makes use of the fact that, from the **orbital elements** of planetary **orbits**, the distance of any of the planets from the sun at any instant can be accurately expressed in terms of the earth's mean distance from the sun as unity. Furthermore, a plane triangle may always be passed through the earth, sun, and any planet and the angles and sides of this triangle may be computed from the orbit, with distances expressed in terms of the astronomical unit. If any one of the sides of the triangle can be determined in terms of the earth's equatorial radius then the other two may be so expressed and one of these sides will be the distance of the earth from the sun. Hence the problem of determination of solar parallax reduces itself to the determination of the **geocentric parallax** of the planet. For increased accuracy in the determination of the parallax of the planet the object should be stellar in appearance, and should be as close as possible to the earth in order that it may have a large geocentric parallax. The **asteroid Eros** is well suited for this purpose and extensive campaigns for determinations of its geocentric parallax have been carried out at the close oppositions in 1900 and again in 1931. At the time of the close approach in 1931 Eros was only about 16,200,000 miles from the earth and hence the parallax was about 6 times as great as the solar parallax.

Several other indirect methods for the determination of the solar parallax have been devised, but the details of their methods are too complex to be included here. Prior to the discovery of Eros in 1898 the planets **Mercury** and **Venus** were used for the determination of solar parallax. The method of using these objects was to measure the time required for these planets to transit across the disk of the sun and expeditions were dispatched to all parts of the earth to observe this phenomenon.

By international agreement the value 8″.80 is used at present for computing the material for various almanacs and ephemerides. A careful investigation of a large number of observations is in progress and it is expected that a third decimal place will eventually be determined. (W.K.G.)

SOLAR RADIATION. The **radiation** from the sun comprises a very wide range of wavelengths from the long **infra-red** rays to the short **ultra-violet** rays, with a maximum intensity in the visible green at about 5000 **angstroms**. However, since the **air** strongly absorbs the wavelengths toward either end of the **spectrum**, the solar radiation received on the surface of the earth is confined, largely, to the visible and near infra-red regions, with a very small proportion of the ultra-violet. This is fortunate, for human beings and many other organisms could not endure the full range of solar radiation. The absorption of the ultra-violet radiation takes place largely in the higher stratosphere, where it probably contributes to the atmospheric ionization (see **Ionosphere**). The longer infra-red is absorbed mainly by dust and water vapor at lower levels, which accounts for the low temperature of the air at high altitudes.

The intensity, or radiant flux density, of the solar radiation is measured by means of various forms of **pyrheliometer** or solarimeter. Its value is known as the **solar constant** and averages about 1.34×10^6 ergs per sq. cm. per sec. The direct **illumination** from the sun approximates 6500 foot-candles. (L.D.W.)

SOLAR SYSTEM. That group of objects which are moving through space with the **sun** is known as the solar system. The following classes of objects are listed as members of the solar system, and the details regarding them as individuals will be found elsewhere: **planets**, **satellites**, **asteroids**, **comets**, **meteors**, and meteorites, and the zodiacal light and gegenschein. The **orbital** and physical data regarding various members of the system may be found tabulated on page 1370. In this article we shall confine ourselves to consideration of the system as a whole.

Examination of the tabular material will indicate several interesting correlations between the various orbital and dynamical factors in the solar system. The

mass is overwhelmingly concentrated in the sun, this parent member of the system having nearly 750 times as much mass as all of the rest of the members combined. The distribution of the **moment of momentum,** another important dynamical factor, is interesting in that the four major planets, **Jupiter, Saturn, Uranus,** and **Neptune,** have about 98% of the total for the whole system. With very few, but nevertheless important, exceptions, the members of the solar system rotate on their axes and revolve, either about the sun, or their primary in the case of satellites, in the same directional sense. Furthermore, the orbital planes of the great majority of the members lie within an inclination angle of 20° to the plane of the **ecliptic.** In so far as we have been able to determine the relative percentages of the various chemical elements which go to make up the various members, the compositions of the different objects bear a remarkable similarity to each other.

For centuries the belief has existed that the solar system is not merely an accidental arrangement of objects in space, but is rather the product of some process of evolution. The mere fact of the common direction of orbital motion of the more than 1300 planets and asteroids is in itself sufficient evidence against any chance arrangement. However, in spite of the labors of the large number of eminent scientists and philosophers, who have worked on the problem during the past three centuries, the origin of the solar system is by no means completely understood.

Since the sun is a typical **star,** which appears abnormally bright to us merely because of its relatively short distance from the earth, the theories regarding its evolution will be found in the material dealing with the stars. The earliest hypothesis, which is worthy of scientific recognition, is to be found in the writings of Thomas Wright, the theologian Swedenborg, and the philosopher Kant, during the 18th century. None of these gentlemen had much scientific training, with the result that their thories can be regarded as pure hypotheses which violate many of the fundamental principles of dynamics. In the middle of the 19th century the astronomer Laplace attempted to put these hypotheses on a scientific foundation and advanced the so-called Nebular Hypothesis.

In spite of the fact that the Laplacian nebular hypothesis has failed to stand the tests of rigorous analysis and even that Laplace himself gave evidence that he did not regard the theory very seriously, nevertheless, the theory has had such a large popular appeal that a few words regarding it will not be out of place. The theory presumes the existence in space of a large nebulous mass slowly rotating and slowly cooling and condensing. As the mass contracts the angular velocity will increase, since the moment of momentum must be conserved and, with the increase in angular velocity, the centrifugal force at the equator will increase until it becomes greater than the gravitational forces holding the mass together. At this point a ring of matter is split off from the equatorial region of the parent mass. The parent mass continues contracting and increases both the angular velocity and equatorial centrifugal force until another ring is split off. In this way successive rings of matter are produced, each surrounding the equatorial part of the central parent mass. These successive rings of matter split and condense into the major planets with, perhaps, their satellites then formed from the cooling masses in much the same way that the planets themselves were formed. Eventually, the central mass condenses to form the present sun. The common forward motion of all of the planets and their satellites, and the approximately coplanar features of the planetary orbits can all be explained on this theory and it was highly satisfactory to those who did not analyze the mathematics too critically. A careful analysis, however, proves conclusively that the rings thrown off from the primary would not condense into single planets, but would form swarms of small bodies, such as the **asteroids** or the rings of **Saturn.**

Other considerations regarding the distribution of angular momentum, etc., completely removed the Laplacian theory from the realm of possibility as an evolutionary process for the solar system. Nevertheless many modifications of the Laplacian theory were proposed during the latter part of the 19th century in the vain attempt to satisfy the dynamics of the observed solar system.

With the dawn of the present century a new idea regarding the birth of the solar system was advanced and the three present theories which are worthy of brief consideration are based upon this new conception. It is known that all of the stars are in motion through space relative to each other and more or less at random. From the observed velocities of the stars, their number, and the volume of space which they occupy, it may be calculated that a close approach, and possibly an actual collision is a probable occurrence during the long life history of the average star. The tidal friction theory of Jeans and Jeffries, and the planetesimal theory of Chamberlin and Moulton both assume the close approach of two stars, while the newer theory of Jeffries postulates a "side-swiping" collision. In either case, one of the stars, or what remains after the side-swiping collision, passes off in a hyperbolic orbit; but either the close approach or the collision will have caused the ejection of material from the star which we shall now refer to as the sun. Three different things may happen to this ejected material: much of it will fall back into the sun due to gravitational attraction, some of it will follow the other star out into space, and some of it will remain revolving about the sun. This latter material is the raw substance of which the planets are constructed.

The fundamental difference between the planetesimal theory and the tidal theory is concerned with what happens to the material ejected from the sun very shortly after it was left behind revolving about the sun. Chamberlin and Moulton in their planetesimal theory postulate that the material condensed and solidified relatively quickly into small objects known as planetesimals, while Jeans believes that the material gathered together in the large masses which now form the major planets. The planetesimal theory then postulates that the planets were formed by the gathering together of the small planetesimals about nuclei and the building up of the planets by a process of accretion. The tidal theory, on the other hand, assumes that the planets were formed by the condensation of large masses of hot diffused material. There are other differences in the theories regarding the distribution of the material about the sun immediately following the catastrophe, but these are too highly technical to be discussed here. The collision theory of Jeffries follows the tidal theory very closely, differing only in the method by which the material was ejected from the sun. None of the theories can be said to be perfect and a great deal of work remains to be done before any positive statement can be made. (W.K.G.)

SOLARIZATION. The term solarization was applied originally to the bronze appearance of the shadows produced on printing-out papers by great overexposure. The term is more generally employed today to describe a condition, resulting from extreme overexposure, which tends to destroy the developability of the image and cause the image to develop as a positive rather than a negative.

The effect varies with different emulsions and with most commercial emulsions requires an increase in exposure of several thousand times. The effect varies also with the time of development, tending to become less pronounced as the time of development is increased.

Solarization does not occur if the film or plate is bathed in a solution of potassium iodide, or a solvent

of silver halide, such as hypo, before development. The incorporation of reducing agents, such as p-hydroxyphenylglycin (glycin) in the emulsion diminishes solarization and in some cases prevents it entirely.

Emulsions which solarize readily can be used to produce non-reversed images (for example a positive from a positive). Such emulsions are prepared by pre-exposure to light, by including chemical fogging agents or the addition of a sensitizing dye and a suitable reducing agent. (C.B.N.)

SOLDER. **Brazing and Soldering.**

SOLDER FITTING. This type of fitting utilizes the phenomenon of capillary action for insuring penetration of molten solder to the entire contact surface. A solder fitting coupling is a sleeve that has a cylindrical bore with an inside shoulder against which the tube ends to be connected fit. Each half of the coupling has an annular groove or solder feed channel, with a solder feed hole entering the groove. The coupling is heated with a blow torch or gas torch, and solder wire is fed through the solder feed hole and melts as it comes into contact with the coupling. The liquefied solder is carried around the entire contact surface by capillary action. This type of fitting is extensively used for nonferrous pipe and tube connection, and is available in a wide variety of sizes, and in elbow, tee, cross, and coupling form. Valves and other accessories with solder fitting ends can also be obtained. (H.C.H.)

SOLDERING. Joining of metals by adhesion using a metallic bonding alloy. The bonding or soldering alloy has a relatively low melting point and is preferably present as a thin film between the parts to be joined. To obtain good adherence and strength most metals require surface preparation, usually through the application of a flux to remove oxides from the surface. Mechanical surface cleaning is also practiced, particularly in soldering lead, also for aluminum and its alloys whose surface oxide layer is very difficult to remove chemically.

The most common soldering alloys are those consisting of lead and tin, such as 50% lead–50% tin for general purpose work and 60% lead–40% tin for making wiped joints in lead sheet and pipe. A wide melting temperature range is required for this type of soldering. A 40% lead–60% tin composition has a narrower and lower melting temperature range than the higher lead varieties and may therefore be used for soldering tin and other low melting-point alloys. Bismuth is added to lead-tin alloys when further lowering of the melting point is required. (See **Lead and Tin Alloys.**)

Heat for melting the solder and warming the parts to be joined is usually applied by means of the familiar soldering "iron," which is a hand tool with a copper tip of appropriate shape. It is often preheated in a gas or other open flame, or may be continuously heated by an internal electrical heating element. A gas blow pipe or other source of heat may be applied directly to the work.

Solder is relatively soft and soldered joints have relatively low strength compared with **brazing** (sometimes called hard soldering) and **welding.** (R.H.H.)

SOLE. Pisces, Teleostei. A term applied to **flatfishes** of numerous species widely distributed in temperate and tropical seas. Some species ascend rivers. The term is properly applied to members of the group, ranked as a family or as a subfamily, of which the genus *Solea* is typical. Since many other flatfishes are edible, the sole of the inland fish markets is often not true sole. (A.W.L.)

SOLENIA. Tubes of endoderm that pass between the various **polyps** through the middle layer (mesoglea) of **alcyonarians.** (A.W.L.)

SOLENOCYTE. An excretory cell from which a **cilium** extends into the associated excretory tubule. These cells are superficially like the flame cells of **flatworms** but they are smaller and simpler. They occur in connection with the excretory organs of **annelid** worms and in Amphioxus of the lower chordates. (A.W.L.)

SOLENODON. Mammalia, Insectivora. An animal of about the size of a rabbit but with a long slender nose and a long naked tail. The claws are strong, those of the fore feet being much larger than those of the hind feet. The two species occur in the West Indies. (A.W.L.)

SOLENOID. This is an electrically energized coil which may consist of one or more layers of windings. It is the basis of all forms of the electromagnet and is thus part of the operating mechanism of many electrically operated devices. One of the simplest forms and at the same time a widely used one is the plunger type solenoid. This is a coil wound on a non-magnetic form in which a magnetic plunger may move. Energizing the coil pulls the plunger up into the coil and thus operates the associated mechanism. The iron clad solenoid is similar except for an iron case surrounding the coil. This increases the magnetic pull on the plunger. Other types use a fixed core and various types of external armatures. Solenoids are widely used for operating **circuit breakers,** track switches, valves, and many other electromechanical devices. (L.R.Q.)

SOLENOIDAL FIELDS IN THE ATMOSPHERE. **Circulation Principle.**

SOLENOIDAL VECTOR. If the **divergence** of a **vector function** of position vanishes everywhere in a certain region, the function is said to be a solenoidal vector in that region.

If a vector function **v** is the **curl** of a vector function **F**, then **v** is solenoidal. (L.L.S.)

SOLFATARA. **Fumarole.**

SOLID EXPANSION THERMOMETER. Many devices have employed the expansion of solid bodies as an indicator of temperature change. Wedgwood, a celebrated 18th-century potter, used small blocks of burned clay to estimate, by their expansion, the temperature of his kilns. Because of the low expansion coefficient, any such direct application of solids is necessarily very insensitive; on the other hand the requirement of durability favors their use in certain cases. One rather crude arrangement, sometimes used, is a long wire passing over pulleys, its length being sufficient to insure a measurable expansion.

More commonly, use is made of the warping produced by the differential expansion of two solid strips fastened together. The Breguet spiral is composed of two spiral strips, like watch springs, made of different metals and securely welded together throughout their length. A change in temperature causes the combination to coil or uncoil, a motion which, communicated through gears to a pointer-shaft, serves to give temperature readings on a dial. (L.D.W.)

SOLID OF REVOLUTION. A solid of revolution is a solid bounded by a **surface of revolution,** or by a surface of revolution and certain planes.

Suppose that the curve whose equation in **rectangular coordinates** is $y = f(x)$ is revolved about the X-axis, generating a surface of revolution. The volume of the solid bounded by this surface and the **planes** $x = a$ and $x = b$ is given by the **definite integral**

$$V = \pi \int_a^b y^2 dx.$$

If the curve whose equation is $x = F(y)$ in rectangular coordinates is revolved about the Y-axis, the volume of the solid bounded by this surface of revolution and the planes $y = c$ and $y = d$ is given by

$$V = \pi \int_c^d x^2 dy.$$

(L.L.S.)

SOLID SOLUTION. For the general meaning of this term, see **Solution** and **Metals and Alloys.** In geology, as defined by A. Holmes this term is applied to compounds which form minerals and is: a crystalline and homogeneous solid, representing a mixture of two or more substances, sometimes composed of isomorphous compounds. The proportions of the mixture may vary within certain critical limits without destroying the homogeneity of the solid solution. Most of the common **silicate** minerals which form the **igneous rocks**, such as the **feldspars, amphiboles** and **pyroxenes**, are complex, solid solutions. (Compare with **Isomorphous.**) (R.M.F.)

SOLIDS. **States of Matter; Statics; Kinetics, Elasticity.**

SOLITAIRE. Aves. 1. Passeriformes. A bird (**Aves**) found in the western mountains from the Black Hills to British Columbia and south into Lower California. It is related to the thrushes and is known for its beautiful song. The full name of this species is Townsend solitaire, *Myadestes townsendi.* 2. Columbiformes. A giant flightless pigeon, *Pezophaps solitarius,* of Rodriguez Island, extinct since the late 18th century. Related to the **dodo.** (A.W.L.)

SOLPUGIDA. The sun **spiders**, a small order of rare arachnids found chiefly in warm and arid regions. The few North American species have been recorded from Florida and from the region between Kansas, Oregon, and the Rio Grande. Although their appearance is rather formidable they are harmless creatures, nocturnal in habits and very shy. (A.W.L.)

SOLUBILITY. **Solutions and Solubility.**

SOLUTIONS AND SOLUBILITY. Solutions are conveniently classified thus:

1. True Solutions
   - *a.* Ordinary . . Sugar (sucrose) in water, ethyl alcohol in water.
   - *b.* Non-ordinary . **Sodium** chloride in water, sodium hydroxide in water, **hydrochloric acid** in water. Salts, acids, bases.
2. Pseudo-solutions (colloidal) Starch emulsion
   Silicic acid gel
   Casein in milk
   Soap in water

Pseudo-solutions are discussed in the article on **Colloidal State.**

It is to be noted that salts, acids, bases are classified as non-ordinary, although commonly encountered, for the reason that such substances in solution are dissociated into two kinds of entities, positively and negatively charged ions. (See **Reactions Involving Recombination of Ions; Reactions Involving Water; Chemical Changes; Reactions Involving Oxidation-Reduction; Electrochemistry.**) A solution consists of one substance (the solute) dispersed in another substance (the **solvent**) in such a fine degree of comminution that the product is homogeneous, has a greater or less range of concentration of solute, is optically void. Pseudo-solutions differ from true solutions in not being optically void when examined in the ultra-microscope, and suspensions differ from both of these in not being optically void when examined by the naked eye or ordinary microscope. Particles in suspension may be separated from a liquid medium by the mechanical processes of filtration or of sedimentation and decantation.

Solute may be gas, liquid or solid, and solvent liquid or solid. Where there exists a solubility range between solids, that is, there is a series of concentrations of two or more solids, the substances are described as forming a solid solution, as for example in the following systems, namely, (1) **silver-gold,** (2) **cobalt-nickel,** (3) **antimony-bismuth,** (4) **magnesium** sulfate heptahydrate-**zinc** sulfate heptahydrate, (5) **iodine-benzene** crystals. Most solutions exist in the liquid state, and water is the most common solvent encountered. (See **Water; Solvents**).

The solubility of substances is expressed in various units (see **Concentration**). Some illustrative examples of the extent of solubility with various solute-solvent systems and resulting generalizations follow.

Saturated Solutions. The maximum amount of solute dissolvable in a given amount of a stated solvent, under definite conditions of temperature and pressure (pressure is important when dealing with gases, otherwise the effect of pressure is minor) and *in the presence of excess* of the solute, is the solubility of the solute in that solvent. The resulting solution is a saturated solution. (See **Concentration.**)

Unsaturated and Supersaturated Solutions. When less than the saturation concentration of solute is present in a solvent, the solution is unsaturated. When more than the saturation concentration of solute is present in a solvent, the solution is supersaturated. The latter condition is brought about in the case of solids by lowering the temperature of a sufficiently concentrated solution in the absence of solute as such, of dust, of mechanical shock, and of nuclei for **crystallization. Sodium** thiosulfate ($Na_2S_2O_3 \cdot 5H_2O$) is a favored substance for producing supersaturated solution, but many other substances exhibit the phenomenon, e.g., sugar solutions, **calcium** gluconate and many organic compounds. In the case of gases dissolved in liquids, supersaturation may be present upon raising the temperature in the absence of rough solid surfaces, of gases, and of agitation. Water saturated with air at 7° C. is reported as having been kept in this way at 18° C. for 6 days.

Physical Properties of Solutions. Certain physical properties of solutions are of predominant importance. Among these are:

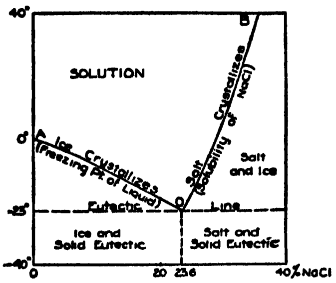
1. The change of **vapor pressure** of a liquid solvent by addition of solute. The vapor pressure is lowered 170 mm. per 1 gram mol of solute in 1000 grams of water for "ordinary solutions," and up to values of about 2 or 3 times this amount for "non-ordinary solutions." For solvents other than water a characteristic value for each is observed.

2. The change of **boiling point** of a solution with the thermometer bulb in the *solution.* The boiling point is raised 0.52° C. per 1 gram mol of solute in 1000 grams of water for "ordinary solutions," and up to values of about 2 or 3 times this amount for "non-ordinary solutions." For solvents other than water a characteristic value for each is observed.

3. The change of **freezing point** of a solution—with the thermometer bulb in the *solution.* The freezing point is lowered 1.85° C. per 1 gram mol of solute in 1000 grams of water for "ordinary solutions," and up to values of about 2 or 3 times this amount for "non-ordinary solutions." For solvents other than water a characteristic value for each is observed.

These three observations were contributed by Raoult (1878).

4. The **osmotic pressure** of a dilute solution (0.5 molar or less). The osmotic pressure at a concentration of 0.1 mol of solute in 1000 grams of water at 0° C. is 2.2 atmospheres, and also proportional to the absolute temperature at constant concentration. This,



Solubility and freezing point diagram of sodium chloride-water mixtures.

as was pointed out by van't Hoff (1885), is not only analogous to but identical with the behavior of gases:

Equation which expresses the behavior of gases (the more "perfect" the gas, the more exact is the relation): $\frac{PV}{T} = R$ where P equals pressure, V volume, T absolute temperature, R constant.

Equation which expresses the behavior of solutes in dilute solutions: $\frac{P}{TC} = R$ where P equals osmotic pressure, C concentration of solution, T absolute temperature, R constant.

Solubility of a Substance in the Presence of Two Immiscible Liquids. Distribution or partition of a third substance between two immiscible liquids is illustrated by the following data for several concentrations in each case. The ratio of concentration of the third substance in each of the two layers is practically constant over a wide range of concentrations.

FORMIC ACID, DISTRIBUTION (13–15° C.) IN

Water Layer	Benzene Layer
1.016 g. HCOOH per 25 ml.	0.016 g. HCOOH per 150 ml.
1.539	0.023
2.112	0.031
3.826	0.062
7.83	0.138

PHENOL, DISTRIBUTION (20° C.) IN

Water Layer	Benzene Layer
0.945 g. phenol per liter	2.073 g. phenol per liter
0.711	1.553
0.475	1.036
0.238	0.518

ANILINE, DISTRIBUTION (25° C.) IN

Water Layer	Benzene Layer
0.0135 g. per 100 ml.	0.1312 g. per 100 ml.
0.0122	0.1282
0.0065	0.0656

OXALIC ACID, DISTRIBUTION (20° C.) IN

Water Layer	Benzene Layer
0.306 g. $(COOH)_2$ per 100 ml.	0.0653 g. $(COOH)_2$ per 100 ml.
1.064	0.326
3.015	1.148
4.511	1.934

(R.K.S.)

SOLUBILITIES OF REPRESENTATIVE GASES

Solute (Gas)	Solvent (Liquid)	Temperature ° C.	Pressure Atmospheres	Solubility ml. of gas (at 0° C., 760 mm.) in 100 ml. solvent, when the pressure of the gas itself is 760 mm. (with exceptions noted)
Ammonia	Water	0	1	105,000
Hydrogen chloride	Water	0	1	50,000
Sulfur dioxide	Water	0	1	8,000
	Water	20	1	4,000
	Water	40	1	1,900
Hydrogen sulfide	Water	0	1	467
	Water	20	1	258
	Water	40	1	166
Chlorine	Water	20	1	226
Carbon dioxide	Water	0	1	171
	Water	20	1	88

	Acetone (50%)	18	1	1.2 grams per liter solution

SOLUBILITIES OF REPRESENTATIVE GASES

Solute (Gas)	Solvent (Liquid)	Temperature °C.	Pressure Atmospheres	Solubility ml. of gas (at 0° C., 760 mm.) in 100 ml. solvent, when the pressure of the gas itself is 760 mm. (with exceptions noted)
Ethylene	Water	0	1	23
	Water	20	1	12
	Alcohol	0	1	360 vol. per 100 vol. alcohol
	Alcohol	20	1	270 vol. per 100 vol. alcohol
Nitric oxide	Water	0	1	7.4
Methane	Water	0	1	5.5
Oxygen	Water	0	1	4.9
	Water	20	1	3.1
	Water	40	1	2.3
Carbon monoxide	Water	0	1	3.5
	Water	20	1	2.3
	Water	40	1	1.8
Nitrogen	Water	0	1	2.4
	Water	20	1	1.5
	Water	40	1	1.2
Hydrogen	Water	0	1	2.1
	Water	20	1	1.8
	Water	40	1	1.6

At a constant temperature, the solubility of a given gas in a given solvent is proportional to the pressure, if the gas is of moderate to low solubility (Henry).

In a mixture of gases, the solubility of each gas is determined by its partial pressure (Dalton).

The solubility of gases decreases with increase of temperature. Most gases are expelled gradually but completely from the solvent upon boiling, or by bubbling an inert gas through the solution, or when allowed to remain exposed to the atmosphere. **Hydrogen chloride** is an exception. Boiling hydrochloric acid of any strength gives ultimately a distillate of boiling point 108.58° C. at 760 mm. pressure and of 20.24 percent HCl. At other pressures the boiling point and concentration are different but definite.

SOLUBILITIES OF REPRESENTATIVE LIQUIDS

Solute or Solvent (Liquid)	Solvent or Solute (Liquid)	Temperature °C.	Solubility
Alcohol	Water		Miscible in all proportions
Benzene	Water	3	0.030
		23	0.061 g. H_2O per 100 g.
		40	0.114
	Carbon tetrachloride	0	85.3 g. C_6H_6 per 100 g. solution
		5.5	Miscible
	Chloroform	0	88 g. C_6H_6 per 100 g. solution
		5	Miscible
	Ethyl alcohol	0	85 g. C_6H_6 per 100 g. solution
		5.5	Miscible
	Phenol	0	78.3 g. C_6H_6 per 100 g. solution
		5.1	Miscible
Aniline	Water	30	3.7 g. $C_6H_5NH_2$ per 100 g. water layer
			5.4 g. H_2O per 100 g. aniline layer
		90	6.4 g. $C_6H_5NH_2$ per 100 g. water layer
			9.9 g. H_2O per 100 g. aniline layer
		150	17 g. $C_6H_5NH_2$ per 100 g. water layer
			24 g. H_2O per 100 g. aniline layer
		168	Miscible
	Ethyl alcohol		Miscible
Phenol	Water	20	8.3 g. C_6H_5OH per 100 g. water layer
			27.9 g. H_2O per 100 g. phenol layer
		50	12 g. C_6H_5OH per 100 g. water layer
			37.3 g. H_2O per 100 g. phenol layer
		68.3	Miscible
	Ethyl alcohol		Miscible
Carbon tetrachloride	Water	20	0.08 g. CCl_4 per 100 g. water

		20	3.2 g. phosphorus per 100 g. benzene
		40	5 8

Increase in temperature generally increases the solubility of a solid in a liquid. Loss of liquid solvent by evaporation at ordinary or elevated temperatures, from a given solution of solid generally results in the recovery of the pure solid as crystals, except when supersaturation occurs.

SOLUTION OF ALGEBRAIC EQUATIONS BY FACTORING. If an equation is in the form of a polynomial in one unknown equated to zero, it may frequently be solved by factoring the polynomial and using the principle: if a product of two or more factors is zero, either one or more of its factors must be zero. (L.L.S.)

SOLUTION OF EQUATIONS. The process of finding the particular values of the unknown for which the two expressions of an equality have identical numerical values is called the solution of the equation.

The process of solution of an equation is therefore the operation of finding the **roots** of the equation.

The term "solution of an equation" is also sometimes used to mean the same thing as the roots of the equation. (L.L.S.)

SOLUTIONS OF A DIFFERENTIAL EQUATION. Ordinary Differential Equations.

SOLUTRIAN. **Paleontology of Man.**

SOLVAY PROCESS. Ammonia-soda process for making **sodium** carbonate. (R.K.S.)

SOLVENTS. The most common solvent is water. Water dissolves a great many gases, liquids, and solids, and is much used for this purpose. (See **Solutions; Water.**) Other liquids similarly dissolve many substances without reacting chemically with them. Important considerations in connection with the choice of solvent for a given case are (1) **vapor pressure** and **boiling point,** (2) solvent power under stated conditions of temperature, (3) ease and completeness of recoverability by **evaporation** and **condensation,** and completeness of separation from dissolved material by evaporation, (4) **heat of vaporization,** (5) miscibility with water or other liquid, if present, (6) inertness to chemical reaction with the materials present, and with the apparatus, (7) inflammability and explosiveness, (8) odor and toxicity, (9) cost of solvent, loss in process, cost of recovering.

Many classes of substances are available as solvents. It is convenient to classify these in the following manner:

1. **Water**
    - Various water solutions, e.g., sucrose, glycerol, ethyl alcohol, zinc chloride, zinc bromide, stannous chloride, ammonio-cupric hydroxide, sulfuric acid concentrated.
2. **Hydrocarbons**
    - Petroleum fractions
        - Petroleum ether
        - Ligroin
        - Higher boiling fractions
        - Normal-heptane
    - Terpenes
        - Turpentine
    - Benzenoid
        - Benzene
        - Toluene
        - Xylenes
        - Mesitylene
        - Cumene
        - Cymene
    - Tetrahydronaphthalene
    - Decahydronaphthalene
3. **Alcohols**
    - Methyl alcohol
    - Ethyl alcohol
    - Normal-propyl alcohol
    - Iso-propyl alcohol
    - Normal-butyl alcohol
    - Amyl alcohol
    - Normal-hexanol
    - Cyclo-hexanol
    - Ethylene glycol
    - Propylene glycol
    - Diethylene glycol
    - Glycerol
4. **Phenols**
    - Phenol
    - Cresols
5. Ethers (See **Alcohols and Ethers**)
    - Dimethyl ether
    - Diethyl ether
    - Dipropyl ether
    - Di-iso-propyl ether
    - Di-normal-butyl ether
    - Ethylene glycol monomethyl ether
    - Ethylene glycol monoethyl ether
    - Diethylene glycol monomethyl ether
    - Diethylene glycol monoethyl ether
    - Ethylene oxide
    - Propylene oxide
    - **1,4-Diethylene oxide**
6. **Aldehydes**
    - Normal-butyl aldehyde
    - Crotonaldehyde
7. Ketones (See **Aldehydes and Ketones**)
    - Acetone
    - Methyl ethyl ketone
    - Methyl iso-butyl ketone
    - Furfural
8. Carboxylic acids (See **Acids, Carboxylic**)
    - Acetic acid
9. **Esters**
    - Methyl acetate
    - Ethyl acetate
    - Iso-propyl acetate
    - Normal-butyl acetate
10. Chloro-organic compounds (See **Chlorine**)
    - Ethyl chloride
    - Chloroform
    - Carbon tetrachloride
    - Ethylene dichloride
    - Trichloroethylene
    - Propylene dichloride
    - 1,1,2-Trichloroethane
    - Tetrachloroethylene
    - Monochlorobenzene
    - Acetylene tetrachloride
    - Ortho-dichlorobenzene
    - Trichlorobenzene
    - Epichlorohydrin
11. Bromo-organic compounds (See **Bromine**)
    - Methyl bromide
    - Ethyl bromide
    - Bromoform
    - Ethylene dibromide
    - Ethylene chlorobromide
    - Ortho-dibromobenzene
12. Nitrogen organic compounds (See **Nitrogen**)
    - Pyridine
    - Aniline
    - Monoethanolamine
        (2-hydroxyethylamine)
    - Diethanolamine
        (di-2-hydroxyethylamine)
    - Triethanolamine
        (tri-2-hydroxyethylamine)
    - Acetamide
    - Tetralkyl ammonium compounds
13. Sulfur organic compounds (See **Sulfur**)
    - Carbon disulfide
    - Thiophene
14. Liquefied gases
    - **Ammonia**
    - **Sulfur dioxide**
    - **Hydrogen sulfide**
    - **Hydrogen chloride**
    - **Hydrogen bromide**
    - **Cyanogen**
    - **Nitrogen** tetroxide
15. Inorganic liquids
    - **Sulfur** monochloride
    - **Phosphorus** trichloride
    - **Phosphorus** tribromide
    - **Phosphorus** oxychloride
    - **Arsenious** chloride
    - **Hydrogen cyanide**

The data available on the subject of solvents is large in amount, but far from complete. The applications are many and growing rapidly. Illustrative selections must necessarily be very limited.

1. **Sulfur, iodine,** yellow **phosphorus** (red phosphorus insoluble) are dissolved by **carbon** disulfide, and, upon evaporation of the solvent at room temperature, these solids remain as a residue.

SOLUBILITY OF VARIOUS SUBSTANCES IN CARBON DISULFIDE

Substance	Temperature, °C.	Grams Substance per 100 Grams Carbon Disulfide
Sulfur	0	22.0
	20	41.8
	40	100.0
Iodine	0	7.9
	20	14.6
	40	25.2
Phosphorus	0	81.3
	10	89.8

2. Sulfur is dissolved by carbon disulfide, **carbon** tetrachloride, **chloroform, benzene, toluene, aniline, phenol,** and many other solvents.

SOLUBILITY OF SULFUR IN VARIOUS SOLVENTS

Solvent	Temperature, °C.	Grams Sulfur per 100 Grams Solvent
Aniline	130	85.3
Benzene	15	1.5
Carbon disulfide	20	41.8
Carbon tetrachloride	25	0.86
Chloroform	19	0.92
Ethylene dichloride	25	0.84
Phenol	174	16.4
Toluene	23	1.48
Trichloroethylene	25	1.63

3. Laszczynski (1894) reported the solubility of about 15 inorganic salts in 7 organic solvents. The following data are illustrative:

Salt	Solvent	Grams Salt per 100 Grams Solvent at Room Temperature
Mercuric chloride ($HgCl_2$)	Ether	6.4
	Ethyl acetate	30.0
	Acetone	126
Stannous chloride ($SnCl_2\ 2H_2O$)	Ether	11.4
	Ethyl acetate (77° C.)	73.3
Potassium thiocyanate (KCNS)	Pyridine	6.1
	Acetone	20.7
Silver iodide (AgI)	Pyridine (115° C.)	8.6

4. In some cases, the solvent, upon evaporation, forms a residue containing solvent of crystallization, e.g., **calcium** chloride tetramethyl alcohol ($CaCl_2 \cdot 4CH_3OH$) below 55° C., calcium chloride triethyl alcohol ($CaCl_2 \cdot 3C_2H_5OH$) above 55° C.

5. The application of solvents is not confined to the solution of solids, but includes also gases and liquids. Nor is it strictly limited to cases where true solutions result, but includes pseudo-solutions, that is, suspensions and emulsions.

6. Common solvents used in pharmacy are water (liquors, aquae, solutions), **ethyl alcohol** plus water (spirits, tinctures, extracts, essences), **sucrose** plus water (syrups), **glycerol** with or without water (glycerites). In the extraction of oils and fats from materials such as seeds, and in dry cleaning of fabrics, such solvents as **carbon** disulfide, carbon tetrachloride, trichloroethylene, **benzene,** ligroin are used. In paints, varnishes and lacquers, **turpentine** is commonly used, also tetrahydronaphthalene, and benzene. Several of the ethers are used in the preparation of **cellulose** nitrate and cellulose acetate lacquers and dopes. In the **explosives** industry, acetone is used, and in certain cases ethyl alcohol-ether mixture.

In general, substances of similar chemical constitution dissolve each other, e.g., hydrocarbons dissolve hydrocarbons. By the use of two or more mutually miscible solvents the field of application is greatly extended.

7. Chloro-organic compounds are among the more chemically inert solvents.

8. In the petroleum industry, solvents serve to extract certain portions of the raw material in the process of refining. Liquid sulfur dioxide may be used for differential solution. Liquid propane is also used.

9. Solvent recovery is usually accomplished by evaporation and condensation, but adsorption by such materials as silica-gel is also utilized. (R.K.S.)

SOMITE. One of the longitudinal series of segments into which the bodies of many animals are divided. These segments are clearly shown in a simple form in the **earthworms.** In man they are made evident by the structure of the spinal column and the series of spinal nerves, but they are overshadowed externally by the high development of the appendages. The term is synonymous with metamere.

The segmental masses of mesoderm in the vertebrate embryo are also called somites. They are the primordia of the axial skeleton, voluntary muscles of the body and appendages, and the inner layer of the skin. (A.W.L.)

SONOMETER. **Musical Sounds.**

SONSTADT SOLUTION. **Thoulet Solution.**

SORGHUM. *Andropogon Sorghum.* Gramineae. Sorghums are annual grasses of tropical origin. They have an extensive system of wiry roots and solid stems 3–15′ tall. The leaves are smaller than those of corn, and capable of rolling up tightly during periods of drought, and quickly unrolling and starting to function when favorable moisture conditions return. Because of this habit sorghums are often grown in regions subject to frequent drought. The **inflorescence** is a **panicle** usually of very compact habit. Ordinarily the **spikelets** are paired, one of the pair being sessile or stemless, the other having a short stem or pedicel. The former is fertile, the latter staminate (see **Stamen**). The grains are enclosed in the glumes and vary considerably in shape in different varieties. There are two main groups of sorghums; the sweet or saccharine sorghums, the juicy pitch of which is a source of syrup; and the grain sorghums, which yield grain, stock food and ensilage. Kaffir is one of the latter group. In Asia grain sorghums are employed in a countless variety of ways, as for fuel, brooms, mats, fences, windbreaks, roof thatch, and in making a fermented drink. (R.M.W.)

SORUS. **Ferns.**

SOUND. Physically, sound is a longitudinal elastic wave motion propagated by alternate compressions and rarefactions of the medium, usually air. If air is compressed by the sudden movement of some object, as a piece of cardboard, its elasticity causes it to expand and compress the air ahead of it. This generates a wave, in which each molecule of the medium oscillates forward and backward. An excellent analogy is the propagation of a bump or a jerk from the engine at one end of a freight train to the caboose at the other.

There are thermodynamic aspects of the propagation of sound, which in the earlier study of the theory were overlooked. The heating and cooling effects of compression and expansion are not negligible; in deriving the following expression for the speed of propagation of

sound, it is assumed that they are **adiabatic processes.** The formula commonly used for gases is

$$v = \sqrt{\frac{\gamma p}{\rho}}.$$

In this equation p is the pressure of the gas in absolute units and ρ is its density, γ is the ratio of the specific heat at constant pressure to the specific heat at constant volume. Thus, for air at normal temperature and pressure $p = 1{,}013{,}250$ dynes per sq. cm. (1 atmosphere), $\rho = 1.293 \times 10^{-3}$ grams per cc., and $\gamma = 1.408$. This gives $v = 33{,}220$ cm. per sec., which is quite near the measured value. For room temperatures the speed is greater (about 34,400 cm. per sec.), since the density ρ is less.

Modern research in **acoustics** has been greatly aided by the instantaneous photography of sound waves, or rather, of their refraction patterns, cast like shadows upon a photographic plate, by the light from an electric spark. In this way the progress of the wave and its reflection, refraction, and diffraction are permanently preserved for study and measurement. **Sound recording** is also much utilized in the analysis of **musical sounds.**

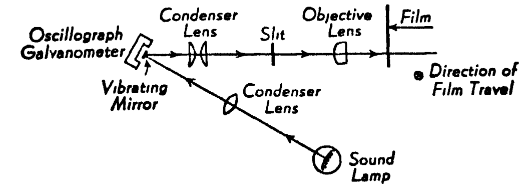
The mechanism of the ear and of hearing is but imperfectly understood. In some way the sound vibrations reaching the inner ear stimulate the auditory nerves; but the extreme sensitiveness and delicacy of discrimination possessed by the ear are hard to explain. It has been shown that our ability to locate the direction from which a sound comes is due to the slight difference in time at which the waves reach the two ears. (L.D.W.)

SOUND FILM. Attempts to synchronize a phonograph with the motion picture **projector** to produce a talking picture are nearly as old as the motion picture itself. For a long time little progress was made but by 1925 developments in telephony and radio had enabled engineers to overcome the difficulties which earlier inventors had encountered and a few years later the talking picture made its appearance the sound being recorded on a wax disk and reproduced in synchronism with the projected picture. This method of recording sound, however, was soon discarded in favor of a sound record on film.

To record sound on film, it is necessary to convert sound waves into variations in exposure on the film. To do this, the sound waves are first picked up from the air by a microphone. In the microphone the vibrations of the diaphragm result in variations in the current passing through the electrical circuit of which the microphone is a part. This current is amplified by means of vacuum tubes and, through a light-valve or galvanometer, varies or modulates the light reaching the constantly moving film in such a way that either the amount of exposure or the area exposed varies directly with the variations of the current. When the amount of exposure is varied, the sound vibrations are recorded on the film as differences in density (variable density record); in variable width records the sound vibrations are represented by differences in the width of the exposed area on the film.

The light valve referred to in the preceding paragraph consists of a loop of duraluminium tape suspended in a plane at right angles to a magnetic field. When the assembly of magnet and armature is complete, the two sides of the loop constitute a narrow slit, the sides of which lie in a plane at right angles to the lines of force and centered in the air gap. The ends of the loop are connected to the output terminals of the amplifier so that, with the magnet energized, the loop opens and closes in accordance with the variations in the intensity of the current. In the recording machine, the light valve is placed between a constant light source and the moving film so that it functions as a shutter which opens and closes thus varying the exposure in accordance with the alterations in the current from the microphones on the set.

In variable width recording the modulated current produced by the sound vibrations on the microphone is carried to a sensitive oscillograph. This oscillograph galvanometer (see figure) consists of a fine wire loop



through which the amplified microphone current circulates. A small mirror is cemented to this loop and the loop suspended in a magnetic field. A high-intensity lamp, similar to the ordinary automobile headlight lamp, furnishes the illumination for making the photographic record. Light from this lamp passes through a condenser lens and is focused on the galvanometer mirror, from which it is reflected through another condenser lens to a slit. The resulting slit of light passes through a projector lens which images it on the film. With current flowing through the galvanometer, the wire loop is set into vibration, carrying the mirror with it, and tracing a line of light the width of the slit across the sound track of the film. The result is a sound record of constant density but variable width.

The usual practice is to record the picture and sound on separate films, the camera and recorder being driven by synchronous motors. This enables the cameras to be moved about more freely and permits two or three cameras to shoot the same scene at different angles, all in perfect synchronism with the sound record. There is also the added advantage in being able to use different types of film for each record and to adjust the processing of each record to secure the best results. The films sent to the exhibitor, of course, have the sound record printed in on one side of the pictures.

The complete installation for the projection of talking pictures consists of (1) the projector with its reproducing units for translating the sound record into electric currents, the variations of which correspond exactly to the sound waves recorded, (2) the amplifying equipment by means of which these tiny currents are greatly increased, and (3) the reproducers and horns which convert these currents into the sound one hears from behind the screen.

Sound film is run through a projector which differs from the usual type only in the introduction of the sound-reproducing unit. This is located between the head mechanism of the projector and the lower magazine.

Since the sound-reproducing unit is separated from the picture gate by several inches, it is evident that the sound record cannot be printed directly beside the picture to which it applies. Accordingly the sound record is placed *below* the picture record and a certain amount of slack is allowed between the sprocket which carries the picture record with an *intermittent* motion past the projection lens and the sprockets which carry the sound record *continuously* past the sound-reproducing unit.

In the sound-reproducing unit, light of high intensity is concentrated by an optical system which focuses it in a fine line across the sound track on the film as it passes the aperture. On the other side of the aperture is a photoelectric cell which produces a small electric current the variations of which correspond to the modulated light which reaches it through the film. Thus there is produced an electrical current the variations of which are identical with that which, coming from the microphone on the set, made the sound record on the film. The current produced by the photoelectric cell is strengthened

first by a small vacuum-tube amplifier built into the sound-reproducing unit and then by a larger and more powerful amplifying unit. The current, now many times stronger than at first, operates the loud-speakers placed behind the screen. (C.B.N.)

SOUND IN THE ATMOSPHERE. At times sound travels with great clarity and intensity for considerable distances, but at other times its character is lost in a comparatively short distance. One reason for this lies in the fact that sound travels with greater velocity in warm air than in cold air. If there exists a layer of relatively cold air near the ground above which there is a much warmer layer, the sound wave will be held to a large extent in the cold layer by the downward bending of the sound waves as they attempt to penetrate the warm layer. On the other hand, if the warmer air lies next to the ground and the air progressively becomes colder with altitude, the sound waves will be carried readily aloft. Surface and near-surface inversions favor the propagation of sounds for great distances along the earth's surface by continual refraction from the inversion surface and reflection from the ground or water surface. As sound waves are propagated by the actual motion of air particles, turbulence and strong winds tend to distort and dissipate them. Still cold nights or mornings are, in general, excellent sound propagation periods as opposed to warm windy afternoons. (P.E.K.)

SOUND PRODUCTION. The incidental production of sound waves in air or similar vibrations in the water by the movements of living things is so common that a sense of hearing serves animals as a valuable means of detecting the presence of enemies, prey, or members of their own species. Together with this sense, the ability to produce sound voluntarily serves many uses, as we know from our own experience. In some cases the act involves only the special use of common organs, as when the beaver slaps the water with his broad tail in a warning signal. Sound production immediately brings to mind, however, organs such as the human larynx with its great range of activity and other organs specially developed for sound production.

Among the vertebrates the production of sound is very commonly associated with the respiratory system, since the air-breathing forms have an opportunity to vibrate special structures by controlled currents of air expelled from the lungs. In the birds the apparatus is the syrinx, located at the inner end of the trachea, and in mammals it is the larynx, near the outer end of the same passage. The frog (Class **Amphibia**) also has a larynx with vocal cords in its very short trachea. Vocal cords are lacking in the reptiles, although some of these animals produce sound by the expulsion of air from the respiratory system, as in the hissing of snakes and the so-called bellow of the alligator. Whispering of human beings is in the same category. Some fishes produce sound by means of the swim bladder. A noteworthy example is the croaker (*Micropogon undulatus* Linn.) of our eastern and southern coastal waters.

Of all vertebrates, the mammals and birds are most generally equipped with elaborate vocal organs, hence the syrinx and larynx of these classes claim special attention. The two organs are quite different in origin and structure.

The syrinx is a chamber located at the junction of the trachea and the two major bronchi. It is supported by modified cartilages and contains a projecting flexible membrane which is thrown into vibration by the expulsion of air from the lungs. Muscular control of the tension of this membrane permits the bird to control the pitch of the sounds produced, which vary from comparatively simple calls to elaborate songs. Some birds are able to mimic sounds very faithfully, hence modulation of the sounds produced by the syrinx is involved, as in the case of human speech. Our mocking bird *Mimus polyglottos*) affords an excellent example of mimicry of the songs of other species, while **parrots** and mynas extend their virtuosity to mimicry of human speech. The mynas, especially, enunciate words with amazing delicacy of inflection.

The larynx is essentially a chamber at the pharyngeal end of the trachea, supported by modified cartilages and in most species of mammals containing vocal folds, or cords, whose tension is regulated by muscles acting on the laryngeal wall. The human larynx is among the most highly developed organs of the kind. A slit-like opening, the glottis, leads into it from the pharynx. This opening is flanked by lobes of the cricoid cartilage and by ligamentous folds, the vocal cords, imbedded in the mucous lining. The larynx is further supported by large right and left quadrangular plates of the thyroid cartilage whose ventral junction forms the "Adam's apple." A flap-like epiglottis closes down over the glottis during the act of swallowing. During ordinary breathing the glottis is V-shaped, becoming more rounded in deep inspiration. When high tones are produced, the tension of the vocal cords closely approximates them and narrows the opening to a mere slit. Although the production of sound by this organ is due simply to the vibration of the cords by the properly controlled ejection of air, sound may be produced, in whispering, without the vibration of the cords and, in either case, an important modulating effect is produced by the mouth and tongue. The oral, nasal and pharyngeal cavities also act as resonators. Individual differences in the pitch of the human voice depend on the length, thickness and elasticity of the cords. In any one individual, pitch is varied by changing the tension of the cords. Supplementary resonating structures occur in some mammals, such as the enormously dilated hyoid bone and cavernous diverticula of the larynx in the howler monkeys (*Alouata* sp.). In the **bats** the voice and the highly developed ears serve to detect obstacles in flight by the reflection of sounds.

Among the insects sound production is highly specialized. Here it is of the type called stridulation. The apparatus varies from a comparatively simple roughening of apposed surfaces which produce vibrations when rubbed together, to the elaborate organs of the male **cicada**. A common example of the simple form is found in the milkweed beetles (*Tetraopes*). By moving the prothorax up and down, its ventral sclerite is rubbed against the mesosternum, producing a squeaking sound audible to the human ear at very short distances. A more elaborate stridulation occurs in the order Orthoptera, exemplified by the crickets, katydids and grasshoppers. The crickets have parts called scrapers and files developed on the basal portion of the wings. When rubbed together they throw the entire wing membrane into vibration, producing the shrill singing so familiar to everyone. The short-horned grasshoppers set the wings into vibration by means of a row of fine projections on the inner surface of the hind legs.

The sound-producing organs of the male cicada consist of a pair of deep depressions at the base of the abdomen, covered with thin plates. Within the cavities are membranes which are thrown into vibration by direct muscular action, thus producing sound, and others which serve as resonators. Although the sound produced by cicadas of different species varies greatly in volume and quality, probably no insects exceed in volume or incisiveness the shrill vibrant singing of some of the common cicadas of the United States.

Auditory organs occur in many insects with special stridulating organs, but in others, such as some members of the order Diptera, their presence suggests that the rapid movement of the wings in flight produces the sound that the insect hears, thus providing for recognition within the species. Certainly the wing beat may have such an effect, since it is quite evident to us in the humming of mosquitoes and midges. (A.W.L.)

SOUND RECORDING. The recording and subsequent reproduction of **sound,** somewhat paralleling the development of photography, ranks among the unique achievements of modern times. The fact that its largest application so far has been to entertainment in no way detracts from its noteworthy character or its potential usefulness. The first practical phonograph was constructed by Edison about 1877 and largely improved in the years following. In the Edison apparatus a needle, attached to a diaphragm vibrating with the sound waves, makes indentations in soft tin-foil or wax. When the needle is again drawn over these indentations, it is caused to vibrate as before, and communicates its motion to the diaphragm, so that the original sound is reproduced. In a much-used modification of this device, the needle vibrates sidewise, producing a wavy groove instead of indentations. The nearest modern counterpart of the original Edison phonograph is the "dictaphone" used in lieu of shorthand in some business offices. (See **Sound Film.**)

In another type of recorder now coming into practical use, the sound record is a series of variations in the magnetization along a steel wire or tape, left there by an electromagnet carrying the current output from a microphone. When this magnetic record is drawn between the poles of an inert electromagnet, it generates a varying e.m.f. in the coils thereof which, when amplified, actuates a speaker or earphone. (L.D.W.)

SOUNDER. The sounder is the receiving device used in the aural type of telegraph reception. It consists of an electromagnet whose armature is restrained at each end of its travel by a brass stop. Since the message is transmitted by a code consisting of dots and dashes it is necessary that the receiver be able to tell by sound just how long the armature is pulled down (this being determined by whether the signal is dot or dash). The sounder is constructed to give slightly different sounds when it strikes the two stops so a skilled operator can tell whether it is closing or opening. (L.R.Q.)

SOUNDING. A knowledge of the depth of water under the keel of a vessel is frequently of great importance to a navigator or pilot. The process of obtaining this depth of water is known as taking soundings. The term is also applied directly to the determined depth. All charts of coast lines give the soundings in great detail out to a depth of 100 fathoms. In addition to the depth of water, the character of the bottom is also given. When a vessel is continually taking soundings and using the contour and character of the bottom for the purpose of directing the pilotage, she is said to be "on soundings."

The simplest, and perhaps most effective, method of taking soundings is to use the old-fashioned lead and line. The lead is simply a piece of lead hollowed out at the bottom and "armed" by placing tallow in this hollow for bringing up a sample of the bottom. The line is graduated in measured lengths, due allowance being made for the distance of the person who is "flying the blue pigeon" from the surface of the water. The great difficulty with this method is that the speed of the vessel must be checked in order that the line may be perpendicular to the surface of the water when the lead reaches the bottom.

To avoid the necessity of stopping the ship various types of sounding machines are used. In these machines the lead is attached to a line or wire and allowed to trail out behind the vessel until it reaches the bottom. The depth of the water is determined, not by the length of line payed out, but by a device attached to the lead which measures the maximum pressure of the water. This maximum pressure of the water is proportional to the depth of water and will be attained when the lead reaches the bottom.

Within recent years the so-called sonic depth-recorder has been developed for taking soundings. This instrument operates on the principle that sound travels with a finite velocity in water and the length of time required for a signal to go from the keel to the bottom of the ocean then be reflected back to the ship is proportional to the depth of water under the ship. A device is placed against the skin of the ship near the keel which sends out a sharp signal. A receiver detects the reflected signal from the ocean floor on its return to the ship's bottom. The time between the sending of the signal and the reception of the reflection is converted into the desired sounding. In the so-called fathometer the entire instrument is operated from the pilot house and is so designed that all that is necessary is to turn a switch and the depth of water appears on a dial, all of the operations being fully automatic. (See **Altimeter.**) (W.K.G.)

SOW-BUG. Wood-Louse.

SOYBEAN. *Glycine max.* Bean.

SOYBEAN OIL. Esters.

SPACE CHARGE. The electric charge on a conductor is to be regarded as confined to an infinitely thin layer at the surface and thus, in a sense, as geometrically 2-dimensional. Even when a current is flowing through the conductor, the quantities of positive and negative electricity within any element of volume at any instant are equal, thus neutralizing each other's electrostatic effect. For this reason **Laplace's equation** applies to the interior of a current-bearing conductor as well as to a complete vacuum. This is true whether the conductor be of the metallic or the electrolytic type.

Quite different are the conditions in a so-called vacuum tube, where streams of **electrons** or of positive **ions** (e.g., **canal rays**) may occupy sizable regions to the virtual exclusion of carriers of the opposite sign. (See **Ionized Gases.**) The electricity thus monopolizing such a region is called a "space charge," and may exert marked influence on the performance of the tube.

A typical instance of this occurs in thermionic **rectifiers.** If the cathode is emitting no electrons, the **potential gradient** across from cathode to anode is nearly uniform; that is, the potential increases by the same number of volts for each centimeter from the one electrode to the other. If now a small emission begins from the cathode (because of its being heated), the electron swarm is more dense near the cathode, due to their accelerated motion, much as the stream of water descending from a faucet is broader near the faucet than farther down. The potential gradient is no longer uniform, and the total increase of potential, that is, the "plate voltage," is less than before. Further increase in emission may result in an actual drop of potential near the cathode (followed by a rise farther on), with still further decrease of plate potential. Such a potential minimum is contrary to the condition expressed by Laplace's equation, which therefore does not hold in a region occupied by a space charge. (Another formula, called Poisson's equation, here applies instead. It is $\nabla^2 V = 4\pi\rho$, where V is the potential and ρ is the electric volume density at the point in question.)

In gas-filled discharge tubes the effect of electronic space charge is largely offset by the presence of great numbers of less mobile positive ions. As a result, such tubes not only have much lower **resistance** but have a more uniform potential gradient and give a better approximation to **Ohm's law.** (L.D.W.)

SPACE FRAME. A space frame or space structure is a three-dimensional **framed structure.** It may be composed of triangles, rectangles or a combination of these forms. Space frames are statically determinate or indeterminate depending on the number of members, sup-

port conditions and the rigidity of the **joints**. **Bridges**, framed domes, transmission towers, radio towers and building frames are all space structures.

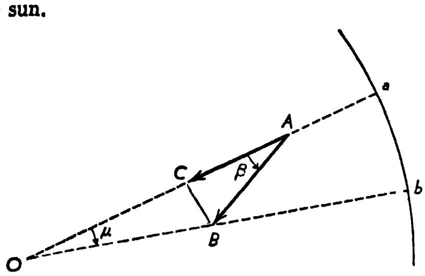
If the space frame is statically determinate it may be analyzed by means of the equations for three-dimensional statics. These equations state that the summation of all forces parallel to three axes, usually taken as mutually perpendicular, must equal zero and the moments of all forces about these axes must also equal zero.

Indeterminate space frames may be analyzed by methods which are applicable to indeterminate planar structures. Bridges and building frames are highly indeterminate when considered as space frames because the joints have a certain amount of rigidity even though they may not have been designed to resist moment. Thus, all parts do participate to some extent in distributing the **loads** to the foundation. Due to this action some members may be subjected to **torsional stress** as well as **direct** and **bending stresses**. However, it is customary to ignore this action in bridges and buildings and treat the component parts as planar structures. (C.W.C.)

SPACE SHIP. **Rocket Flight; Rockets.**

SPACE STRUCTURE. **Space Frame.**

SPACE VELOCITY. The space velocity of a star is its actual velocity in space relative to the sun. The term "fixed star" is one which has been handed down to us from the era when philosophers believed that the stars were fixed on a sphere, rotating about the earth, which they referred to as the celestial sphere. At the present time we believe that practically all of the stars are actually in motion in space with velocities comparable in magnitude to the velocities with which the **planets** are moving about the sun in their orbits. In measuring any velocity it is necessary to have a definite reference point and the space velocity of a star is its velocity referred to the sun.



In the figure we have the space velocity of a star represented by the **vector** (directed straight line proportional to the velocity in direction and magnitude) AB. The angle β which this vector makes with the direction of the star from the sun at any particular instant gives the direction of the space velocity at that instant.

As observed from the solar system this space velocity may be resolved into two components: AC the **radial velocity**, and μ the **proper motion**. The radial velocity is determined directly in terms of linear velocity (i.e., in miles or kilometers per sec.) but the proper motion may only be determined in angular units, usually expressed in seconds of arc per year. In order that the space velocity may be known the proper motion must be converted into a linear velocity, commonly known as the transverse velocity of the star. This may be accomplished only if the distance of the star is known. Expressing the distance in terms of the stellar parallax, P'', and calling the transverse velocity T (the line CB in the figure), the following relations may be derived:

$$T = 4.74\,\mu/P'' \text{ kilometers/sec.}$$

or

$$T = 2.94\,\mu/P'' \text{ miles/sec.}$$

With both the transverse velocity, T, and the radial velocity, R, known in the same units, the problem of determining the space velocity S in the same units is merely that of solving the plane right-triangle ACB. This solution yields:

$$S^2 = T^2 + R^2. \qquad \cos\beta = R/S. \qquad \sin\beta = T/S.$$

(W.K.G.)

SPACE-TIME. **Relativity.**

SPADIX. **Flower.**

SPAN. **Bridge; Truss.**

SPAN, EFFECTIVE WING. **Wing Span.**

SPANDREL BEAM. A **beam** supported by the adjacent exterior **columns** of a multiple-story building which carries the wall **load** of any story is called a spandrel beam. Spandrel beams may also support a part of the floor load. (C.W.C.)

SPANISH FLY. A pharmaceutical preparation consisting of the dried and powdered bodies of a European species of blister beetle. These **beetles**, constituting the family Meloidae, contain a poisonous substance known as cantharidin from the family name Cantharidae formerly applied to the group. Cantharidin is a powerful irritant, dangerous when taken internally. It blisters the surface of the skin and is used as a counter-irritant. (A.W.L.)

SPANISH MOSS. **Tillandsia usneoides.** Bromeliaceae. Spanish Moss is in fact not a moss at all, but a flowering plant related to the Pineapple. The plant is a perennial herbaceous plant growing as an **epiphyte** on any solid support available. It is found throughout tropical and subtropical America from Brazil to the southern United States.

Spanish Moss is rootless, and has a long, slender, branching stem which reaches a length of 2–6′, and narrow tapering leaves. The entire plant surface is covered with grayish scales capable of absorbing water. The flowers are small and yellow; the fruit, a dry **capsule**. The plant propagates itself readily by means of small fragments which are blown about by the wind. Again the plant may be carried by birds, who seek the plant as nest-building material.

The entire plant is frequently used as a packing material or for stuffing furniture. From the stem is obtained a coarse, stiff, black fibrous material, very like horsehair in appearance; this also is used in upholstery. There are several other species in the genus. Other common names applied to this plant are Southern Moss, old man's beard, vegetable horsehair, and long moss. (R.M.W.)

SPANNER. **Wrench.**

SPAR. In marine parlance a spar is a round timber used to extend a sail. Used with this meaning it could be a mast, a boom or a yard.

A structural member used similarly to extend a surface to obtain an air reaction is found in the **wing** of an **airplane**. There, the spar is a principal structural member running the length of the wing. Usually there are two, parallel to one another, but wings have been built having only one spar. In such a design the spar is required to take torsion as well as compression and bending. The spars support the ribs upon which the wing covering is stretched. The reaction of the air upon the latter is transmitted to the spars which in turn are attached to the fuselage. The air reaction may be carried

by the spars entirely by bending as in the case of a truly cantilever wing, or it may be carried by spars which are braced outboard of the fuselage by wires or struts. (See **Wing**.) (F.T.M.)

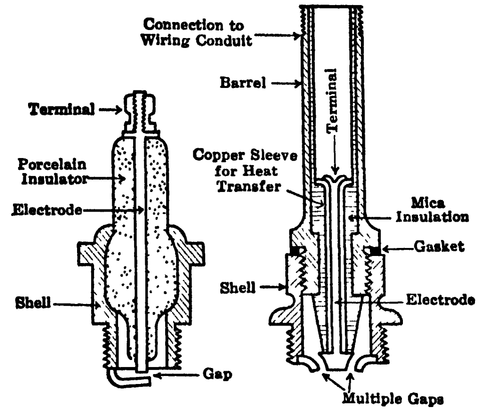
SPARAGMITE. A general and somewhat local term for late **Proteozoic** poorly graded **clastic**, sedimentary formations including such distinctive types as **arkose** and **graywacke**, intermixed or interbedded with conglomerates and intraformational **breccas**. Some of the pebbles in the conglomerates are **dreikanter**, and the total textural and structural features of the sedimentary suite suggest arid to semi-arid, **torrential**, and **intermontane** conditions of deposition. (R.M.F.)

SPARK. An electric spark is a sudden breakdown of the insulating strength of the dielectric separating two electrodes, due to the formation of ions by an intense electric field, accompanied by a rush of electricity across the "spark gap," and a flash of light indicating very high temperature. Unlike the arc, glow, and brush discharges, the spark is of very short duration. It may be oscillatory or intermittent, several discharges taking place in quick succession. In gases, the spark takes place only at appreciable pressures, such as normal atmospheric pressure.

If the voltage across a spark gap is progressively raised, a spark passes when it has become sufficiently high. The lowest voltage at which the spark will pass is the "sparking potential"; but there is usually a time interval, called the "spark lag," between the attainment of this voltage and the passage of the spark. Also the voltage may be increased for a moment considerably above this value without producing a spark. These characteristics depend upon the condition of the gas, especially upon the ions and the vapors present in it. After one spark has passed, others follow at lower sparking potential, because of the ions already formed; and this is also true if the "pilot spark" takes place across another neighboring spark gap. Paschen found that for a given pressure the sparking potential is a nearly linear function of the length of the gap, and for a given gap it is a nearly linear function of the pressure. For spherical terminals, the relation is so definite that the "sphere gap" is often used as a rough measure of high voltages. Thus with spherical electrodes 5 cm. in diameter, a 2-cm. spark in air at normal pressure corresponds to a potential difference of 56,300 volts; a 5-cm. gap to 102,250 volts. With 10-cm. spheres, the corresponding voltages are 59,460 and 123,850.

When metallic terminals are used, the light from the spark may exhibit the spark **spectrum** of the vaporized metal. The spark is also the source of a type of ultraviolet radiation known as **Entladungsstrahlen**, which accounts for the effect of the pilot spark, referred to above. (L.D.W.)

SPARK PLUG. The spark plug is a device inserted in the **combustion chamber** of spark ignition engines (**Otto engine**) to provide the insulated electrode and the gap necessary in the high-tension jump spark **ignition system**. As the electrodes are oxidized and pitted by usage, and since insulators may suffer damage, or carbon and oil may accumulate to cause short-circuit, the firing points should be made removable for adjustment, cleaning, or replacement. Universally a threaded hole is provided through the wall of the combustion chamber and the ignition points are built into a small compact "plug" which is provided with a threaded steel shank so that the plug may be screwed into the combustion chamber. Only one of the electrodes leading to the gap needs to be insulated since the electrical circuit is completed through the plug shell and engine body by grounding one end of the high-voltage supply. In operation, parts of the plug remain at high temperatures. The electrodes are made of special alloy steel suitable for resisting the high temperature and the insulator must be capable of withstanding both high temperature and electric stress of the order of several thousand volts.



Automotive Aviation (Shielded)

Molded porcelain and built-up stacks of mica rings are used. Satisfactory operation of the engine is dependent upon proper spark plug temperature.

Plugs can be designed with longer or shorter travel of the heat from the interior tip of the insulator to its point of contact with the shell resulting in higher or lower plug operating temperatures. If the plug is too cool carbonizing and short-circuiting of the gap will be probable; if too hot it may promote pre-ignition and detonation. The length of the gap affects the energy of the spark and the voltage required to produce it. Small gaps reduce electrical stress, make starting easier, but are more easily fouled by bits of carbon and do not ignite the gasoline as efficiently, as has been proved by tests for thermal efficiency under different gap settings. About .03 in. ($\pm$.01) covers the recommendations for plug gaps for all engines except aeronautical, where the gaps are much smaller because of advantages of limiting voltage stress on the plugs and ignition wiring at high altitudes.

A greater variety of spark plugs has been produced for aeronautical service than any other because service conditions are more severe and reliability more desirable than in other internal combustion engine fields. Also the use of radio receiving equipment is an important adjunct to navigation and the ignition system, including spark plugs, will interfere with radio reception unless properly shielded. Operation of aircraft at extremely high altitudes poses further problems in corona loss from the high voltage portions of the ignition system. Electrically shielded and gas-pressurized plugs and ignition wiring harness are employed to meet these special problems of aircraft ignition. (F.T.M.)

SPARROW. Aves, Passeriformes. A common form of small seed-eating bird (**Aves**) of the family Fringillidae. The many species are for the greater part rather quietly colored in browns and grays with streaked and spotted plumage, but some bear conspicuous black or white marks and the browns of some species are very bright. Some of the sparrows have beautiful songs, although none rival such outstanding singers as the brown thrasher and the mockingbird.

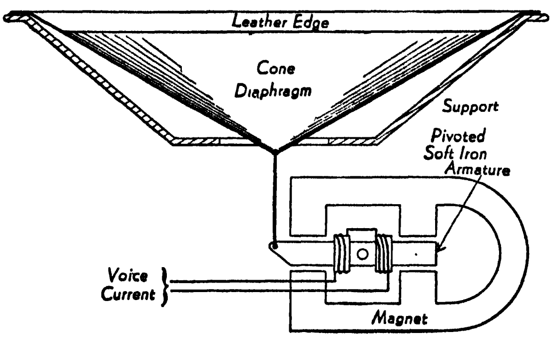
The field sparrow, *Spizella pusilla*, chipping sparrow, *S. passerina*, white-throated, *Zonotrichia albicollis*, and white-crowned, *Z. leucophrys*, sparrows, song sparrow, *Melospiza melodia*, and in the west the lark sparrow, *Chondestes grammacus*, are among the well-known North American species. (A.W.L.)

SPASTIC COLON. Constipation.

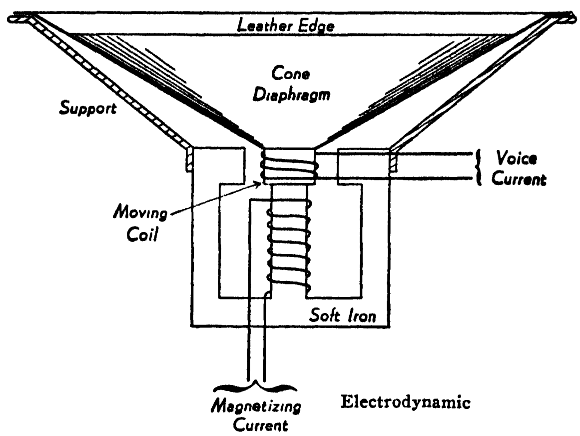
SPATHE. Flower.

SPATIAL DEGREE. Degree.

SPEAKER. The speaker, or loud-speaker, is the electro-acoustical device which converts electrical current variations in a communication circuit into sound for general coverage. The head-set also performs this function but is used only where general coverage by the sound is not needed. All modern radio receivers for home use utilize the speaker but many communications receivers use head phones since reception is usually by only one operator. While various types of speakers have been developed and used at different times, the majority of those in use at present are dynamic speakers. Referring to the figure, the magnet, which may be



Magnetic
(Balanced Bipolar)



Electrodynamic

electromagnet or permanent magnet, sets up a high flux across the gap containing the voice coil. This coil consists of a few turns of rather light wire wound on a form rigidly attached to the cone. The voice currents, i.e., the output of the audio-frequency **amplifier,** are passed through the voice coil. This current flowing in the presence of the magnetic field produces a force on the coil. As the force varies with the current, the cone is moved back and forth at the frequency of and with amplitudes proportional to the voice currents, thus producing sound waves. An older form of speaker is the magnetic which usually employs a balance armature as shown. This type has been superseded by the dynamic. The basic speaker is usually part of a more complete sound-reproducing apparatus. Thus the ordinary small radio or amplifier unit utilizes the cabinet as a baffle to aid in the reproduction of low-frequency notes. A speaker will not satisfactorily reproduce notes whose wavelength is greater than four times the distance from the cone to the edge of the baffle. More elaborate speaker arrangements involve special acoustical networks, horns, etc., to give a more uniform frequency response over the range desired. For proper operation careful design of these auxiliary components is necessary. Since proper reproduction of low frequencies requires a rather large cone while high frequencies require small cones, may installations use both types in the same unit, sometimes side by side on the same baffle, sometimes as a single coaxial unit. (L.R.Q.)

SPEARMINT, OIL OF. Volatile Oils.

SPECIES. The smallest taxonomic category, excluding the various subdivisions recognized in very detailed study. A species is made up of a group of individuals, but beyond this limitation the definition of the term has varied from the denial of its existence as a natural entity to various attempts at rigid characterization.

As a rule the individuals of a species resemble each other within established limits of variation, but in some species the sexes are conspicuously different, in some the component individuals differ with the seasons, and in some there are various forms of individuals adapted for different tasks. The principle of fertility as a test of the relationship has been adopted by some biologists, but here again species differ. In some extremely variable species individuals may be found which are incapable of mating, and in some cases different species produce fertile hybrids when crossed. The two criteria, reproductive association and structural resemblance, seem to provide a workable definition when taken together. According to this concept a species may be defined as a natural group of individuals which are either similar in form or associated in a reproductive sequence. Like all other definitions it will be found difficult to apply to certain specific cases, but it is more generally applicable than most. (A.W.L.)

SPECIFIC. Any **drug** or treatment which has a special or individual action in the cure of some disorder or disease, such as **quinine in malaria** or **salvarsan in syphilis.** (R.S.M.)

SPECIFIC GRAVITY. Density and Specific Gravity.

SPECIFIC GRAVITY BOTTLE. Pycnometer.

SPECIFIC HEAT. The specific heat of a substance is the quantity of heat required to impart a unit increase in temperature to a unit mass of that substance; commonly expressed in **calories** per centigrade degree per gram. (Some writers regard the specific heat as the abstract ratio of the quantity just defined to the corresponding value for water.) The "thermal capacity" of a body of any mass is the quantity of heat required to raise its temperature one degree (calories per gram), so that the specific heat of a substance may be defined as its thermal capacity per unit mass. Of all known substances, except one of the phases of liquid **helium,** that having the greatest specific heat is hydrogen, for which, at constant volume, it is 2.418 calories per gram per degree; next is water, with specific heat unity (at 15° C.). For gold it is only about 0.031 calories per gram per degree.

These wide variations are qualitatively explained by the fact that, since the atoms of gold are much more massive than those of hydrogen and hence there are much fewer of them in a gram, and since the temperature is determined by the kinetic energy per molecule, the total energy required for a gram of gold is correspondingly less than for a gram of hydrogen. Dulong and Petit (1819) concluded, indeed, that the specific heats of elements are inversely proportional to their atomic weights. (See **Dulong and Petit's Law of Specific Heats.**) The specific

heats of crystalline solids have afforded in recent years a fruitful though difficult subject of research. The work of Debye in this field, especially with reference to the variation of specific heats with temperature, is outstanding.

It is necessary to discriminate between the true or temperature specific heat and the apparent or total specific heat which we encounter when the thermal energy imparted is allowed to do more than agitate the molecules or atoms of the substance. Expansion with rise of temperature may require energy because of work done against external pressure or against cohesion. This is notably true with gases, the specific heats of which are, on the average, some 40% greater when they are allowed to expand at constant pressure than when kept at constant volume as the temperature is raised.

SPECIFIC HEATS OF SOME COMMON SUBSTANCES AT ORDINARY TEMPERATURES

Substance	Specific Heat	Substance	Specific Heat
Air (c.v.)	0.171	Iron	0.107
Alcohol (0° C.)	.548	Lead	.031
Aluminum	.214	Mercury	.033
Copper	.090	Nitrogen (c.v.)	.176
Glycerine	.576	Oxygen (c.v.)	.156
Helium (c.v.)	.075	Silver	.056
Hydrogen (c.v.)	2.418	Water	1.000
Ice	.493	Zinc	.090

(L.D.W.)

SPECIFIC SPEED. The specific speed of a **hydraulic turbine** is the member of rpm at which it would develop 1 hp. under 1-foot head, all dimensions of the turbine being reduced proportionally to enable it to meet these conditions. Mathematically, the specific speed is

$$\frac{\text{rpm}\sqrt{\text{hp.}}}{(\text{head, in ft.})^{5/4}}$$

The specific speed is the most important single dimension of a turbine. It very fully indicates the characteristics of the **runner**. By making a comparison of specific speeds, the characteristics of turbine runners can be judged without considering their actual speed, head, or power. And yet the specific speed is not completely satisfactory because it is not non-dimensional but is based on the respective dimensional systems, i.e., English or metric.

In general, runners of low specific speeds are suitable for high heads and those of high specific speed are suitable for low heads. The combination of **head** and specific speed is such as to keep the generator speeds within reasonable range for all values of head. This is fortunate since the possible range of head in present-day hydroelectric developments is from 5 to 5000 ft. The range of specific speeds is served by the various types of turbines about as follows:

N_s	Type
10–20	Pelton
20–120	Francis
120–150	Nagler, Kaplan

For an average generator, the cost decreases as the speed increases, at least within certain limits; hence as high a specific speed as can be safely used is chosen.

Specific speed is also a useful reference dimension in the centrifugal pumps field. However, since discharge is more important than power in this field, the specific speed equation has a different form. Centrifugal pump specific speed is

$$\frac{\text{rpm}\sqrt{\text{Discharge, gal. per min.}}}{(\text{head, in ft.})^{3/4}}$$

(F.T.M.)

SPECTRA. Spectrum.

SPECTRAL CLASS. Examination of stars with the unaided eye will indicate that they are not all of the same apparent color. This fact has been noticed from earliest times, and we find the names of many of the stars carrying an indication of their color, e.g., **Antares** was undoubtedly so named because of its reddish color similar to that of the planet Mars. With the application of the **spectroscope** to astronomical research, several attempts were made to classify the stars according to their spectra. Secchi and Vogel each proposed spectral classification sequences based upon visual observations. The system which is now universally employed was developed by Dr. E. C. Pickering, Director of the Harvard College Observatory from 1877 to 1919. The first results of his classification were published by the observatory with funds made available by Henry Draper, and the classification system is known either as the "Harvard system" or as the "Henry Draper system."

The Harvard system of classification is based upon the relative intensity of certain selected **absorption** lines in the stellar spectra. The various types are designated by letters, and the principal characteristics of the different classes are:

Class B—Helium stars—Absorption lines of helium and hydrogen characteristic features.

Class A—Hydrogen stars—Intensity of helium lines weaker and hydrogen lines the most prominent feature.

Class F—Calcium stars—The *H* and *K* lines of calcium are much stronger than the hydrogen lines, although the latter are still prominent. A few metallic lines are present.

Class G—Solar stars—Calcium lines the most prominent feature, with the hydrogen lines distinctly fainter. Many metallic lines.

Class K—Metallic lines—Calcium lines still strong but spectrum predominated by multitude of lines due to metals. The violet end of the continuous background distinctly weaker.

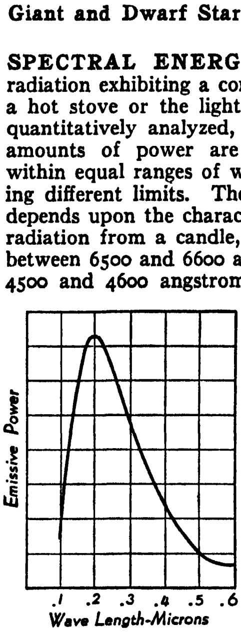
Class M—Molecular compound lines—Calcium and many metallic lines still prominent, but characteristic feature is the presence of bands due to molecular compounds. The violet end of the continuous background extremely weak.

Accompanying the above changes in the absorption lines there is a progressive change in the position of maximum intensity of the continuous background, the colors of the stars changing from blue for the B-type through yellow for the G-type to red for the M-type. This is an indication of a temperature sequence for the stars, those of the B-type being hottest and those of the M-type coolest. Ninety-nine per cent of all stars thus far examined may be fitted into this sequence of six letters. Stars with spectra intermediate between the various types are designated by a decimal system, e.g., a G5 star is half way between a G- and a K-type star. To provide for the few stars which cannot be fitted into the main sequence there are a number of small classes. For example, certain blue stars, some of which show bright lines, are known as O-type, while red stars, other than M-type, are grouped under N, R, and S.

More than 275,000 stars have been classified at the Harvard Observatory on the foregoing system. The spectra were obtained by **objective prism** photography, and examined and classified by Dr. Annie J. Cannon. These results are published in the Henry Draper Catalogue and its extensions. Other observatories, using objective prisms, or large reflectors and slit spectrographs, have classified large numbers of stars fainter than those included in the Henry Draper Catalogue, and have also made critical examinations of high dispersion spectra to determine slight differences within the individual classes. The correlations between spectral type and the physical

characteristics of the stars will be found in the article on **Giant and Dwarf Stars.** (W.K.G.)

SPECTRAL ENERGY DISTRIBUTION. When radiation exhibiting a continuous spectrum, as that from a hot stove or the light from an incandescent lamp, is quantitatively analyzed, it is found that quite different amounts of power are represented by the radiation within equal ranges of wavelength or of frequency having different limits. The proportion in any such range depends upon the character of the source. Thus, in the radiation from a candle, the ratio of the energy output between 6500 and 6600 angstroms (red) to that between 4500 and 4600 angstroms (blue-violet) is greater than the corresponding ratio for the radiation from an arc lamp. If we divide the spectrum into small intervals of wavelength, say 10 angstroms, and plot the power output for each range as ordinate with the mean wavelength of the interval as abscissa, the result is a curve showing the distribution of power through the spectrum. When the radiation is due to high temperature, as in the above examples, there is always a wavelength interval having maximum power, that is, the curve has a "peak," from which the ordinates fall off in both directions. Wien pointed out that the higher the temperature of the source, the farther toward the short-wavelength end of the spectrum does this peak lie. (See **Wien's Laws, Planck's Equation,** and **Radiation Pyrometer.**)



Spectral energy distribution for black body at 1170° C. (1443° Abs.), with peak at 2000 A. (.2 micron).

An instrument utilizing a prism for dispersing the radiation, together with a thermocouple or similar device for measuring its flux density in different ranges, may be used to analyze infra-red thermal radiation, and is called a "spectroradiometer." The **spectrophotometer** performs a similar service for visible light, except that the results in this case are usually tabulated in terms of the visibility rather than the actual power of the emission. (L.D.W.)

SPECTRAL SERIES. **Atomic Spectra; Molecular Spectra; X-Ray Spectra.**

SPECTROBOLOMETER. **Bolometer.**

SPECTROGRAPH. **Spectroscope.**

SPECTROGRAPHY. The photography of spectra. A spectrograph is a form of spectroscope designed particularly for photographing spectra. (See **Spectrum, Spectroscope.**)

Visual examination in a spectroscope is adequate (1) if the spectrum of the substance is simple and easily recognized, (2) if a permanent record is not required, (3) if the substance can be positively identified by the lines occurring in the visible region. If many of the lines are faint or close together, necessitating exact measurement, or if important identifying lines occur in the ultra-violet or infra-red, the photographic method is the more precise. The procedure is to photograph the spectrum of the sample whose composition is to be determined and then on the same plate, above or below it, the spectrum of a substance whose characteristic lines are well known and can therefore be used in determining the wavelengths of the lines in the spectrum of the unknown substance.

If the substance is known or believed to contain certain elements, the spectra of these may be photographed on the same plate. Then if identical lines are found in both spectra, it is only necessary to determine the wavelengths of the lines which do not correspond to find the other elements present.

Photography extends the range of the spectroscope beyond the visible range into the infra-red and the ultra-violet. No great difficulty is experienced with modern plates in photographing to a wavelength of 1200 millimicrons (12,000 Å) in the infra-red. Ordinary blue-sensitive materials may be used in the ultra-violet up to a wavelength of about 250 millimicrons (2500 Å). Beyond this it is necessary to use (1) plates prepared with a minimum of gelatin (Schumann plates) to overcome the absorption of ultra-violet radiation by gelatin, or (2) to coat the emulsion with materials which fluoresce in the ultra-violet and through fluorescence produce visible light of spectrum lines in the ultra-violet region which can be photographically recorded on regular plates. Various oils have been used by different workers with varying success, the plate being bathed in the oil immediately before use. Lyman in this way was able to reach a wavelength of 580 Å in the extreme ultra-violet. Special plates coated with a fluorescent material for ultra-violet spectrography are now available commercially. The fluorescent coating is removed by washing the plate with acetone before development, or brushing the plate with a soft camel's-hair brush while in the developer.

Spectrography finds many important applications in science and industry. The spectra of the stars show that they are composed of the same elements which we find on the earth. Helium in fact was found in the spectrum of the sun before it was isolated in the laboratory. The spectrum of a star is also an indication of its temperature, age, and the direction and speed in which it is moving.

In the laboratory, spectrography is used in the detection of gases, particularly inert gases such as **krypton, xenon,** etc., studies of full combustion in motors, the presence of impurities in metals and in foods, the composition of alloys, the characteristics of dyes, **pigments,** and coloring matters, etc. (C.B.N.)

SPECTROHELIOGRAPH. As the construction of the term indicates, the spectroheliograph pictures the sun in its **spectrum.** Essentially the instrument consists of a high dispersion spectrograph with a second slit placed directly in front of the photographic plate so that the radiation from only one spectral line is received on the plate. If the instrument is so placed that the first slit is in the principal focus of a telescope directed toward the sun, a narrow strip of the sun's image will be admitted by the first slit and an image of that narrow section of the sun will be formed on the photographic plate in the particular radiation for which the second slit is adjusted. The instrument is so constructed that the first slit may be moved across the image and at the same time the second slit moves across the photographic plate at the same rate. Hence, it is possible to obtain a photograph of the sun in the monochromatic radiation of any particular element, say calcium.

From the **flash spectrum** we can determine the heights to which various elements rise in the solar atmosphere, and thus by means of the spectroheliograph it is possible to obtain photographs of the sun at various levels above the **photosphere.** (W.K.G.)

SPECTROMETER. **Spectroscope.**

SPECTROPHOTOMETER. An instrument for analyzing the **spectral energy distributions** of sources of light. It is thus a spectroradiometer for visible radiation. Various types are in use. A representative form includes a **monochromatic illuminator,** from the slit of which proceeds an isolated, narrow frequency range of the light under examination. This may be com-

pared, by means of a **wedge photometer** device or otherwise, with the light of the same frequency range from a source whose spectral energy distribution is known. In interpreting the results, it is important to take into account the visibility factor (see **Photometry**), and thus to distinguish between the relative absolute (energy) and apparent (visual) intensities for different wavelengths. There are spectrophotometers which exhibit directly an approximate curve of apparent intensity distribution. A simple type consists of a spectrometer with a neutral absorbing wedge placed with the thick base over the upper end of the slit and the thin edge over the lower. The spectrum then appears as a strip whose upper margin, penetrating visibly to various distances into the region of greater absorption, corresponds to the distribution curve. (L.D.W.)

SPECTRORADIOMETER. **Spectral Energy Distribution; Radiation Pyrometer.**

SPECTROSCOPE. Many types of instrument for producing and viewing spectra are included under this term. Variations in form are due, not only to differences in principle, but also to the type of radiation to be examined, which ranges all the way from **infra-red** to **x-rays.**

The earlier spectroscopes, developed by Fraunhofer, Ångström, and others in the early part of the last century, adapted **Newton's** discovery of the **dispersion** of light by **a prism.** The essential features (Fig. 1) are

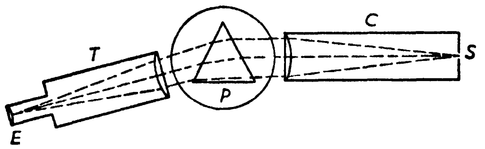


Fig. 1. Diagram of simple prism spectroscope. *C*, collimator with slit *S*; *P*, prism; *T*, telescope for viewing spectrum at eyepiece *E*.

a slit, S, a **collimating** lens, C, for rendering the light from the slit parallel before entering the prism, one or more dispersing prisms, P, and a **telescope,** T (or a **camera**), for forming images of the slit in the various wavelengths and thus providing a method for viewing or photographing the **spectrum.** The light passes through these in the order named, being deviated by the prism through various angles according to the wavelength. When a spectroscope is provided with a graduated circle for measuring deviations, it is called a "spectrometer." The "direct-vision" or non-deviation spectroscope, employing an **Amici prism,** is a compact instrument for qualitative purposes. The photographic spectroscope, known as a "spectrograph," is now almost universally used in spectral research. (See **Spectrography.**)

Many modern spectroscopes employ the **diffraction grating** instead of the prism. In the concave grating spectroscope, developed by Rowland, the collimating lens and telescope or camera objective are unnecessary be-

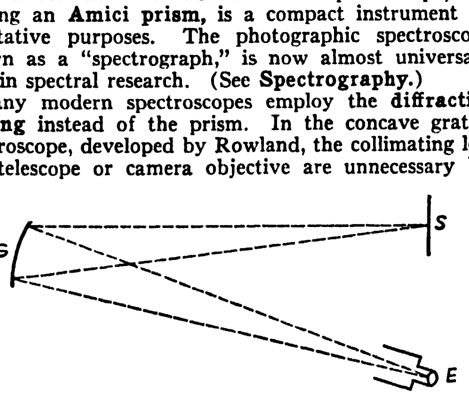

Fig. 2. Concave grating spectroscope. *S*, slit; *G*, grating; *E*, eyepiece (or plate-holder). (Diagrammatic.)

cause of the focusing effect of the grating itself (Fig. 2). Other types of instruments developed for particular purposes will be found described under **X-Ray Spectrometer** and **Objective Prism.** (L.D.W.)

SPECTROSCOPIC BINARIES. Within the past 50 years we have become acquainted with a class of **binary stars** which are not **double stars** in the ordinary sense of the term, because of the fact that the components are too close together for them to be observed separately even in **telescopes** of the highest **resolving power.** In such binaries the period is usually short and the orbital velocities high. Unless the orbit plane happens to be perpendicular to the line of sight, the orbital velocities will have components in the line of sight and the observed **radial velocity** of the system will vary periodically. Since radial velocity is measured with the **spectroscope,** employing the **Doppler-Fizeau principle,** the binaries so observed are known as spectroscopic binaries. In some spectroscopic binaries the spectra of both stars are visible and the lines are alternately double and single. Such stars are known as double-line binaries. In others the spectrum of only one component is seen and the lines in this spectrum move periodically from violet toward the red and back again.

The determination of the **orbit** of a spectroscopic binary is made from a long series of observations of the radial velocity of one or more components of the system. The observations are first plotted against time and from the resulting curve the period may be obtained. With this period determined observations are then reduced to a single epoch and the best possible curve drawn through the points, obtaining what is known as the velocity curve of the system. If the orbit is circular the velocity curve will be a sine curve, if elliptical, the shape of the curve will depend upon the eccentricity of the ellipse and the orientation of the major axis with reference to the line of sight. From the shape of the velocity curve the orbit of the system in space may be determined. In the solution of the spectroscopic orbit it is impossible to determine individually the semimajor axis, a, and the inclination of the orbit plane, i. However, the product of the semimajor axis by the sine of the inclination (i.e., $a \sin i$) may be determined directly in linear units (i.e., in either miles or kilometers). If either a or i can be obtained from other types of observations, as in the case of **eclipsing binaries,** a complete solution for the orbit can be made. (W.K.G.)

SPECTROSCOPIC PARALLAX. The term spectroscopic parallax of a star is applied to a determination of the distance of a star in which the **stellar parallax** is determined from observations of spectral peculiarities of the star together with determinations of the apparent brightness of the object.

The apparent brightness of a star depends upon two fundamental factors: the intrinsic brightness of the star and its distance from the observer. Expressed on the **stellar magnitude** scale, we find the apparent magnitude, mg, the **absolute magnitude,** M, and the stellar parallax, π'', to be connected by the analytical expressions: $M = mg + 5 + 5 \log_{10} \pi''$. The apparent magnitude of a star may be determined by a variety of methods of **stellar photometry,** and if a method is available for the determination of the absolute magnitude the value of the stellar parallax may be determined.

The relative intensities of certain **spectral lines** are different in **giant and dwarf stars** of the same spectral type. The relative intensities of selected pairs of lines may be compared in stars of the same spectral type and known absolute magnitudes and a "calibration curve" obtained. The relative intensities of the same pairs may then be found in stars of unknown absolute magnitudes and the calibration curves used to determine the absolute magnitude. Thus, the parallax may be determined from a study of spectra. The accuracy of the determinations of spectroscopic parallax compares very favorably with parallaxes obtained from the relative trigonometric methods. (W.K.G.)

SPECTRUM. This term usually refers to the array of wavelengths or frequencies resulting from the **dispersion** of light or other **radiation**, as by a **prism** or a **diffraction grating**, and revealed by the **spectroscope**. The emission spectrum of a substance is that of the radiation which it emits when "excited," while the result of passing white light through the substance is its **absorption spectrum**. Incandescent solids, liquids, or gases under high pressure give a continuous spectrum, while gases under a relatively low pressure give either an **atomic spectrum** made up of lines, or a **molecular spectrum** of bands, or both. The spectrum of the same substance may differ according to the method of excitation. Thus we may have the flame spectrum, the arc spectrum, or the spark spectrum of, say, iron. That is, iron salts may be vaporized in a flame, or an arc or a spark may be passed between iron electrodes. **X-ray spectra**, while in many essential respects similar to those of light, belong in a distinct class, because of the differences in technique required by the much shorter wavelengths employed. (L.D.W.)

SPEED RATIO. Chain; Belting; Gearing.

SPEED REDUCERS. Geared speed reducers afford all the advantages of toothed gearing and require very little attention or maintenance other than periodic inspection of the oil supply, if they are properly selected and installed. Practically all types of gearing are employed in their construction; the most important forms of reducers are those with parallel input and output shafting, for which spur, helical, and herringbone gearing are used; and those with perpendicular shaft axes, which employ spiral bevel, hypoid, or worm gearing. One of the simplest forms of speed reducers is the gearmotor shown in Fig. 1. The unit illustrated is an "offset" reducer, in which a helical pinion on the end of the motor shaft drives a helical gear on the output shaft. The gear case is supported by the motor housing, and can be adjusted so that the output shaft is in the same horizontal plane as the motor shaft, or in several intermediate positions as well as in the position shown, thereby making the unit adaptable to various conditions of installation. Double and triple reduction units are available for high-speed ratios; in some of these the motor is flange-mounted on the reducer case. Planetary gear motors, with the motor and output shaft axes in alignment, are available in single and double reduction units and for a wide range of ratios and power capacities up to about 75 hp.

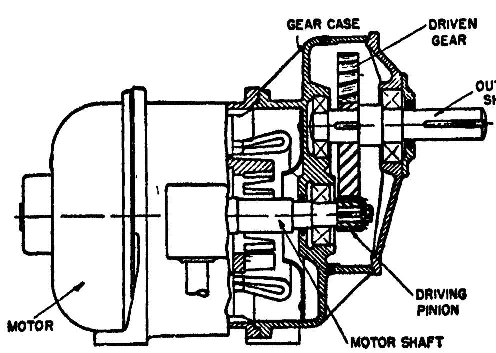

Fig. 1. Gearmotor speed reducer.

Parallel shaft reducers with a single set of helical or herringbone gears are used for reductions up to 10:1, and are known as single-stage reducers; two-stage units, with two sets of gears, are used for reductions from 10:1 to 60:1; and three-stage reductions over 60:1.

Right-angle, two-stage speed reducers with a spiral bevel gear set for the high-speed stage, and a helical gear set for the low-speed stage, are common. Single and triple reduction units are also available. Units of this character can also be procured with vertical output shafts, projecting either above or below the gear case, for agitator and mixer drives.

Worm gear reducers are frequently employed for high velocity ratios and heavy power demands. The driving motor is generally connected to the input or worm shaft by means of some form of flexible coupling; the drive from the worm gear shaft, or output shaft, to the driven machine can be effected either through a flexible coupling for direct-connected drives, or by spur gearing, belt or chain drives.

A commercial worm gear reducer is shown in Fig. 2. It has a high-helix angle worm integral with the input shaft, and is carried in ball bearings. The gear has a bronze rim bolted to a cast iron spider mounted on the slow-speed or output shaft and is carried in roller bearings. Horizontal units are also available in which the worm is above the gear; there are also double reduction units in which two sets of worm gearing are incorporated in a single case.

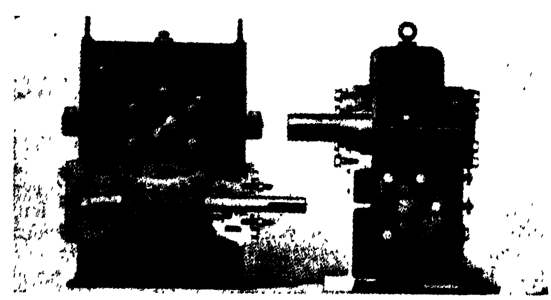

Fig. 2. Worm gear reducer.

Worm gear reducers should be selected upon consideration of three important factors: the mechanical rating of the unit, which involves the strength and wear load capacities of the gearing; the thermal rating, which takes into account the operating temperature of the unit; and the efficiency. These factors in turn depend upon various conditions of service, which have been classified by the American Gear Manufacturers' Association as Class 1, Class 2, and Class 3 service. Class 1 service is based upon smooth, steady operation, for from 8 to 10 hours per day; Class 2 service consists of 24-hour steady, smooth operation or 8- to 10-hour recurrent shock load service; while Class 3 consists of 24-hour shock load operation. SPEED, TAKE-OFF. **Airplane.**

SPELTER. **Galvanizing.**

SPENOLITH. A term proposed by Burckhardt in 1906 for wedge-shaped **igneous** intrusions. (R.M.F.)

SPERM. **Gamete.**

SPERM DUCT. Any of the ducts of the testes. **Reproductive System.** (A.W.L.)

SPERM SAC. **Seminal Vesicle.**

SPERM VESICLE. A dilation of the terminal portion of the vasa deferentia of the arrow worms. Unlike the seminal vesicles of most animals, which are nearer to the testes, these reservoirs open directly to the exterior. (A.W.L.)

SPERMACETI. **Esters.**

SPERMATHECA. **Receptaculum seminis.**

SPERMATOPHORE. A packet of spermatozoa. In some of the invertebrates, including **annelid** worms, **arthropods,** and **mollusks,** instead of swimming freely in a seminal fluid the reproductive cells of the male are transferred to the female in these small bundles. The formation of the packets is a function of the male genital ducts, which secrete a retaining envelope about the masses of sperm cells. (A.W.L.)

SPERMATOPHYTA. Seed Plants. This is the largest division of the plant kingdom, comprising over 130,000 species. Members of this division, including nearly all plants of economic value, are of the utmost importance to man, for from them come practically all his food and that of his domestic animals, his clothing, and, to a great degree, his shelter.

Seed plants are much more complex than are those in the other divisions. Their common distinguishing feature, of course, is the **seed.** A seed is composed of an **embryo** plant which has developed from a mature egg, usually after the latter is fertilized, together with a certain amount of reserve food which may surround the embryo or be stored within its tissues, and one or more seed coats which completely surround the embryo plant and the food reserves.

In seed plants there occurs a definite alternation of generations. The **gametophyte** generation, however, is very much reduced, and entirely dependent on the **sporophyte** throughout its brief existence. The familiar seed plants are the sporophyte generation.

Seed plants are divided into two groups, the **gymnosperms** and the **angiosperms,** of which the gymnosperms are the more primitive. In them the seed is formed on the surface of an ovuliferous scale. Pines, spruces, cedars, larches, and cycads are all gymnosperms. The angiosperms are more advanced, and are generally called flowering plants. Two groups of angiosperms are recognized, the **dicotyledons** and the **monocotyledons.** Plants in these two groups are separated by the number of seed leaves or cotyledons present in the embryo. Roses, grapes, lilies, maples, and orchids are all angiosperms. (See also **Paleobotany.**) (R.M.W.)

SPERMATOZOA. The male sex **cells,** which are formed in the testicles and are the main element of the semen or seminal fluid. With coitus they are ejaculated into the vagina, where under favorable conditions a single spermatozoon unites with an **ovum.** In a single ejaculation several million spermatozoa are contained in the semen. The spermatozoon is a small cell about 1/500″ in length; in shape it resembles a tadpole in that it has a head, a long body, and a long tail which is responsible for its motility. (R.S.M., D.M.H.)

SPERMOPHILE. Mammalia, Rodentia. A small slender animal with short legs, small external ears, a short hairy tail, and large cheek pouches. Also called ground squirrel and gopher. The name spermophile is derived from the genus *Spermophilus,* in which these animals were formerly grouped.

Most of the several species of spermophiles are confined to limited areas in the arid lands of the west. The striped species, commonly called the gopher, ranges from central Ohio to the Rockies and from Canada to Texas. This species is brown with alternating clay-yellow stripes and rows of spots on the back and sides. It is destructive to crops and damages lawns. (A.W.L.)

SPERRYLITE. A mineral diarsenide of platinum, $PtAs_2$. Crystallizes in the isometric system. Hardness, 6–7; specific gravity, 10.58; color, white; opaque. Named after Francis L. Sperry, Sudbury, Ontario. (R.M.F.)

SPESSARTITE. **Garnet.**

SPHAGNUM. **Bryophytes.**

SPHALERITE — ZINC BLENDE — BLENDE. Sphalerite is **zinc** sulfide, ZnS, crystallizing in the **isometric** system frequently as **tetrahedrons,** sometimes as cubes or **dodecahedrons,** but usually massive with easy **cleavage,** which is dodecahedral. It is a brittle mineral with a conchoidal fracture; hardness, 3.5–5; specific gravity, 3.9–4.1; luster, adamantine to resinous, commonly the latter. It is usually some shade of yellow brown or brownish-black, less often red, green, whitish, or colorless; streak, yellowish or brownish, sometimes white; transparent to translucent. Certain varieties are phosphorescent or fluorescent. Sphalerite is the commonest of the zinc-bearing minerals, and is found associated with **galena, chalcopyrite, tetrahedrite, barite, fluorite,** etc., as a result of contact **metamorphism,** and as replacements, and **vein** deposits. There are very many foreign localities, including Saxony, Bohemia, Switzerland; Cornwall, in England; Spain, Sweden, Japan, and elsewhere. In the United States sphalerite is found in Arkansas, Iowa, Wisconsin, Illinois, Colorado, New Jersey, Pennsylvania, Ohio, and especially in the so-called Tri-State area which includes parts of Kansas, Missouri, and Oklahoma, the largest zinc-producing district in the world at the present time. The word sphalerite is derived from the Greek, meaning treacherous, and its older name, blende, meaning blind or deceiving, refers to the fact that it was often mistaken for lead ore. (E.S.C.S.)

SPHENE. **Titanite.**

SPHENISCIFORMES. The penguins. An order of birds (**Aves**) characterized by the paddle-like wings, webbed feet, and upright posture when out of the water. They are remarkable swimmers, using both wings and feet under the water. Penguins are confined chiefly to the more southern parts of the southern hemisphere, including the Antarctic regions, but one species is found on the Galapagos Islands. (A.W.L.)

SPHENOID. A bone located in the anterior part of the base of the skull. It forms part of the floor of the brain cavity and is of complex shape, articulating with most of the other bones of the skull. (A.W.L.)

SPHENOPHYLLALES. **Paleobotany.**

SPHERE. A spherical surface is a **surface** all points of which are at a fixed distance, its radius, from a fixed point, its center. It is often referred to as a sphere, although this term frequently means the solid bounded by the spherical surface.

The equation in **rectangular coordinates** of a sphere with center at (h, k, l) and radius r is:

$$(x - h)^2 + (y - k)^2 + (z - l)^2 = r^2.$$

Any equation of the form

$$x^2 + y^2 + z^2 + Ax + By + Cz + D = 0$$

represents a sphere.

For a sphere of radius R, the area of the surface is $4\pi R^2$ and its volume is $\frac{4}{3}\pi R^3$. (L.L.S.)

SPHERE PHOTOMETER. Integrating Photometer.

SPHERICAL ABERRATION. If the surfaces of a **lens** or the reflecting surface of a mirror are spherical, the rays refracted through or reflected from the outer portions will be brought to a focus in a different plane than those from the center, thus producing a blurring of the resultant image known as spherical aberration. This effect is more pronounced in short-focus lenses or mirrors than in long-focus instruments, for the curvature of the surfaces of the short-focus instruments is greater.

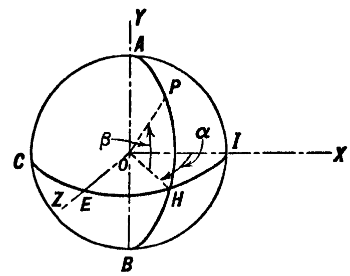
The decrease of spherical aberration with increase in focal length was discovered very early in the history of optical instruments, and during the 17th century we find telescope builders increasing the focal lengths of their instruments to tremendous proportions. Telescopes with focal lengths between 100 and 200′ were not uncommon during this period, and the problem of supporting the long thin tubes so that they could be used for astronomical purposes and remain straight was one calling for great ingenuity. Descartes in 1637 published the theory of spherical aberration and showed that theoretically it could be corrected by grinding the surfaces of lenses and mirrors in curves other than spheres. The difficulties of grinding the required lens curves were apparently greater than those of operating the long-focus telescopes. About the middle of the 18th century John Dolland published the fact that spherical aberration could be corrected by the same method employed for the treatment of **chromatic aberration,** i.e., by using two lenses, one convergent and the other divergent. All modern telescopic lenses of good quality now employ the double object glass with the figures of the lenses and the separation between the components depending upon the ideas of the makers. For wide-angle, short-focus lenses, such as are used in modern hand **cameras** and in astrographic cameras, the simple pair of lenses does not provide sufficient correction for all of the aberrations, and three or more lenses are used in combination. Perhaps the most common is the so-called doublet, in which two pairs of lenses are used with a considerable separation between the pairs.

Spherical aberration may be corrected in the case of a mirror by grinding the concave surface in the form of a **paraboloid** of revolution instead of in the form of a sphere. This provides almost complete correction for rays entering the mirror parallel to the axis of revolution of the paraboloid, i.e., along the principal axis of the mirror; but for rays entering at a moderately large angle, spherical and various other aberrations make their appearance in the resultant image. Hence, while the reflecting type of telescope can be more easily corrected for the aberrations along the axis, nevertheless it cannot be used to obtain photographs of large areas with good definition throughout. (See **Telescope.**) (W.K.G.)

SPHERICAL ANGLE. A spherical angle is formed by two intersecting arcs on the surface of a **sphere;** it is measured by the plane angle formed by the **tangents** to the arcs. (L.L.S.)

SPHERICAL COORDINATES. The spherical coordinates of a point in space are three numbers which determine the position of the point and which are particularly adapted to problems involving **spheres.** In case the point is assumed to be located on the surface of a sphere of known or unknown radius two angular coordinates are sufficient for locating the position of the point on the surface of the sphere.

The accompanying figure represents reference frames for both spherical and also 3-dimensional rectangular



coordinates. In setting up the spherical system an origin, O is first selected, and assumed to be the center of the sphere of reference. A line, AB, is then passed through the origin and must intersect the sphere in diametrically opposite points. This line is known as the fundamental line for the spherical system. A plane is then passed through the origin perpendicular to the fundamental line, and this plane becomes known as the fundamental plane. Since the fundamental plane passes through the center of the sphere it must intersect the sphere in a great circle, $CEHI$. Since the fundamental plane is perpendicular to the fundamental line, AB, the points A and B must be poles of the great circle on the sphere. For reference purposes some fundamental direction, say OI in the figure, must be selected in the fundamental plane.

To determine the position of the point, P, on the sphere a plane, $AOBHP$, is passed through the fundamental line, intersecting the surface of the sphere in the great circle, $APHB$. One angular coordinate, α in the figure, is measured in the fundamental plane from the fundamental direction to the line of intersection of the plane passed through the point with the fundamental plane. The other angular coordinate, β in the figure, is measured in the plane, $AOBHP$, through the point from the fundamental plane to the radius of the sphere through the point P. Both angular coordinates may be measured by the arcs of the great circles cut out on the sphere by the planes involved, e.g., α may be measured by the arc, IH, of the fundamental plane, and β by the arc, HP, of the plane through the point and the fundamental line.

To define the position of P in 3-dimensional space referred to the point O as origin the radius of the sphere, ρ, is also necessary. The transfer from spherical to **rectangular coordinates** may readily be made by passing the XY, XZ, and XY planes through the sphere as shown in the figure. Then we have at once:

$$x = \rho \cos\beta \cos\alpha; \quad y = \rho \sin\beta; \quad z = \rho \cos\beta \sin\alpha,$$

$$\rho^2 = x^2 + y^2 + z^2; \quad \tan\alpha = \frac{z}{x}; \quad \tan^2\beta = \frac{y^2}{x^2 + z^2}.$$

(W.K.G.)

SPHERICAL HARMONICS. A spherical harmonic is frequently defined as any homogeneous **polynomial** V_n in the variables x, y, z of the n^{th} degree which satisfies **Laplace's equation**

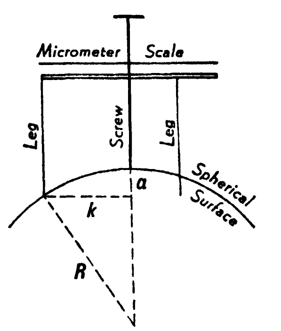
$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0.$$

If this equation is transformed to **spherical coordinates** r, θ, ϕ, the solution is called a solid spherical harmonic, U_n. If this function be divided by r^n, we obtain a function of θ and ϕ only, which is called a surface spherical harmonic. When the spherical harmonic is independent of ϕ, it is called a surface zonal harmonic and satisfies Legendre's equation, and is therefore a **Legendre function.** (L.L.S.)

SPHEROCLAST. Phenoclast.

SPHEROIDAL STATE. Ebullition.

SPHEROMETER. An instrument for measuring the curvature of solid spherical surfaces, either convex or concave, such as those of lenses; a measurement in which high precision is not easily attained. The most familiar mechanical device for this purpose is a form of **micrometer.** It resembles a small three-legged stool, the sharp steel points of whose legs form an equilateral



Diagrammatic section of spherometer.

triangle. The micrometer screw, also with a sharp point, is mounted at the center of this supporting trivet, and is adjusted to read zero when all four points are in one plane, as determined by standing the instrument on a flat plate of glass and screwing the micrometer point down to it. The distance from each of the legs to the central axis must be accurately known. If it is called k, and if the elevation (or depression) of the micrometer point to fit a given spherical surface is a, then the radius of curvature of the surface is readily calculated as

$$R = \frac{k^2 + a^2}{2a}.$$

The chief sources of error are in determining just when contact takes place between micrometer point and surface, and in measuring k. (L.D.W.)

SPHERULITES. In lavas there are frequently to be found radial or concentric aggregates of **mineral** crystals from microscopic size to an inch or two in diameter, although rarely their dimensions may be much greater. These radial aggregates are believed to be the result of rapid growth of small **crystals** at favorable points in the quickly cooling lava. (E.S.C.S.)

SPHINCTER. A ring of muscle fibers surrounding a hollow organ or the opening of a duct. By their contraction sphincters constrict or close the passages with which they are associated. Muscles of this kind are found in the iris of the **eye** around the margin of the pupil, in the wall of the **anus,** at the union of the urethra with the urinary **bladder,** at the **pylorus** between the stomach and the duodenum, and in other similar relations. (A.W.L.)

SPHYGMOMANOMETER. An apparatus for measuring the **blood pressure.** It consists of a rubber-bag cuff which is wrapped around the upper arm. This is inflated by a hand bulb. The cuff is connected by rubber tubing to a measuring device which is either a sealed column of mercury or a spring scale. Sufficient pressure is pumped into the rubber cuff to compress the brachial artery in the upper arm. A stethoscope is applied over the artery below the cuff and air is gradually allowed to escape from the cuff until the pulse can be heard. The reading on the scale or column of mercury at this point indicates the systolic pressure or the highest pressure in the arteries during contraction of the **heart.** The deflation of the cuff is continued, and that point on the scale when the last sound of the disappearing pulse is heard is the diastolic pressure, or lowest pressure in the artery during diastole, or relaxation of the heart muscle between beats. The normal systolic reading of an adult varies from 110 to 130 or 140 mm. of mercury. Normal diastolic readings vary from 60 to 90 mm. of mercury. (R.S.M., D.M.H.)

SPICA. Spica (α **Virginis**) is a brilliant first **magnitude star.** Spica is particularly interesting in that it is believed to be the star that provided Hipparchus with the data which enabled him to discover the **precession** of the equinoxes. The temple at Thebes was oriented with reference to Spica in about 3200 B.C. Later, temples which were oriented to this same star indicated the motion of the star due to precession and provided the necessary data. (W.K.G.)

SPICULE. A small hard body formed within the tissues of animals. Spicules are formed in all sponges (**Porifera**) by cells called scleroblasts in the mesogloea. They vary in form from simple rods to complex structures radiating from a common center on three to six axes. Some are straight with expanded ends. In the **coelenterates** spicules appear only in some of the **alcyonarians,** where they are formed in the mesogloea by cells that migrate from the ectoderm. The term has also been applied to the radiating hard structures of the 1-celled **radiolarians.** The formation of bone in the embryos of vertebrates begins with the deposition of spicules which are later consolidated into larger masses of bone. (A.W.L.)

SPIDER. Arachnida, Araneina. **Arthropods** of almost exclusively terrestrial habits, known commonly for their ability to spin silken webs. They differ from other arthropods in one or more of the following characters: The body is divided into **cephalothorax** and abdomen, and the latter is unsegmented. The head bears a group of simple eyes. Four pairs of legs are present. The jaws are perforated by the ducts of poison glands. The ventral surface of the abdomen bears the openings of the **lung books,** respiratory organs of peculiar form, and a group of **spinnerets** through which the ducts of the silk glands open.

Spiders are widely known and unaccountably repulsive. In fact, they are among the most interesting of all animals, and with a single known exception, the black widow spider, are harmless. Even though they secrete poison most of them are too small to bite a human being unless on a very thin fold of tissue, and most seem to have no inclination to bite. Even the large hairy species commonly called banana spiders or tarantulas are mild-mannered creatures.

To what extent the bad reputation of the black widow, *Latrodectus mactans*, is deserved seems difficult to establish. Apparently its bite is severely poisonous and occasionally fatal, and apparently it is vicious in habits. There is contradictory evidence, however, so the case is not wholly settled.

Spiders vary greatly in habits. Some spin funnel-like webs in which they hide to await their prey, others

form irregular webs, and still others make the orb webs so beautifully demonstrated in our gardens on dewy mornings. Other forms spin no web but capture their prey by pouncing on it from concealment or by open chase. Among these forms are the crab spiders, named from their short broad form, which lie in wait on plants and are sometimes almost perfectly hidden in flowers by their concealing coloration. The wolf spiders are stout hairy species, often black in color. They hunt like the predators for which they are named.

The spiders that capture prey without the use of webs have other uses for silk, such as the formation of cocoons or egg-sacs in which the eggs are deposited, and the construction of a smooth lining for their hiding places. The most remarkable example of the latter use is the nest of the trapdoor spiders of warm regions. These nests consist of a silk-lined burrow with a beveled margin at the surface of the ground. A lid hinged with tough silk fits perfectly into this beveled depression and can be held shut by the spider, which provides in its lining two depressions to be gripped by the claws.

The mating habits of spiders are also remarkable. The male, in many species much smaller than the female, goes through a courting procedure as complex as that of the birds, and is often killed by his consort. Reproductive adaptations are also peculiar in the males, in that the **palpi** are modified to convey the seminal fluid to the genital passages of the female. When sexually mature the male spins a web in which the contents of the reproductive organs are discharged, to be taken up into the cavities in the palpi. When the individual is successful in securing a mate he thrusts the palpi one at a time into her genital aperture. (A.W.L.)

SPIKE. **Flower.**

SPIKE, HOOK-HEAD RAILWAY. **Railway Track. Spline. Key.**

SPIKELET. **Flower.**

SPILITE. A term used to define a **basaltic** rock whose **feldspars** are chiefly **albite** or soda-rich oligo**clase.** (R.M.F.)

SPILLWAY. One of the important adjuncts of a **dam** of the overflow type is a spillway, which is simply an opening through or over which excess water may flow when the reservoir is full. The spillway may be a certain overflow section of the dam, or it may be cut in rock along the normal reservoir line at one side of the dam. It is necessary for the crest to be sufficiently long that maximum expected floods may be passed through it without the depth of water on the spillway crest exceeding a predetermined depth. A plain spillway fixes the maximum depth of water in the reservoir. The discharge over a spillway is something like that over a weir, and the rate of flow is proportional to the length of crest and the $\frac{3}{2}$ power of the **head** over the crest. It is possible to raise the water level several feet above the spillway, and yet preserve the safety features, by equipping it with crest gates, which normally will be lowered onto the crest of the spillway, obstructing it and raising the water level, but which may be raised out of the way and leave the stream unobstructed during the flood seasons. (See **Gates.**) (F.T.M.)

SPINAL ANAESTHESIA. **Anaesthesia.**

SPINAL CORD. The large axial structure of the central **nervous system** of **vertebrates**, extending from the brain back through the body. It lies in the dorsal body wall and is surrounded by the neural arches of the **spinal column**. It consists of nerve tracts or aggregations of fibers for communication of impulses to and from other parts of the nervous system, and of nuclei, which are aggregates of cell bodies of **neurons**.

In man the spinal cord is a cylindrical mass of nervous tissue about 18″ long within the vertebral canal of the spine. Thirty-one pairs of nerves are attached to the **spinal cord**. The spinal cord diminishes in size from above downward, and is suspended within the spinal canal by certain ligaments and membranes, and bathed in **spinal fluid**.

The functions of the spinal cord are exceedingly complex, and cannot be understood without a thorough knowledge of the equally complex anatomy. In general, the cord may be said to be the central receiving and distributing plant for all nervous impulses going to and coming from all parts of the body. This includes sensory and motor impulses, voluntary and involuntary impulses, and **reflex** impulses. Some of the fiber tracts running in the cord have elaborate connections with the higher centers in the **cerebrum**, where conscious control is exerted. (A.W.L., R.S.M., D.M.H.)

SPINAL FLUID. The spinal canal contains spinal fluid which is in free communication with the fluid surrounding the brain and filling its ventricles. This fluid is produced by the vascular choroid plexus of the ventricles of the **brain**. It is crystal clear and contains minute amounts of chlorides and other inorganic salts, plus traces of glucose and plasma proteins. The spinal fluid serves as a fluid cushion for the **spinal cord**. Removal of spinal fluid by means of a spinal tap is commonly used for diagnostic information and therapeutic procedures. The fluid is cultured for bacterial growth, examined chemically, the cells counted, and its pressure within the canal measured, as well as other specific tests. (A.W.L., R.S.M., D.M.H.)

SPINDLE. **Shaft.**

SPINE. The vertebral column or backbone, in man, composed of thirty-three vertebrae which, grouped according to regions, are as follows: seven cervical, twelve thoracic, five lumbar, five sacral, and four coccygeal vertebrae. (R.S.M.)

SPINEL. The mineral spinel is one of a group of minerals which crystallize in the **isometric** system with an **octahedral** habit, and whose chemical compositions are analogous. These minerals are combinations of bivalent and trivalent oxides of **magnesium, zinc, iron, manganese, aluminum,** and **chromium,** the general formula being represented as $R''O \cdot R'''_2O_3$. The bivalent oxides may be MgO, ZnO, FeO, and MnO, and the trivalent oxides Al_2O_3, Fe_2O_3, Mn_2O_3, and Cr_2O_3. The more important members of the spinel group are **spinel,** $MgAl_2O_4$; **gahnite,** zinc spinel, $ZnAl_2O_4$; **franklinite** $(Fe \cdot Mn \cdot Zn)$, $(Fe \cdot Mn)_2O_4$, and **chromite,** $(Fe \cdot Mg)Cr_2O_4$. True spinel has long been found in the gem-bearing gravels of the Island of Ceylon and in the limestones of Burma and Siam. Spinel usually occurs in isometric crystals, octahedrons, often twinned. It has an imperfect octahedral **cleavage**; conchoidal fracture; is brittle; hardness, 8; specific gravity, 3.5–4.1; luster, vitreous to dull; transparent to opaque; streak white; may be colorless, rarely through various shades of red, blue, green, yellow, brown, or black. These colors are doubtless due to small amounts of impurities. The clear red spinels are called spinel-rubies or balas-rubies and were often confused with genuine rubies in times past. Rubicelle is a yellow spinel. A violet-colored manganese-bearing spinel is called almandine. Spinel is found as a **metamorphic** mineral, also as a primary mineral in **basic rocks**, because in such **magmas** the absence of alkalies prevents the formation of feldspars, and any aluminum oxide present will form corundum or combine with magnesia to form spinel. **This fact ac-**

counts for the finding of both ruby and spinel together. Besides the localities mentioned above, in Burma and Siam, the Ceylon yields beautiful specimens. Spinel is found in Italy and Sweden and on the Island of Madagascar. Also in the United States in Orange County, New York, and in Sussex County, New Jersey, are many well-known spinel localities. Spinel is found also in Macon County, North Carolina, and in Canada in Quebec and Ontario. The name spinel is derived from the Greek, meaning a spark, in reference to the fire-red color of the sort much used for gems. Balas ruby is derived from Balascia, the ancient name for Badakhshan, a country of central Asia situated in the upper valley of the Kokcha River, one of the principal tributaries of the Oxus. (E.S.C.S.)

SPINNERET. A spinning organ of the **spiders**. The spinnerets are located on the ventral surface of the abdomen, near or at its tip, and vary from one to three pairs. They are conical to cylindrical in form. Each has a membranous terminal portion called the spinning field, through which run many minute spinning tubes from the silk glands. The nature of the spinning tubes varies, different tubes producing different kinds of silk.

In the act of spinning the liquid silk is forced through the spinning tubes, to harden on exposure to the air as silk. The spinnerets bear spines, some of them apparently tactile, and are moved by muscles, so that the spider is able to form and place its threads with precision. See page 243 for use of spinneret in formation of rayon filaments. (A.W.L.)

SPINNING. Ductile sheet metals that can be cold-drawn can also be fabricated by spinning into cylinders and other shapes having rotational symmetry. The sheet blank is held in a spinning lathe between a former or chuck, which establishes the inside contour, and a rotating tailstock. The sheet is worked by means of pressure of a tool against the outer surface. Several chucks of progressively deeper contour may be required for deep vessels, and the metal may require process annealing between operations to overcome the work-hardening. Soft aluminum, copper, brass, and low-carbon steel are readily shaped by spinning, while harder metals such as stainless steel can be spun with proper tooling and annealing practice.

Spinning is a relatively inexpensive process especially suited to the production of small numbers of parts for which the cost of drawing dies would be excessive. It is sometimes used in combination with drawing and other fabricating operations. (See **Press Working.**) (R.H.H.)

SPINTHARISCOPE. A simple apparatus, also called a scintilloscope, designed by Sir William Crookes for observing the scintillations produced by alpha rays (see **Radiactive Emissions**). It consists of a short metal tube with a screen of phosphorescent zinc sulfide closing one end, and a strong magnifying lens at the other, focused upon the screen. Projecting out in front of the screen, inside the tube, is a narrow metal point, the tip of which bears a trace of radium. The alpha particles emitted by the radium fall upon the screen and produce scintillations which, under suitable conditions, are plainly visible through the lens, looking like minute sparks. To see them clearly, one must have been in a dark room for some minutes; also care should be taken not to expose the screen to a strong light beforehand, or its phosphorescence may obscure the scintillations. A large-scale modification of the instrument has been used for counting scintillations and hence estimating the emission of alpha particles from radioactive substances. (L.D.W.)

SPINULOSA. Asteroidea.

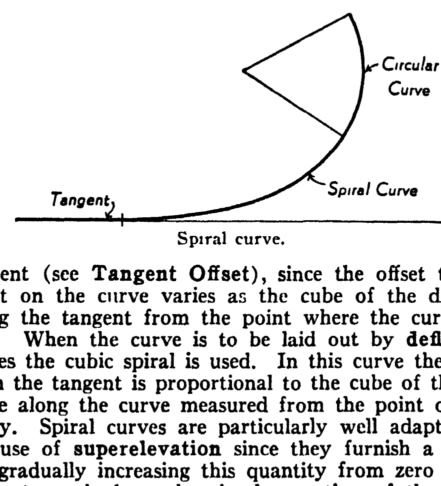
SPINY ANTEATER. Echidna.

SPIRACLE. 1. A small opening on the surface of the insect body, leading into an air tube of the **respiratory system**. Insect spiracles are simple openings in some species, but usually they are guarded by some structure which prevents the entrance of foreign particles. This guard varies from a fringe of hairs to an elaborate sieve-like plate. Some insects depend on a closing apparatus of the associated **trachea** for the exclusion of particles.

In the primitive condition spiracles apparently were paired and **metameric**, one opening on each side of each segment. This arrangement is only slightly modified in some species, which are said to be peripneustic. In other cases the number of openings is greatly restricted, only one or two pairs providing the sole entrance to the respiratory apparatus. Insects with a single pair at the anterior end of the body are called propneustic, those with a pair at the posterior end metapneustic, and those with a pair at each end amphipneustic. The spiracles may also be associated with tubes, either extending the tracheae beyond the general surface of the body or forming external conduits for air, by which the insect may reach the air from within the water or decaying matter in which it lives. 2. The greatly reduced external opening representing the first of the series of **gill slits** in elasmobranch fishes. (A.W.L.)

SPIRAL BEVEL GEARING. Bevel Gearing.

SPIRAL CURVE. In railway or highway alignments a spiral curve, sometimes called an easement or transsition curve, is one which provides a gradual change of curvature when passing from a tangent (straight line) to a circular curve. The cubic parabola and cubic spiral are curves well suited for this purpose. The former is used when spirals are to be laid out by offsets from the



Spiral curve.

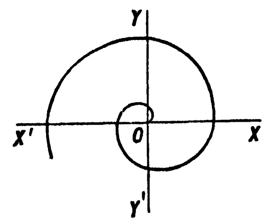
tangent (see **Tangent Offset**), since the offset to any point on the curve varies as the cube of the distance along the tangent from the point where the curve begins. When the curve is to be laid out by **deflection** angles the cubic spiral is used. In this curve the offset from the tangent is proportional to the cube of the distance along the curve measured from the point of tangency. Spiral curves are particularly well adapted for the use of **superelevation** since they furnish a means for gradually increasing this quantity from zero to the amount required on the circular portion of the curve. Railroads use a combination of spiral and circular curves to connect the tangents on their main lines. The value of the spiral is being recognized in modern highway design for high-speed traffic. (C.W.C.)

SPIRAL GEARING. Helical gears used for transmitting power between shafts whose axes are neither parallel nor intersecting are commonly, although incorrectly, called spiral gears. They may be adapted to any shaft axes angle, although they are usually employed for shaft axes at 90° to each other. The tooth elements are similar to those of parallel-shaft helical gears; the usual method of tooth measurement is by normal diametral pitch P_n. In 90° shaft-angle gearing, both pinion and gear have helical teeth of like hand, with complementary helix angles H_p and H_g. Spiral gear pitch diameters, like parallel-shaft helical gear diameters, may be adjusted in design to accommodate a special or unusual center dis-

tance. Power-transmitting capacity of spiral gearing is limited. Although some operating characteristics are analogous to worm gearing, the contact area between the teeth of spiral gears is theoretically a point, and in actual practice is confined to a very small area. Spiral gears are generally used when motion rather than power is of major importance. (See **Helical Gearing.**) (H.C.H.)

SPIRAL MILLING. **Milling.**

SPIRAL OF ARCHIMEDES. The spiral of Archimedes is a mathematical curve of spiral form, as shown in the accompanying figure. Its equation in polar coordinates is $r = a\theta$. (L.L.S.)



Spiral of Archimedes.

SPIRAL VALVE. A thin ridge projecting from the lining of the intestine of elasmobranch fishes to the center of the cavity and following a spiral course through the length of the tube. The structure provides greatly increased surface for the digestion and absorption of food. It is so arranged that the food must follow a spiral course, but beyond this regulating effect is not a valve in the usual sense. It merely slows the passage of food. (A.W.L.)

SPIRALS. In mathematics, the term spiral is applied to a number of curves. The important spiral curves are: the **spiral of Archimedes**, the **logarithmic spiral** (or equiangular spiral), the **hyperbolic spiral**, the **parabolic spiral**, and the **lituus.**

In astronomy, the use of the term spiral is as follows. For many years the extra-galactic **nebulae** were known as spiral nebulae, but recent researches have proved conclusively that they are a totally different class of objects from the galactic nebulae. Their **spectra,** instead of being characterized by the bright lines commonly found in the galactic nebulae, are of the absorption type such as would be produced by a large number of stars of various **spectral classes.** Long-exposure photographs of the extra-galactic nebulae, taken with instruments of long focal length, have definitely proved the hypothesis that these objects are in reality large groups of very distant stars.

In at least five of the extra-galactic nebulae **Cepheids** have been discovered, and the application of the period-luminosity relation for Cepheids gives distances of between 100,000 and 1,000,000 **light years** from the sun. By various statistical methods, largely developed by Hubble at the Mount Wilson Observatory, the distances of a number of other extra-galactic objects have been obtained. Distances of the order of magnitude of one billion (1,000,000,000) light years have been obtained; which seems to be about the limiting distance at which these objects can be distinguished with the 100-in. telescope. Researches on the distances of the extra-galactic nebulae will be one of the first problems for the new 200-in. telescope.

The extra-galactic nebulae are classified by Hubble as: 1. Spirals (with subdivisions of normal spirals and barred spirals. 2. Elliptical. 3. Irregular. A more detailed subdivision of each main type has been suggested, but is too complex to be considered here. Of the extra-galactic nebulae which are bright enough to have been classified thus far, about 77% belong to the first type, 20% to the second type, and 3% to the third.

The normal spirals are characterized by two main whorls, each of which may have several branches, which come out from opposite sides of a large central condensation and wind about this condensation in the same plane and in the same direction. The central condensation is distinctly ellipsoidal in form, being much more extensive perpendicular to the plane of the whorls than are the whorls themselves. The spirals are found in all types of orientation, some with the plane of the spiral perpendicular to the line of light, and in others with the whorls seen edge on. In the latter cases a dark bank is observed passing across the nucleus as though there was a dark extension in the plane of the whorls which would otherwise be unobserved. The barred spirals differ from the normal spirals in that the arms begin at the ends of a long bar which extends outward from the central condensation or nucleus.

The elliptic extra-galactic nebulae show no structural forms even when examined with the most powerful instruments. They are ellipsoidal in form, ranging from spheres to thin lens-shaped volumes. The elliptic nebulae which apparently have the largest size, are the companions to the Andromeda spiral.

The irregular extra-galactic nebulae are relatively rare objects. As the name implies, they have no definite form, and appear like clouds in space. The largest one known is found in the constellation of Sagittarius.

A spectrographic study of some of the brighter spirals indicates that these objects are in rotation about their minor axes. From the rotational speeds and sizes of these objects Hubble estimates their total masses to be of the order of magnitude of 600,000,000 to 1,000,000,000 times the mass of the sun.

The absorption lines in the spectra of the extra-galactic nebulae show strong displacement to the red, with the amount of displacement increasing with the distance of the object from the sun. If this "red shift" is interpreted as a **radial velocity** effect it implies that all of the extra-galactic nebulae are receding from the sun, with the more distant ones receding the more rapidly. The implication from these results is that the entire universe of nebulae is expanding, and several attempts have been made to explain this theoretically. However, Hubble and other observational workers are by no means convinced that the red shift of the lines in extra-galactic nebular spectra is due to a radial velocity effect, although they are unable as yet to find any other satisfactory explanation. Until the question as to whether these observations prove the expansion of the universe is answered, it does not seem desirable to enter upon a discussion of so controversial a problem.

Statistical studies of extra-galactic nebulae indicate that there are between 50 and 100 million of these objects within the limiting distance of observation with the 100-in. telescope. Studies of the distribution of these objects throughout the immense volume of space (approximately 1,000,000,000 light years in extent) indicate clustering of the objects in certain regions. The surveys are still in progress and results are uncertain, but it seems probable that there are galaxies of galaxies in space. The suggestion has been made that our own **galactic system** may be such a group. (L.L.S., W.K.G.)

SPIRE. The portion of a conical **snail** shell above the large whorl into which the aperture leads. (A.W.L.)

SPIRIFIER. **Invertebrate Paleontology.**

SPIRILLUM. **Bacteria.**

SPIROGYRA. **Algae.**

SPITTLE BUG. **Frog Hopper.**

SPLEEN. An organ of vertebrates derived from **mesenchyme** and lying in the **mesentery.** It is closely associated with the **circulatory system.** The organ consists of masses of tissue of granular appearance, known as lymphoid tissue, located around fine terminal branches of veins and arteries. According to one interpretation, these vessels are connected through the spleen pulp by modified capillaries called splenic sinuses. The pulp is supported by a reticular tissue foundation and contains blood cells of all kinds in addition to the characteristic mesenchymal cells. The functions of the organ are the formation of **blood** cells, the destruction of old red corpuscles, the removal of other debris from the blood stream, and as a reservoir for blood.

The human spleen is situated in the left upper part of the abdomen, behind the stomach, just below the diaphragm. This organ, in the normal individual, measures about 5″ by 3″ by 2″ in size. In certain diseases it often increases in size, and it may even fill a large portion of the left side of the abdomen. The spleen enlarges in **malaria, bacterial endocarditis, leukemia, pernicious anemia, Hodgkins' disease, Banti's disease, tumors,** and **cysts** of the spleen.

The spleen is classified as a ductless gland. Its presence is not necessary for life. It may be removed surgically and often is, following abdominal injuries with rupture and hemorrhage from the spleen, or in the treatment of certain blood diseases (**hemorrhagic purpura, familial jaundice,** etc.), or for the removal of splenic tumors or cysts. Congenital anomalies such as accessory spleens occur, and rarely the spleen has been found to be completely absent. The ancients are said to have removed the spleen from runners, believing that this increased their speed. (A.W.L., D.M.H.)

SPLICE. A splice is a connection which is used to transfer **stress** in a direct line between two adjacent members or between the separate, adjacent parts of the same member. In general, a splice consists of splice material and **fastenings,** each of which must be strong enough to carry the stress. Structural steel is spliced by plates or angles which are fastened by means of **rivets, bolts** or **welding.** A **gusset plate** is not ordinarily considered a splice plate unless it is used in conjunction with other splice material to transfer stress between adjacent **chord** members at a **joint.** Structural timber is spliced by steel plates and bolts or by additional splice timbers which are connected by bolts or by timber connectors. The reinforcing rods of **reinforced concrete** are spliced by welding or by overlapping them far enough to assume that bond (see **Bond Stress**) will produce the stress transfer.

Splices are made for two reasons. First, there is a limiting length to all manufactured material. When the length of the member exceeds the limiting length of any of its parts, it is necessary to use two or more pieces for each of these parts. Splices are used to form one continuous piece. Secondly, transportation conditions and erection equipment limit the length of structural members or parts of structures which can be completed at a fabricating plant. This necessitates a field connection. A splice which is made at a fabricating plant is a shop splice while one made in the field is a field splice. (C.W.C.)

SPLIT SWITCH. Railway Track.

SPLIT-TAIL. Pisces, Teleostei. A small silvery minnow, *Pogonichthys macrolepidotus,* of central California. (A.W.L.)

SPODUMENE. The mineral spodumene is a **lithium aluminum silicate** corresponding to the formula $LiAl(SiO_3)_2$ and occurs in **monoclinic** prismatic crystals, occasionally of very large size. It also occurs massive. Spodumene has a perfect prismatic **cleavage** often very noticeable; uneven to splintery fracture; brittle; hardness, 6.5–7; specific gravity, 3.13–3.20; luster, vitreous to pearly; color, grayish- to greenish-white, green, yellow and purple. Its streak is white; it is transparent to translucent. Spodumene is characteristically a mineral of the **pegmatites,** and it is found in Sweden, Ireland, Madagascar and Brazil. In the United States it is found especially in the pegmatites of Oxford County, Maine; in the towns of Goshen, Huntington and Chesterfield in western Massachusetts; at Branchville, Connecticut; in North Carolina; in South Dakota in huge crystals and in San Diego and Riverside Counties in California. The name spodumene is derived from the Greek meaning ash-colored, particularly appropriate for the slightly weathered varieties. Hiddenite, the beautiful emerald-green or yellow-green spodumene that is used as a gem, was named for W. E. Hidden. Kunzite, named in honor of the late George F. Kunz, is a transparent lilac to rose-colored spodumene from Madagascar and California, also used as a gem stone. Spodumene alters rather readily to a mass of **albite** and **muscovite.** The commercial use of spodumene is chiefly as a source of lithium compounds. (E.S.C.S.)

SPONDYLITIS. Infection of the vertebrae of the of the spine. Tuberculous and pyogenic **osteomyelitis** are the common causes. (D.M.H.)

SPONGE. An animal of the phylum **Porifera.** In the vernacular the word refers to the sponge of commerce, which is the skeleton of a sponge from which the animal matter has been removed by maceration and washing. The material of which these sponges are composed is spongin. Calcareous (**calcium**) and siliceous (**silicon**) sponges are, of course, too harsh for similar use.

Commercial sponges are derived from various species and come in many grades, from the fine soft lambs' wool sponges to the coarse grades used for washing cars. They come from fisheries in the Mediterranean and in the West Indies and nearby waters. The industry has reached a value of about $3,000,000 annually but the manufacture of substitutes from rubber and cellulose is destined to reduce its importance. Cellulose sponges, in particular, have the good qualities of natural sponges with greater uniformity. (A.W.L.)

SPONGIN. A horny material found in the skeletons of sponges. In some species it unites **spicules** of other materials and in some it forms fibers in which the spicules are imbedded. The sponges of commerce have a skeleton formed wholly of a fibrous mass of spongin. (A.W.L.)

SPONGIOBLAST. A form of cell in the mesogloea of **sponges** by which the fibrous structures of the body are formed. (A.W.L.)

SPOONBILL. 1. Pisces, Chondrostei. The **paddlefish** of the Mississippi River system. 2. Aves, Ciconiiformes. Large long-legged wading birds related to the herons and flamingoes. The beak is very long and broad, with the terminal portion still further broadened to give it a spoonlike form. 3. Aves, Anseriformes. The **shoveller ducks.** (A.W.L.)

SPORANGIUM. Flower.

SPORE. A spore is a special type of reproductive cell which develops directly into a new plant. Spores are of many kinds. In the Thallophytes they may be asexual cells or zygotes. Thick-walled spores formed after the union of isogametes are called zygospores. **Oöspores**

are fertilized eggs. In the higher plants spores are always produced by diploid plants and develop into haploid gametophytes. In Selaginella and the seed plants small spores, microspores, produce male gametophytes; large spores, megaspores, produce female gametophytes. Pollen grains in the seed plants are microspores. (See also **Paleobotany.**) (R.M.W., B.S.M.)

SPOROBLAST. A stage in the life cycle of some of the 1-celled animals of the class **Sporozoa.** After **fertilization,** the **nucleus** of the **zygote** subdivides. Each of the daughter nuclei, together with a surrounding mass of **cytoplasm,** becomes a sporoblast which secretes an enveloping membrane and becomes a spore. (A.W.L.)

SPOROCYST. A stage in the life cycle of some 1-celled animals, characterized by the presence of a heavy protecting wall enclosing a number of separate cells, the **spores.** (A.W.L.)

SPORONT. The stage in the **reproductive** cycle of 1-celled parasites of the class **Sporozoa** which subdivides to produce the active **sporozoites.** The sporozoites begin a new life cycle. (A.W.L.)

SPOROPHORE. **Fungi.**

SPOROPHYLL. A sporophyll is a **spore-bearing leaf.** It actually bears the sporangia which contain the spores. It may be greatly modified in structure and appearance. (R.M.W., B.S.M.)

SPOROPHYTE. In plants in which there is a distinct **alternation of generations,** the generation which bears the spores is called the sporophyte generation. A spore-bearing plant is a sporophyte. Its cells all contain the diploid or double number of **chromosomes.** (R.M.W.)

SPOROSAC. A **sessile** medusoid (**medusa**) that remains attached to the parent colony. Since the medusoids produce reproductive cells, these individuals, without need for locomotion, retain no other conspicuous function. (A.W.L.)

SPOROTRICHOSIS. A fungus infection caused by the genus *Sporothrichium.* It is characterized by tumor-like nodules, abscess formation and ulcers of the skin. Most of the cases in the United States have been reported in the Middle West where the parasite has been found on vegetable matter.

Treatment by **iodine** compounds orally is usually successful in arresting the disease. (R.S.M., D.M.H.)

SPOROZOA. One-celled animals of parasitic habits which are usually incapable of locomotion. The immature stages of some species form pseudopodia but neither cilia nor **flagella** are ever present. A class of the phylum **Protozoa.**

The sporozoans absorb nutriment from the body of the host, a type of nutrition rarely possible save in parasites. In connection with their parasitic habits also they undergo intricate cycles of **reproduction,** often associated with life in alternating hosts of different species. They attack animals of almost every phylum, sometimes with fatal results or with more or less serious disturbances of normal functions. In man these relations are illustrated by the **malarial** parasites whose complex life cycle is completed in Anopheles **mosquitoes** and the human blood stream. Malaria, the result of their presence in the human body, varies from the periodic chills and fever of the milder forms to an extremely virulent disease.

The classification of the sporozoans is work for an expert, depending upon highly technical distinctions. In brief summary the class is divided as follows:

- Subclass Telosporidia.
  - Order Coccidia. Intracellular parasites in digestive **epithelium.** Some are transmitted by blood-sucking animals. Parasitic in invertebrates and vertebrates.
  - Order Haemosporidia. Parasitic in the blood of vertebrates and in the alimentary tract of blood-sucking invertebrates. The malarial parasites belong here.
  - Order Gregarinida. Parasitic in various stages in the cells and in the cavity of the invertebrate intestine.
- Subclass Cnidosporidia.
  - Order Myxosporidia. Mostly parasitic in fishes; a few in amphibians and reptiles.
  - Order Actinomyxidia. In the body cavity or the lining of the alimentary tract of aquatic **annelids.**
  - Order Microsporidia. Mostly intracellular parasites in **arthropods** and fishes.
  - Order Helicosporidia. A single known species, parasitic in insects.
- Subclass Acnidosporidia.
  - Order Sarcosporidia. Parasitic chiefly in the muscles of mammals, some in birds and reptiles.
  - Order Haplosporidia. Found in invertebrates and lower vertebrates. (A.W.L.)

SPOROZOITE. A stage in the reproductive cycle of the 1-celled parasites of the class **Sporozoa.** The sporozoites are the active individuals formed by the subdivision of the zygote or sporont. (A.W.L.)

SPORULATION. The process of **spore** production, a type of reproduction more common in plants than in animals, but highly developed in some of the 1-celled forms. In this process the parent cell subdivides to form a number of smaller active cells which begin a new life cycle. (A.W.L.)

SPOT FACE. **Counterbore.**

SPOT WELDING. **Welding.**

SPOT-TAIL. Pisces, Teleostei. A small **minnow,** *Hybopsis hudsonius,* widely distributed and abundant in the fresh waters of the eastern half of the United States. Also called the **shiner.** It usually has a black spot at the base of the tail. A species with a similar mark in a closely related genus, *Cyprinella stigmatura,* is called the spotted tail. The latter is found only in the southeast. (A.W.L.)

SPRAIN. A variety of injuries in or about a joint which occur when the movement of the joint is carried beyond its normal range, or forcibly in a direction where its range is limited. Sprains occur in the ankle, knee, wrist, elbow, and spine, in that order of frequency. An injury in which a sudden wrenching or twisting produces tearing of the **ligaments** or **tendons** is a common form of sprain. Displacement of **cartilages** between joints, tearing of muscles around the joint, and tearing of the synovial membrane are others. The symptoms of a sprain are those of **inflammation** with pain, swelling, and limitation of motion of the part.

Treatment consists of immobilization of the joint with an adhesive strapping or an elastic bandage, elevation of the extremity, and sometimes aspiration of the joint cavity if an effusion or outpouring of inflammatory fluid occurs. (D.M.H.)

SPRAT. Pisces, Teleostei. A small marine food fish (**Pisces**), *Clupea sprattus,* related to the herring. It occurs on the Atlantic coast of Europe. (A.W.L.)

SPRAY PATTERN. Foundry Practice.

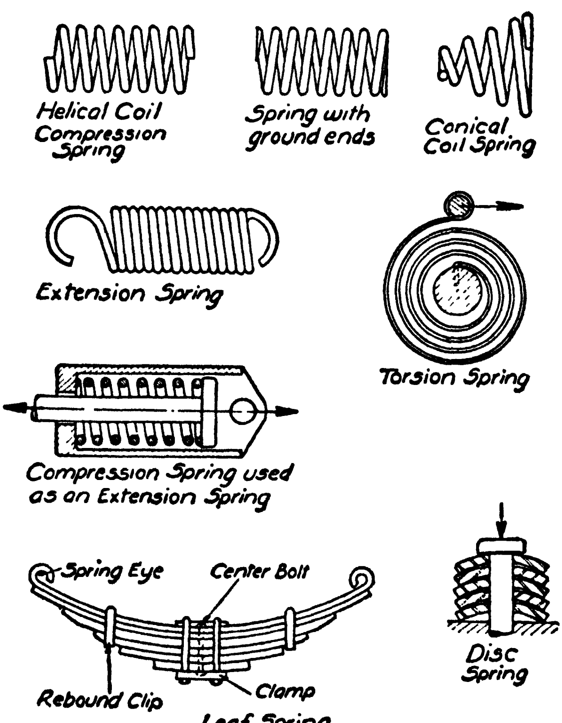
SPRING INDEX. The ratio between the mean diameter of the coil of a helical compression spring and the diameter or radial thickness of the spring wire or strip. The spring index is used as a modifier in computing the safe load a spring may carry. (H.C.H.)

SPRING PEEPER. Amphibia, Anura. A tree **frog,** *Hyla crucifer,* about an inch in length, with an elongate X on its back. The color varies greatly, including shades of brown, yellow, green and gray. The species is found through most of the eastern half of North America. It is named from the early appearance of the animals in the spring, when their not unmusical tones are one of the first indications that hiberating animals are active again. (A.W.L.)

SPRING TAIL. Collembola.

SPRINGBOK. Mammalia, Artiodactyla. A small South African **antelope,** *Antidorcas marsupialis,* of striking appearance. One of the **gazelles.** The animal is cinnamon and white with a dark brown streak on the sides. (A.W.L.)

SPRINGS. Used to absorb energy or shock as in automobile chassis springs; to serve as a source of power as in clocks or watches; and to provide a force to maintain pressure between contacting surfaces as in friction clutches. Springs with ground ends are generally more



satisfactory than those with plain ends; compression springs are more desirable for heavy loads than extension springs, because of the possibility of stress concentration in the loop of the extension spring. Compression springs can, however, be employed for tensile loading. Conical coil springs, if properly designed, may be compressed flat under load. Disk springs represent a recent development that is being extensively employed for heavy loads. Laminated or leaf springs are used in vehicles of various types, although coil springs are now being used in automotive applications. Coil springs may be made of square, rectangular, or round wire. (See also **Ground Water.**) (H.C.H.)

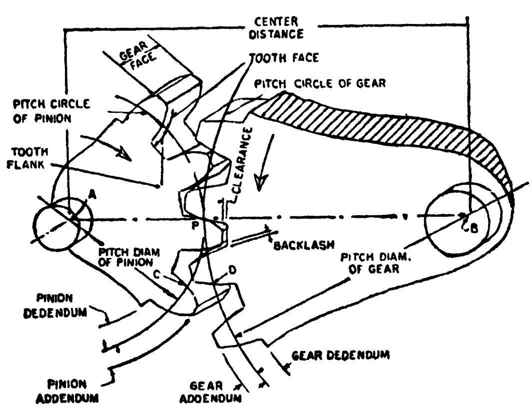
SPRUCE. Conifers.

SPRUE. A disease of tropical countries, marked by anemia, wasting, gastrointestinal disturbances, sore tongue, and diarrhea with the passage of voluminous, fatty, frothy, foul-smelling stools. An exactly similar clinical picture known as **celiac disease** occurs in children in tropical and non-tropical countries. It is believed that sprue and celiac disease are manifestations of the same pathological entity.

The exact cause of sprue is unknown, but there is evidence to suggest that it is a deficiency disease. The deficiency may be in the nature of dietary lack, or digestive tract disturbances which interfere with the proper absorption of food. Treatment is especially effective in early cases. A high protein and low fat diet, injections of liver, brewers' yeast or other forms of **vitamin B** complex by mouth are followed by improvement and remission. Celiac disease is treated similarly; it tends to undergo permanent remission as maturity is reached.

The anemia of sprue is of the macrocytic type, i.e., the red cells are pale and large. Recently it has been discovered that synthetic folic acid, one of the vitamin B complex, causes an improvement in the anemia of sprue and a marked improvement also in the symptoms of the disease. (D.M.H.)

SPUR GEARING. This form of toothed gearing is used for transmitting power between shafts whose axes are parallel; the figure illustrates the important elements of a set of spur gears. The velocity ratio of a spur



gear set is the ratio of the number of revolutions of one gear to the number of revolutions of the other. The **pitch circles** of a pair of spur gears are those imaginary circles that are equivalent to the peripheries of a pair of friction wheels that would operate without slipping at the same velocity ratio and center distance as the gears themselves. The point of tangency P of the pitch circles on the line of centers is the pitch point of the gearing. The smaller of the two gears is usually referred to as the pinion.

Circular pitch is the distance from a point on the profile of one tooth to a corresponding point on the profile of an adjacent tooth measured on the pitch circle. In the figure, the arc CP or DP is the circular pitch of the pinion or the gear. The relation of circular pitch and pitch diameter is as follows:

$$\text{Pitch diameter} = \frac{\text{Number of teeth} \times \text{Circular pitch}}{\pi}.$$

Diametral pitch is the ratio of the number of teeth to the pitch diameter and is expressed as follows:

$$\text{Pitch diameter} = \frac{\text{Number of teeth}}{\text{Diametral pitch}}.$$

Circular pitches may be given as ½", ¾", 1¼", etc.; diametral pitches as 4, 6, 8, 16, etc. Diametral pitch is commonly employed for commercial gearing since pitch diameters and center distances can be thereby expressed in whole numbers or commonly-used fractions.

It may be seen from the above that the velocity ratio of a gear set is dependent upon, and inversely proportional to, the numbers of teeth in the pinion and gear, or:

$$\frac{\text{rpm pinion}}{\text{rpm gear}} = \frac{\text{Number of teeth in gear}}{\text{Number of teeth in pinion}}.$$

In order that spur gears may operate at a constant angular velocity of the driven member for each increment of rotation of the driving member, the tooth curves must be such that the common perpendicular to the tooth profiles at any point of contact will pass through the pitch point. Theoretically, almost any curve may be used for the profile of the teeth of one gear; if the tooth profile for the mating gear is constructed so that the common normal to the point of contact passes through the pitch point, the gearset will operate at a constant angular velocity, and the gears are said to be conjugate. In practice, only one curve, the involute of a circle, is used. The directrix of a gear tooth involute is the base circle tangent to an angular line passing through the pitch point. The angle between this line and a perpendicular to the line of centers of the gear axes is known as the pressure angle, or angle of obliquity, of the gearing. Two angles, 14½° and 20°, are in common use; the 20° gear is available in two types, the full length tooth and the 20° stub tooth. Proportions of the teeth are given in the table, where P_d is the diametral pitch:

Tooth Type	Addendum	Clearance
14½ full length	$1''/P_d$	$0.157''/P_d$
20° full length	$1''/P_d$	$0.2''/P_d$
20° stub	$0.8''/P_d$	$0.2''/P_d$

Gears with teeth of standard proportions have equal addenda; in some specialized applications, gearsets in which the driving member has long-addendum, and the driven member short-addendum teeth, are used to obtain greater tooth strength and smoother action.

Gear teeth subjected to continuous service may lose their utility because of excessive wear rather than tooth breakage. Excessive wear may result from improper or insufficient lubrication, from the presence of foreign particles in the lubricant, or from excessive pressure on the surfaces in contact. Suitable lubrication and encasing or housing the gearset may eliminate some of this trouble, but the teeth must be of such proportions that compressive fatigue failure of the materials cannot occur.

An internal gear or annular is a ring in which gear teeth are cut on the inner periphery; it is literally a spur gear turned inside out. Compared to spur gearing, an internal gear operating with a pinion has several advantages: shafts can rotate in the same direction without the use of an idler gear; annular teeth are stronger than spur gears of the same size and number of teeth; and the center distance between shaft axes is equal to the difference of the pitch radii of the gear and pinion, instead of to the sum. Tooth interference is more likely in internal gearing than in spur gearing, however, and somewhat more limited methods of cutting annular gears are availab'e.

A rack is a straight-line spur gear, and may also be defined as a spur gear whose pitch radius approaches infinity as a limit. A rack and pinion may be used in combination to convert rotary to reciprocating, or reciprocating to oscillatory motion. (H.C.H.)

SPUR-FOWL. Aves, Galliformes. Long-tailed Indian and Ceylonese **partridges** which resemble pheasants. (A.W.L.)

SPURGE FAMILY. Euphorbiaceae. Members of this large family are found in many tropical and temperate regions. The greater number are trees or shrubs, with a few herbaceous species, especially in cooler regions. Many of the tropical species are interesting xerophytes, plants capable of enduring the driest climates. Often these have a habit very similar to that of species of *Cactus,* with which they may easily be confused, especially if not in flower. However, nearly all members of the spurge family contain a milky juice which exudes from them when the surface is cut or broken. This milky juice, or latex, will readily distinguish them from cacti, which lack latex. Leaves, when present, are usually alternate and have **stipules.** In many species, such as the frequently cultivated *Euphorbia splendens,* or "Crown of Thorns," the leaves soon drop off, leaving a spine-covered stem. In one genus, *Phyllanthus,* leaves are frequently reduced to minute scales, and the stem flattened and green; in these the small pinkish flowers are borne around the edge of the flattened stem. In some species of *Euphorbia* the leaves near the top of the stem become brilliantly colored, as in *Euphorbia pulcherrima,* the poinsettia, where they are bright red. Such leaves, surrounding the inconspicuous flower masses, are often mistaken for parts of the flower.

The **inflorescence,** in members of this family, is often very complex. In many species the individual flowers are crowded together in such a way as collectively to resemble a single large flower. The flowers are unisexual. The plants are either **monoecious** or **dioecious.** In many cases the flowers entirely lack both **calyx** and **corolla,** in others a calyx is present, but no corolla, while in some both calyx and corolla are present. They are regular flowers with the **perianth** commonly 5-parted. The number of stamens varies from one to many; in many cases they are variously united; in some, as in the castor bean, they are branched. The ovary is usually 3-celled, with one or two ovules in each cell. The **fruit** is a capsule, which when mature often opens with considerable force, throwing the seeds out, often to considerable distances. The **seeds** have an abundant endosperm and a caruncle.

Among the members of this family are some plants of great economic importance. Many others are poisonous plants.

Hevea brasiliensis, the Para **rubber** plant, is perhaps the most valuable member. Species of *Ricinus* supply castor oil. Species of *Manihot,* a South American genus, yield cassava or mandioc, a starchy foodstuff, prepared from the large roots. *Manihot esculenta,* for instance, has long been cultivated in Brazil. It is a large, somewhat bushy herb with long-petioled leaves, the smooth blades of which are deeply cleft into 3–7 lobes. The roots, which have the appearance of sweet potatoes, are eaten in much the same way as sweet potatoes. Grated, they yield a starchy product used like bread. From the roots tapioca may be prepared. The poisonous principle which is present in many species of *Manihot* is removed by squeezing or destroyed by heating. From other species of this genus may be obtained, by tapping, a milky juice which is a source of rubber.

Hura crepitans, the sand box tree, is another member of the family of some slight commercial value. The plant is a fairly large tree the stem of which is covered with short, sharp spines, and bears long-petioled, toothed leaves. The fruit is composed of numerous hard carpels which, when mature, explode violently, throwing

the seeds out forcibly. These fruits, about 3" in diameter, were formerly gathered and wired to prevent bursting. When dry they were used as containers for the fine sand which was then used to blot ink—hence the common name of the tree. The wood of the tree is used locally, but rarely exported. The milky juice of the tree is very poisonous. This juice, mixed with meal or similar substances, and thrown into the waters of a stream or lake, stupefies the fish present therein, so that they may be readily captured. The poison does not render the fish unfit for human consumption.

Several species of *Croton* yield important purgative drugs. *Croton eluteria* gives Cascarilla bark, used as a tonic.

Jatropha Curcas, a small shrub or tree, bears egg-shaped green fruits which contain a high percentage of an odorless oil called "curcas" oil, used in making paints, as a lubricant, and in soap-making. From the leaves of this tree, natives of the Philippine Islands prepare a fish poison used in much the same way as that obtained from *Hura.*

Aleurites species, natives of the East Indian region, are important sources of oil. (B.S.M.)

SPURIOUS CORRELATION. Spurious correlation is **correlation** which is misleading. Take two variables x and y which are independent. Consider a third variable z which is correlated with x and with y. Form $v = f(x, z)$ and $w = f(z, y)$, then frequently v and w will show considerable dependence which may be traced to the correlation of x with z and y with z. In general, then, spurious correlation may be defined as correlation which is introduced by other variables rather than the ones under study.

The real question at issue in correlation is actually this. Are the variables in which we are interested x and y or v and w? If the variables are x and y then the correlation of v with w is spurious. If the causal variables, however, are v and w and not x and y, then the correlation of v with w is valid and not spurious. If two variables have no logical connection of any kind, naturally any correlation found between them will be spurious. (L.A.A.)

SPUTTERING. A result of the disintegration of the metal **cathode** in a **vacuum tube** due to bombardment by positive **ions.** Atoms of the metal are ejected in various directions, leaving the cathode surface in an abraded and roughened condition. The ejected atoms alight upon and cling firmly to the tube walls and other adjacent surfaces, forming a blackish or lustrous metallic film. This effect is often utilized to form very fine-grained coatings of metal upon surfaces of glass, quartz, etc., purposely exposed to the sputtering. Films of different metals can be obtained by using cathodes made of these metals. Glass plates may be thus silvered, or suspension fibers of spun quartz rendered conducting for use in electrometers, etc. (L.D.W.)

SQUALL. A sudden, strong wind which may or may not be accompanied by a wind shift is a squall. Rain and snow squalls are showers accompanied by strong gusts. (P.E.K.)

SQUALL LINE. Thunderstorms, rain showers or squalls, and snow showers or squalls often appear in a long line sometimes reaching hundreds of miles but only one squall in depth. Such lines of squalls or squall lines normally move perpendicular to their leading edge. Squall lines are of two types, cold-front and prefrontal. Cold-front squall lines are composed of numerous thunderstorms, squalls, or showers occurring at the cold front, as it moves across the terrain, because the cold air behind the front is underrunning and lifting the warm air ahead of the front. It is necessary that the warm and lifted air be unstable or potentially unstable and possess sufficient moisture to permit the development of cumulonimbus clouds. Along a normal cold-front squall line there are breaks in the squall clouds. Thus it is possible for a cold front to pass a given locality with nothing more than broken clouds as evidence (also a wind shift), whereas a locality 5 miles away may experience a severe thunderstorm and considerable damage.

Prefrontal squall lines originate from a combination of several factors, probably three:

1. A tongue of moist air in advance of and parallel to a cold front.

2. Strong southerly winds at low levels ahead of the cold front carrying warm air northward at a rapid rate, and westerly winds at high levels carrying comparatively cold air over the northward-moving warm air, thus creating instability.

3. Lifting of the air well in advance of the cold front because of its fluid properties, and because of convergence in the warm sector of a cyclone. These three conditions are most often satisfied in the warm sector of a temperate-zone cyclone just ahead of the cold front.

Prefrontal squall lines may begin with a few scattered showers or thunderstorms located in the moist tongue, but some develop rapidly into a solid line of showers or thunderstorms located from 50–200 miles ahead of the cold front. A prefrontal squall line, once developed, travels like the cold-front squall line, perpendicular to its leading edge and with the cold front. Prefrontal squall lines are usually violent and destructive, often accompanied by tornadoes, hail storms, gusty surface winds, and severe turbulence. Velocity of a prefrontal squall line is usually greater. (P.E.K.)

SQUAMATES. **Fossil Reptiles.**

SQUARE. **Screw Thread; Measurement.**

SQUARE WAVES. Any periodic **wave,** regardless of its shape, may be analyzed into a series of sine and cosine components whose frequencies are harmonically related. The number of these components will be determined by the shape of the wave, but in general the sharper the corners of the original wave the more component terms. Thus a square wave will require a wide range of frequencies to express it. These components are not mere mathematical fictions but are true electrical components in the case of an electric wave. They may be separated and examined by means of proper filter circuits. Since a square wave will contain a long series of frequencies it may be used for rapidly determining the frequency response of a piece of equipment by applying the wave to the input and noting the distortion of the output wave. The distortion is due to certain frequencies of the original wave being attenuated or amplified out of proportion in passing through the circuit. Thus the necessity of making a laborious series of tests at various frequencies using sine waves is avoided. When an operator is properly trained in interpreting the results of such testing it offers a rapid means of checking amplifiers, networks, etc. These square waves may be generated by a variety of electronic circuits. (L.R.Q.)

SQUASH. *Cucurbita maxima* (*pepo*) and (*C. moschata*). **Gourd Family.**

SQUASH BORER. Insecta, Lepidoptera. The **larva** of a **moth,** *Melittia satyriniformis,* which bores in the root and stem of squash vines, often killing the plant. The moth is a beautiful species with olive fore wings, transparent hind wings, and legs tufted with orange and black.

The larva thrusts waste material out of holes in the stem. When detected by this means it can be cut

out of the plant and killed. In large fields where hand control is impossible, deep plowing when the vines are dead kills many of the insects. Other methods depend on an accurate knowledge of the time of deposition of the eggs. Spraying is effective during that period. (A.W.L.)

SQUASH BUG. Insecta, Hemiptera. A true **bug**, *Anasa tristis*, about ⅝" long, gray-brown above and mottled with yellow below, showing red in flight from areas beneath the wings. It sucks the juices of pumpkins, squash, and related vines and spreads a bacterial wilt.

The adults hibernate beneath debris on the ground and may be trapped under pieces of board and destroyed. Colonies of young are said to be destroyed by dusting with calcium cyanide (see **Calcium**) (50% or 25% cyanide), and the masses of eggs are large enough to be seen and destroyed by hand. They are often deposited on the underside of leaves, however, where they are difficult to see. (A.W.L.)

SQUID. Mollusca, Cephalopoda. Marine animals with usually elongate bodies bearing a pair of lateral fins. The head is provided with large eyes and ten tentacles, two much longer than the rest and expanded at their tips.

The squids vary in size from the little butterfly squid of the Maine coast, scarcely more than an inch long, to the giant squids of the deep seas with bodies, exclusive of the tentacles, 20' long. The common squids of the genus *Loligo* are also called calamaries.

Squids are eaten by the Chinese, who regard them as a delicacy. In North America they are important as bait in the marine fisheries of the northern Atlantic coast. (A.W.L.)

SQUIRREL. Mammalia, Rodentia. An arboreal or terrestrial **rodent** with a long bushy tail. These animals, together with the chipmunks, ground squirrels, woodchucks, and flying squirrels, make up the family Sciuridae. Representatives of the true squirrels are found on all continents but Australia.

Flying squirrels belong to a subfamily distinguished from the true squirrels and related forms by the presence of folds of skin stretching from the front to the hind legs along the sides of the body. These folds, held extended by the legs, support the animal in the air during long gliding leaps.

Still another small division of the family contains the pigmy squirrels of Africa, Borneo and the Philippines. These few species are about as large as mice.

North America has ten species of true squirrels, some widely distributed and extremely variable, and two species of flying squirrels, *Glaucomys*. The little red squirrel, *Sciurus hudsonicus*, is the most widely known, with the gray, *S. carolinensis*, and fox, *S. niger*, squirrels very close. The two last are valued as small game; their flesh is excellent. (A.W.L.)

SQUIRREL-CAGE MOTOR. **Motor, Electric.**

SQUIRTING CUCUMBER. *Ecballium Elaterium.* **Gourd Family.**

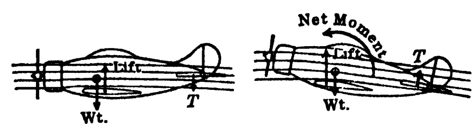
STABILITY. **Equilibrium of Forces; Least Energy Principle; Buoyancy; Stability, Mechanical.**

STABILITY, AIRPLANE. The aerodynamic stability of an airplane in flight is a form of **mechanical stability**. As the airplane has three degrees of freedom, it possesses three components of stability, viz., longitudinal, lateral, and directional.

Longitudinal stability is stability around the lateral axis. For normal flight this is an important type of stability. An airplane which is stable longitudinally will, if the controls are released, recover from a dive or a climb and resume normal flight automatically. This will not happen instantly. In most cases, if the ship is diving and the controls are released, it will come out of the dive and begin to climb until the speed drops appreciably. It then will dive again but much less steeply, and once more begins to climb, but at a smaller angle than in the first case. Any alternating motions are known technically as *oscillations*, those from dive to climb being called *phugoid oscillations*. Most airworthy airplanes will resume normal flight after 3 to 5 oscillations.

Longitudinal stability is the most important of the three stabilities because small angular rotations about the lateral axis create large variations of aerodynamic reaction on the wing. Each angular degree of pitch changes the angle of attack a degree. (The range of angle of attack from no lift to maximum lift is often no more than 16°). Tendencies to longitudinal instability would be extremely hazardous during landing maneuvers. Lateral and directional instability are undesirable, but while they might cause piloting to be tedious, they do not pose the same risks as longitudinal instability. Longitudinal stability is more difficult to achieve than the others, because an airplane is unsymmetrical about its pitching axis but symmetrical about the rolling axis.

An airfoil is inherently unstable but the combination of wing and stabilizer can have positive stability provided the center of gravity is located at about the 30% chord point of the wing. As shown in Fig. 1, a stable



Trimmed Displaced

Fig. 1.

monoplane is flying in "trim" at comparatively low angle of attack. Center of pressure is well back on the wing and the stabilizer is operating at negative angle of attack. Neglecting the small, and nearly balanced, thrust and drag moments, the moment of the stabilizer lift equals the moment of the wing lift. Now assume that the pilot introduces a disturbance by operating the controls momentarily to "nose-up" the airplane. The higher angle of attack moves the lift center forward so that the wing, of itself, would move to an even larger angle. However, the stabilizer lift will have diminished, or even reversed in direction in an amount sufficient to overcome adverse wing moment and produce a net stabilizing moment which returns the airplane to its original attitude. While the angular momentum may carry the airplane through the neutral position, the direction of the stabilizing moment correspondingly reverses and after a few reversals the phugoid oscillation is completely damped. If the center of gravity is displaced forward or backward far enough, this positive stability will disappear, therefore it is necessary to control disposable load (baggage, fuel, etc.) and keep center of gravity within predetermined stability limits.

Lateral or Rolling Stability. Lateral motions involve one translation, side slipping, and two rotations: rolling, about the longitudinal axis; and yawing, about an axis that is normally vertical. Each of these rotations affects the position of the axis of the other one. So lateral motions are more complicated than longitudinal. For one motion, let us assume that the pilot keeps the airplane from yawing, by the use of the rudder. It may roll and slip then, but it cannot yaw. Stability in this motion will be called *rolling stability*.

Rolling stability may be obtained in two ways. The most common procedure is to build or rig the wings with a **dihedral** varying from 1–3°. When a ship is banked without turning, it tends to sideslip or slide downward toward the low side. If the wings have dihedral, the air then strikes the low wing at a much greater angle of

attack than the high. This, of course, increases the lift on the low wing, and restores the ship to its normal position. Rolling stability may also be secured by the use of *sweep-back,* though the effect of sweep-back is not as pronounced as dihedral. An airplane with an ordinary amount of dihedral or sweep-back will stay more or less right side up if kept to a fixed heading with the rudder, without any use of ailerons.

Directional or Yawing Stability. An airplane has directional stability if forces, called into action when it is yawed, tend to restore it to its original direction of flight. Positive stability of this nature is secured by the use of a large vertical *fin* at the tail. The directional stabilizing action is similar to that of a weathervane. Wing sweep-back also secures some measure of directional stability through the unbalance of drag when such a wing is yawed.

General. Stability is always desirable, but not necessarily in the maximum possible degree. Excessive stability reduces maneuverability and renders the airplane "stiff" to the controls. The degree of stability secured by dihedral must be carefully balanced against that secured by fin, else there may result one of two types of lateral-directional instability.

1. "Dutch roll" from too small a fin for the dihedral used.
2. Spiral instability from too large a fin.

Most airplanes that are statically stable are dynamically stable also. Even when dynamically unstable, this will usually occur at high speed and show up during altitude tests rather than during takeoff or landing. Dynamic analysis is tedious and costly and is not ordinarily performed, except for unconventional or large and costly airplanes. Most wind-tunnel tests are devised to obtain static stability characteristics and the model needs to be a small replica only of the external shape of the airplane. For dynamic stability the model must also be dynamically similar, that is, have a mass and moment of inertia which mirrors the prototype. (F.T.M.)

STABILITY, FREQUENCY. This term is commonly used to denote the accuracy with which the carrier frequency of a radio transmitter maintains a constant value. Various methods are used to improve this, among them being crystal control of the oscillator, electron coupling of the oscillator, high Q tuned circuits, etc. (See also **Frequency Deviation.**) (L.R.Q.)

STABILITY, INSTABILITY, AND VERTICAL CURRENTS. Everywhere that air is in motion some vertical perturbations are present. Isolated parcels and currents of air are thus started upward or downward in a layer of surrounding air. The action of the environment on the displaced parcels is a measure of the sta-

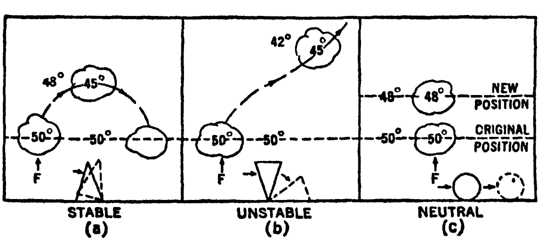


Fig. 1. Equilibrium (mechanical and atmospheric).

bility or instability of the air. If the parcel is forced back to its original position, the air is stable and does not favor vertical motions; if the parcel is accelerated in its vertical movement then the air is unstable and favors vertical motions; if the parcel comes to rest at a new position, neither rising nor falling, then the air is in an equilibrium state. See Fig. 1. Thus, vertical currents occur only if favored by unstable air. Otherwise, displaced parcels will oscillate with a definite period and displacement until the oscillations are damped out. Stability criteria are directly related to the amount and distribution of water vapor in the air.

1. Dry air moves upward and downward with a temperature change of approximately 5.5° F. per 1000'.

   a. When the temperature in the surrounding air decreases less rapidly than 5.5° F. per 1000', a rising parcel will grow colder than its environment, will be more dense, and will sink to its original position. The air is then said to be stable for such displacements.

   b. When the temperature in the surrounding air decreases more rapidly than 5.5° F. per 1000', a rising parcel will grow warmer than its environment, will be less dense, and will accelerate in its vertical path. Air is then said to be unstable for such displacements.

   c. If the temperature in the surrounding air decreases exactly 5.5° F. per 1000', the parcel will remain the same temperature as its environment, will remain of the same density, and will slowly come to rest due to friction. Air is then said to be in a neutral state or in equilibrium with regard to rising and sinking parcels.

2. Saturated air moves upward with a temperature drop equal to the moist adiabatic rate of cooling for the particular temperature and pressure of the parcel. These rates of cooling vary from 1.8° F. per 1000' for very warm air to nearly 5.5° F. per 1000' for very cold air. Cooling rates for rising saturated air also change continuously as the parcel rises, becoming greater as the parcel rises.

   a. If saturated air parcels move upward and remain always colder than their environment, they will be more dense and will tend to sink to the somewhat lower position. The air is then stable for saturated rising parcels. Because sinking parcels do not long remain saturated, they are governed by the laws of unsaturated but water-containing air.

   b. If saturated air parcels move upward and remain always warmer than their environment, they will be less dense and will rise with accelerated velocity. The air is then unstable for saturated rising parcels.

3. Unsaturated but water-containing air is governed by the stability criteria for dry air while it remains unsaturated, and for saturated air after it becomes saturated due to cooling in ascent. In most cases sinking air is governed by the rules of dry air because such parcels soon become unsaturated.

   a. If the lapse rate is greater than the dry-adiabatic rate of 5.5° F. per 1000', the air is absolutely unstable for both the unsaturated and the saturated states because any rising parcel will be warmer than its environment.

   b. If the lapse rate is less than the moist-adiabatic rate for any saturated parcel, the air is absolutely stable because any rising parcel will cool with a greater rate than the lapse rate in its environment. It will be more dense than its environment at all points during the ascent with a constant tendency to sink.

   c. If the lapse rate lies between the dry-adiabatic rate and the moist-adiabatic rate then the air is conditionally unstable. It is stable for all parcels so long as they remain unsaturated, but can become unstable if the parcels become saturated and then are carried upward into a region where their temperature is greater than their environment.

In all cases of stability and instability for parcels, the ultimate criteria are solely these: 1. If the parcel is and will remain warmer than its environment, it will rise with accelerated velocity and the environment is unstable for that parcel. 2. If the parcel is and will remain colder than its environment, it will tend to sink and the environment is stable for that parcel.

Oftentimes a whole layer of air is lifted bodily along a front or sloping terrain. Lifting of a layer of air is nearly

always a destabilizing process and if the layer grows unstable after lifting, it is said to have been convectively unstable, i.e., convection of the layer created an unstable state.

1. All stable air which remains unsaturated during the total lift remains stable after lift, but its stability is slightly reduced by the process.

2. Unsaturated stable layers which become saturated uniformly through the layers during lift remain stable after lift, but their stability is slightly reduced by the process.

3. Unsaturated conditionally unstable layers which become saturated uniformly through the layers during lift become unstable upon saturation.

4. All layers of air which are more nearly saturated at the top than at the base will remain stable during lift because of the difference in cooling rates of unsaturated air and saturated air.

5. All layers of air which are more nearly saturated at the base than the top will soon become unstable if lifted because the top continues to cool at the rate for unsaturated air after the base becomes saturated and cools at the rate for saturated air.

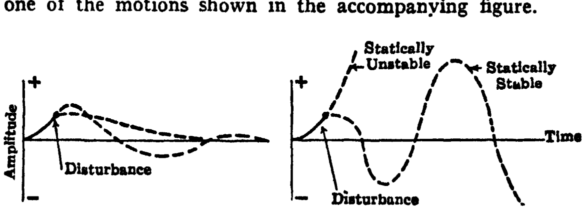
6. All saturated stable layers of air which are lifted remain stable but their margin of stability is slightly reduced by the process.

Stable air is unfavorable to vertical currents and is therefore conducive to stratification of clouds and smoke, to comparatively poor visibility, and to smooth flying. Unstable air favors vertical currents and therefore is conducive to billowed cumuloform clouds, to thunderstorms and showers, to good visibility, and to rough flying air. (P.E.K.)

STABILITY, MECHANICAL. Stability is that property of a body which will cause it to develop forces in opposition to any position or motion disturbing influence. The subject may be divided into *static stability* and *dynamic stability*. The former is concerned with the production of the restoring forces, the latter with the oscillations that are set up in the system as a result of the restoring forces.

Another classification is into (1) *positive stability* when the displaced object returns to an initial state of equilibrium after a temporary disturbance, (2) *neutral stability* when the object tends to remain in a definite position but when disturbed may come to rest in a new position, (3) negative stability (i.e., instability), when the object assumes an entirely new position when disturbed from its initial state. A simple damped pendulum illustrates the first; a sphere the second; while a slender cylinder standing vertically on end is a case of negative stability.

Let it be assumed that an object at rest or in a state of uniform motion receives a disturbing force. Depending on the kind of stability possessed, it might react with one of the motions shown in the accompanying figure.



Left: Positive stability (both statically and dynamically stable). *Right:* Negative stability (both dynamically unstable).

If it is dynamically stable as well as statically stable, its motion-time history may be one of diminishing oscillation or of simple subsidence, depending on the magnitude of damping, and inertial effects. Dynamic instability may occur with either static stability or static instability. These lead to divergent oscillation, or to complete divergence. (F.T.M.)

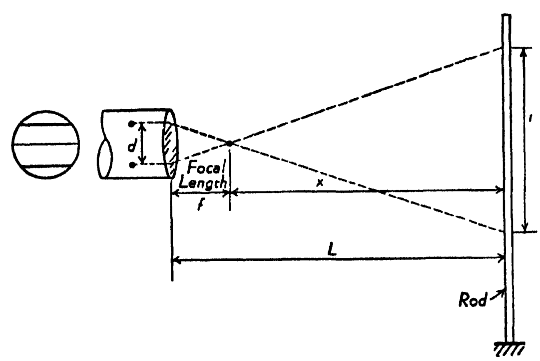
STABILIZER, AIRPLANE. Any airfoil whose primary function is to increase the stability of an aircraft. It usually refers to the fixed horizontal tail surface of an airplane, as distinguished from the fixed vertical surface. (F.T.M.)

STABLE FLY. Insecta, Diptera. A true fly, *Stomoxys calcitrans,* similar in appearance to the house fly but with a mouth fitted for piercing and sucking. It is common in barns, breeding in manure and other organic refuse, but it sometimes enters houses. The impression that house flies bite is due to the occasional attacks of this similar species. (A.W.L.)

STACK. In geology a rock pillar or monument which occurs relatively close to marine cliffs which have usually been developed in hard horizontally bedded but jointed sedimentary rocks. In some cases a stack is the remaining pillar of an arch. Both sea arches and stacks are well developed on the coast lines of the Gaspé Peninsula and the North East Highlands of Scotland. (R.M.F.)

STADIA. This term refers to a method of obtaining distances and elevations of points on the earth's surface with respect to some known point by means of a transit equipped for stadia readings and an ordinary level rod. Stadia measurements are most useful when applied to measurement of inaccessible lines or some limited area such as a farm. It is not applied to precise control work such as the triangulation surveys of the Coast and Geodetic survey. Since contour data for all surrounding points may be taken from one instrument station, the stadia method is particularly adaptable to topographical surveying.

The stadia transit is equipped with two parallel horizontal wires which appear in the field. These are in addition to the ordinary centering hairline. The principle of distance measurement by stadia is explained in connection with the diagram. The telescope



of the instrument is sighted on the rod which is held erect at the point whose distance from the instrument is to be measured. The rays of light coming from the points on the rod which appear in line with the wires are shown dotted. They cross at the optical center, creating two similar triangles. The equation of similarity of bases and altitudes of these triangles is:

$$\frac{x}{f} = \frac{i}{d},$$

which reduces to:

$$x = i\frac{f}{d}.$$

The above shows that to measure distance L one needs to read the intercept on the rod of the stadia wires, multiply it by a factor which is a characteristic of the instrument, and add the focal length. This gives

the distance from the point to the objective lens of the telescope. To this must be added the distance from the objective lens to the center of the instrument in order to get the total distance from the point to the transit setup. This last quantity is variable, depending upon the focusing of the telescope. However, an average value may be used without appreciable error. If c is this average value and H is the total distance from center of instrument to rod, then,

$$H = i(f/d) + (f + c).$$

If the ground elevation at the rod is different from that at the transit certain corrections must be applied to the above method. The corrections involve trigonometric functions derived from the angle of elevation read on the vertical circle of the transit. This angle is also employed to find the elevation of the distant point above the instrument station. (F.T.M., E.W.S.)

STAGE. Steam Turbine.

STAGE EFFICIENCY. By stage efficiency is meant the fraction of **isentropic** heat drop in a **steam turbine** stage that is transferred to the rotor as mechanical energy. The remainder goes to reheating the steam at the lower pressure. The failure of any stage to convert all the heat drop into mechanical energy may be accounted for in:

1. Friction of steam on nozzles, blades, and casing.
2. Throttling flow of steam through clearance spaces.
3. Shock loss.

A well-designed turbine may have a stage efficiency as high as 85%. (F.T.M.)

STAGNATION POINT, FLUID FLOW. A point in the **boundary layer** of fluid flow where viscous friction has brought part of the boundary layer to rest. Stagnation sometimes allows reverse flows along the wall, resulting in an unstable fluid surface which breaks up into vortices and random fluid motions. As long as this point is well to the rear on an airfoil the profile drag is low and lift is sustained, but let the stagnation point advance towards the leading edge and large drag increases accompany a dwindling lift. (See **Fluid Flow.**) (F.T.M.)

STAINLESS AND HEAT-RESISTING STEELS. The development of stainless steels began in 1913 when Harry Brearley in England observed the rust-resistance of alloys containing about 12% chromium, and Benno Strauss in Germany discovered that the addition of nickel to high-chromium steels produced remarkable changes in the mechanical properties.

The original chromium-type steel is hardenable by heat treatment and its first important commercial applications were for cutlery (No. 3 in the table). Modifications with higher carbon and chromium contents, such as Nos. 4 and 5, are now used for the best quality cutlery. By lowering the carbon content (No. 1) a heat treatable steel is produced having strength and hardness suitable for machine parts and stressed structures. A modification having a high sulfur (or selenium) content has improved machinability (No. 2).

By further reduction in carbon content and increase in chromium content, steels are produced which harden only slightly by heat treatment (Nos. 6 and 7). The 17% chromium alloy is widely used as sheet or strip which can be fabricated by cold drawing and forming. The 27% chromium alloy is used primarily for heat-resisting applications.

All of the high chromium and chromium-nickel alloys have good strength and resistance to scaling at elevated temperatures compared with ordinary steels, hence they have many applications in processing equipment in the food, chemical, oil, synthetic rubber, and munitions industries where both corrosion and heat resistance are required. In general, the scaling resistance increases with the chromium content and the chromium-nickel compositions have the highest tensile and creep strengths.

Austenitic grain structure of 18–8 stainless steel at 100 times magnification. Etched by electrolysis in 10% perchloric acid. (See **Metallography.**)

By the addition of 6½% or more nickel, alloys are obtained having physical and mechanical characteristics not found in the carbon or low-alloy steels. The basic alloy (No. 9) is known as 18–8 for its chromium and nickel content. In these alloys the austenitic crystal structure, which is the normal structure for carbon steels at high temperatures, is retained at room temperature. (See **Steel.**) This structure has a high capacity for plastic deformation and develops considerable hardness and strength by **cold working.** Because of the absence of a structural transformation range at elevated temperatures, these alloys are not capable of hardening by **heat treatment,** thus they are dependent on the cold-working processes such as rolling and drawing of sheets, and drawing of rods, wire, and shapes to develop high strength. Even in the soft condition, which is obtained by rapid cooling from a high temperature such as 2000° F., these austenitic alloys have a relatively high tensile strength of the order of 90,000 lbs. per sq. in. One grade (No. 8) develops up to 200,000 lbs. per sq. in. tensile strength in the full hard condition. (See **Temper.**) Its **hardness** is about 42 Rockwell "C" or 400 Brinell, which is not high enough to retain a good cutting edge. These steels are used principally for aircraft, railway cars, and other structural applications requiring a high strength-weight ratio.

Because of their high combination of ductility and strength, the austenitic stainless steels can withstand severe cold drawing operations. Another aid in fabricating these materials is their good weldability, especially in spot welding. When welded structures are to be subjected to highly corrosive media, precautions must be taken to prevent intergranular **corrosion.** This type of failure can occur if the material has been "sensitized" by migration of chromium carbides to the grain boundaries. This occurs during exposure to temperatures in the range 900–1600° F. or during slow cooling through this temperature range. Such exposure can occur in material adjacent to welds, in heating operations during fabrication, or in service. Corrosion failure of this nature can be prevented by the use of "stabilized" grades (Nos. 10 and 11) in which sufficient titanium or columbium is present to combine with the carbon and

prevent the formation of chromium carbides at the grain boundaries.

The corrosion resistance of stainless steels is believed to be the result of a protective oxide film which is stable, tightly adherent, and submicroscopically thin. When broken, the film regenerates itself provided oxygen is available. This accounts for the exceptional resistance to nitric and other oxidizing acids and the lesser resistance to hydrochloric acid and other reducing agents. Materials which depend on protective films for corrosion resistance, including aluminum and nickel alloys in addition to stainless steels, are subject to corrosion by pitting when the film is permanently broken at a given point on the surface. This is a particularly dangerous type of corrosion since a single hole through a sheet or plate usually makes the part unserviceable. Small particles of foreign substances which attach themselves to the surface are believed to be a cause of pit or contact corrosion under certain conditions. Proper cleaning and maintenance of processing equipment is a safeguard against this form of corrosion. The molybdenum-bearing composition (No. 12) is especially resistant to pitting.

* American Iron and Steel Institute.

† The maximum sulfur and phosphorus contents are 0.04% except as noted. The maximum silicon content is 1%. The maximum manganese content is 1% for the chromium grades and 2% for the chromium-nickel grades.

‡ Quenched to full hardness and given a stress-relieving tempering treatment at a temperature under 700° F. All others are in the annealed state.

For high strength and resistance to scaling up to temperatures as high as 2000° F., high chromium-nickel content steels such as No. 13 are used. (See also **Nickel Alloys.**)

The stainless-steel types that have been selected for discussion represent less than ½ the total number recognized by the industry. Other modifications are available in which special properties such as machinability, **spinning** quality, or scaling resistance are developed to a high degree. (R.H.H.)

STALACTITE. A stalactite is a deposit of **calcium carbonate** which hangs icicle-like from the roof or wall of a **limestone** cavern, and is formed by the dripping of mineralized **solutions.** Corresponding columnar structures built upward from the floors of caves beneath the stalactites in a similar manner, are called stalagmites. Stalactite is derived from the Greek, meaning to fall in drops; stalagmite, from the Greek, meaning that which drops. (R.M.F.)

STALAGMITE. Stalactite.

STALL. A term in common use to describe the condition of an aerodynamic burble upon a wing. An airplane that has "stalled" has had the organized streamline flow over the upper wing surface partly destroyed. The lift is partially lost so weight and lift are out of equilibrium. Since the forward end of a conventional airplane is the heaviest it drops faster than the tail, hence a stall is followed by a nosing down motion accompanied by rapid loss of altitude. (See **Stagnation Point, Airfoil, Auto-Rotation.**) (F.T.M.)

STAMEN. Flower.

STAMPING. Press Work.

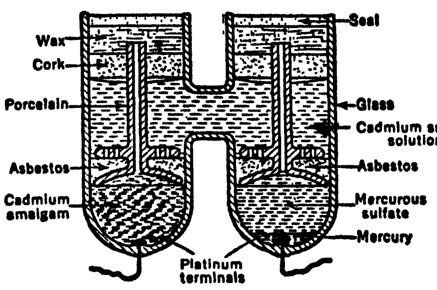
STANDARD ATMOSPHERE. A standard atmosphere is defined as one in which the sea-level temperature is 15° C.; the sea-level pressure, 1013.2 millibars; and the lapse rate 6.5° C. per km. up to 11 km. (the stratosphere). In the ft.-lb.-sec. system this amounts to very nearly a sea-level temperature of 59° F., a sea-level pressure of 29.92″ of mercury, and lapse rate of very nearly 3.5° F. per 1000′. The real atmosphere only occasionally duplicates the standard atmosphere. (P.E.K.)

STANDARD CELL. Precise measurements of electromotive force, as with a **potentiometer,** require a constant, known source of voltage. The only practicable means of supplying this is by some special type of **electrolytic cell.** Of these, two have been highly developed and much used.

The older is the Clark standard cell, which, as improved by Carhart, has a mercury **cathode** and an amalgamated zinc **anode.** The cathode is submerged in a **mercurous** sulfate paste, and the **electrolyte** is a solution of **zinc** sulfate saturated at 0° C. The whole is sealed in a suitable glass tube. This cell has an electromotive force of 1.440 volts at 15° C., with a decrease of 0.00056 volt per degree rise in temperature.

In 1891 Weston substituted **cadmium** amalgam for zinc, and a continuously saturated solution of cadmium sulfate for the zinc sulfate electrolyte, the whole in an H-shaped tube. The Weston normal cell has a somewhat lower voltage than the Clark (1.0183 volts at 20° C.), but its temperature coefficient is practically negligible. The official adoption of the voltage above given for the Weston normal cell by the standards laboratories of Great Britain, the United States, and Germany (1911) gave in effect an alternative definition of the volt, i.e., 0.98203 of the electromotive force of the

Weston normal cadmium cell at 20° C. An unsaturated type of Weston cell is much used commercially in the United States. (See also **Reactions Involving Oxidation-Reduction.**) (L.D.W.)



Cross-section of standard Weston normal cadmium cell.

STANDARD DEVIATION. The standard deviation is a measure of **dispersion** and **variability** and is undoubtedly the most important of any measure of variability. If the standard deviation is large, the **variates** are dissimilar; if the standard deviation is small the variates are more alike. Consider the variates $x_1, x_2, \cdots, x_N$, then the standard deviation of x, σ_x is defined by

$$\sigma_x = \sqrt{\frac{(x_1 - \bar{X})^2 + (x_2 - \bar{X})^2 + \cdots + (x_N - \bar{X})^2}{N}} = \sqrt{\frac{\Sigma(x_i - \bar{X})^2}{N}}$$

where $\bar{X}$ is the **mean** $= \frac{\Sigma x}{N}$. In the case of a **frequency distribution** with class marks x_i and class frequencies f_i the formula for σ_x becomes

$$\sigma_x = \sqrt{\frac{\Sigma f_i(x_i - \bar{X})^2}{\Sigma f_i}}$$

where $\bar{X}$ is the mean as before. Usually, however, an arbitrary origin, a, is used and class interval c, $d' = \frac{x - a}{c}$ and for computational purposes

$$\sigma_x = c\sqrt{\frac{\Sigma f_i d'^2}{\Sigma f_i} - \left(\frac{\Sigma f_i d'}{\Sigma f_i}\right)^2}.$$

Using the definition of $\mu_{2:x}$, $\sigma_x = \sqrt{\mu_{2:x}}$. The square of the standard deviation is the **variance**. The quantity $\sqrt{\frac{\Sigma(x - a)^2}{N}}$ where a is any value is a minimum when $a = \bar{X}$, an important property of the standard deviation.

Given r sets with $N_1, N_2, \cdots N_r$ variates, respectively, and respective means and variances $\bar{X}_1, \bar{X}_2, \cdots \bar{X}_r$, $\sigma_1^2, \sigma_2^2, \cdots \sigma_r^2$, then the variance of the combined group σ^2 may be found from either of the formulas

$$N\sigma^2 = N_1\sigma_1^2 + N_2\sigma_2^2 + \cdots + N_r\sigma_r^2 + N_1(\bar{X}_1 - \bar{X})^2 + \cdots + N_r(\bar{X}_r - \bar{X})^2,$$

or

$$\sigma^2 = \frac{N_1(\sigma_1^2 + \bar{X}_1^2) + \cdots + N_r(\sigma_r^2 + \bar{X}_r^2)}{N} - \bar{X}^2,$$

where

$$N = N_1 + N_2 + \cdots + N_r,$$

and

$$\bar{X} = \frac{N_1\bar{X}_1 + N_2\bar{X}_2 + \cdots + N_r\bar{X}_r}{N},$$

the mean of the combined sets. The variance of the combined set is always greater than or equal to the smallest variance in all the sets. The **expected value** of the **sample** variance in a sample of N variates is $\frac{N - 1}{N}$ times the **population** variance, and is not the population variance.

The standard deviation is used in the **coefficient of correlation**, in **regression** lines, in the **normal curve**, in finding **standard units**, in the measure of **skewness** a_3, and the measure of **kurtosis** a_4, in the **coefficient of variation** and in many other cases. When squared it is used in the **analysis of variance.** Two sample variances from the same normal population may be tested by use of **Snedecor's *F* distribution.** (L.A.A.)

STANDARD ERROR OF ESTIMATE. Error of Estimate.

STANDARD ERROR OF SAMPLING. Consider a statistic θ' calculated from **samples** of N **variates.** Its standard error, $\sigma_{\theta'}$, is defined as the **standard deviation** of θ'. (L.A.A.)

STANDARD METER. The fundamental unit of the **metric system** is called the meter. The standard platinum meter bar, known as the **mètre des archives,** deposited at Sèvres, was supposedly so constructed that at 0° C. its length is one ten-millionth of the earth's meridian quadrant at sea level. It is one of three similar bars constructed at the same time (1793) and kept in different places. This standard superseded a provisional meter based on the length of a seconds pendulum. Its ratio to the standard yard of the **English system** is about 1.0936 (1 U. S. yard equals 0.9144 meter). The international prototype meter is defined as 1,553,164.13 times the wavelength of the red line of **cadmium** in air at 760 mm. pressure and 15° C. (This method of fixing the standard was suggested by Professor A. A. Michelson.) (L.D.W.)

STANDARD INTEGRALS. Integration, Technique of.

STANDARD NOTATION FOR NUMBERS IN DECIMAL FORM. The use of positive and negative **exponents** finds useful practical application in the so-called standard (or scientific) notation for numbers in decimal form. In much scientific work and elsewhere, very large and very small numbers need to be expressed in convenient form. For this purpose, a number between 1 and 10 is multiplied by the appropriate power (positive or negative) of 10. Thus, 93,000,000 would be written 9.3×10^7, and 0.000,000,065 would be written 6.5×10^{-8}. (L.L.S.)

STANDARD TIME. With the adoption of mean solar **time** and the improvement in the manufacture of time pieces, each locality set its clocks to indicate its own local mean time. As railway systems developed, an intolerable confusion resulted from so many different local times being used along the lines. The first step toward standard time was the introduction of so-called "railway time" which was the local civil time of some important station on a particular railroad. As interstate and international communication expanded, particularly after the invention of the telephone and telegraph, it became apparent that a universal standardization of time must be adopted.

The modern plan developed from a suggestion made by Sandford Fleming in 1878 and is now used by the armed services and international sea and air transport systems. This **Zone Time** is described in a separate article but has never been adopted for civilian life, although it is approximated to in the Standard Time system which is in general use. A few of the smaller nations still use the local civil times of their individual capitals as standard everywhere within their borders. The larger nations employ a system on which the earth is divided into standard time zones. Each zone is 15° of **longitude,** or one hour of time, in width, with the center of each

zone an integral number of hours east or west of Greenwich, England.

In Canada and the United States five standard time zones are employed. These are known as Atlantic (Maritime), Eastern, Central, Mountain, and Pacific, and the centers of each are 4, 5, 6, 7, and 8 hours west of Greenwich, respectively. The boundaries of each zone are not set along meridians of longitude, but are determined by national, state, municipal, or commercial convenience. In regions close to the zone boundaries there is still some confusion remaining, but the conditions are infinitely better than those of 50 years ago.

In 1916 the so-called "daylight saving" or "summer time" practice was introduced. Originally the use of daylight saving time was left to local option and much confusion resulted, particularly since the railroads were required by interstate commerce commission ruling to operate on the regular standard time for each region. During World War II, the use of daylight saving time was enforced for the entire country under the name of "war time." On this system each zone was shifted 1 hour toward Greenwich with Eastern War Time being actually Atlantic Standard Time, Central War Time being Eastern Standard, and so on across the continent. (W.K.G.)

STANDARD UNIT. A **variable** may be changed to standard units by the transformation $t = \dfrac{x - \bar{X}}{\sigma_x}$, where t is in standard units, x is the **variate,** $\bar{X}$ is the **mean,** and σ_x is the **standard deviation** of the distribution. In such cases t is said to have a mean zero and a standard deviation of 1.

A standard unit in metrology is a unit whose definition is fixed by law or by some recognized authority; e.g., the U. S. standard yard, the international ohm, etc. (L.A.A., L.D.W.)

STANN(IC), (OUS). Tin.

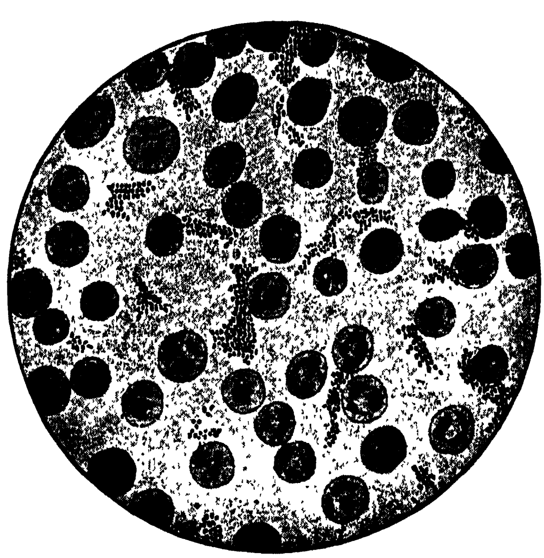
STANNITE. The mineral stannite is a **sulfo-stannate of copper and iron,** sometimes with some **zinc,** corresponding to the formula $Cu_2S \cdot FeS \cdot SnS_2$. It is **tetragonal;** brittle with uneven fracture; hardness, 3.5; specific gravity, 4.3–4.5; metallic luster; color, gray to black, sometimes tarnished by **chalcopyrite; streak,** black; opaque. It occurs associated with **cassiterite,** chalcopyrite, **tetrahedrite** and **pyrite,** probably the result of deposition by hot alkaline solution. This mineral occurs in Bohemia: Cornwall, England; Tasmania, Bolivia and in the United States in South Dakota. It derives its name from the Latin word for tin, *stannum.* (E.S.C.S.)

STANNUM. Tin.

STAPHYLOCOCCI. A group of organisms which are the commonest agents causing suppurative or pus-forming **lesions.** They are spherical cocci which usually grow in grape-like clusters. On solid media, they produce different pigments, a property which is the basis of their classification as *staphylococcus aureus, albus,* and more rarely, *citreus,* the yellow, white and green pigment-producers respectively.

Staphylococci are constantly in the air, water, and on the surface of the body. Different strains vary widely in their ability to produce disease in man. The most virulent infections are produced by *hemolytic staphylococcus aureus. Staphylococcus albus* is relatively nonpathogenic. Boils, furuncles, and **abscesses** in any organ or tissue are most frequently caused by staphylococci. **Osteomyelitis,** or infection of bone, is due to staphylococcus infection in 75% of cases. If the organisms gain entry into the blood stream (**septicemia**) widespread abscesses in such sites as the brain, meninges, kidney, liver, lung, etc., may result. Sometimes **pneumonia** is a primary staphylococcal infection.

The treatment of staphylococcal infections depends on their nature and site. The organisms are highly susceptible to the action of **sulfonamides** and **penicillin.** Penicillin particularly has resulted in the control and cure of many fulminating infections that would otherwise have been fatal. (D.M.H.)



Staphylococci from an abscess of the parotid gland (Jakob). The staphylococci are seen as clumps of dots between pus cells. (*Todd and Sanford, Clinical Diagnosis by Laboratory Methods, W. B. Saunders Co.*)

STAR ALTITUDE CURVES. Celestial Navigation.

STAR CATALOGUES. Any listing of stars, usually arranged in order of increasing **right ascension,** is known as a star catalogue. Originally, star catalogues were intended merely for the purpose of providing accurate positions of the stars for use by navigators, but many modern catalogues are designed to provide particular characteristics of the stars.

The oldest existing star catalogue is contained in the **Almagest** of Ptolemy issued about 137 A.D. This is undoubtedly a reissue of the catalogue of Hipparchus of which no copy is known to exist. The Almagest catalogue was the only one of any real value until the 15th century when an Arabian catalogue made its appearance. Tycho Brahe's catalogue of 1580 marks the dawn of the modern era of star catalogues and since that time many others have appeared. Probably the most comprehensive catalogue issued is the **Bonner Durchmusterung,** which first appeared about 1850, together with the various extensions which have since been published. During the last half of the 19th century the Astronomische Gesellschaft sponsored a catalogue of accurate positions of the majority of the stars contained in the Bonner Durchmusterung.

With application of photography to astronomy several projects have been launched for obtaining comprehensive star catalogues. By far the most ambitious of all of the photographic catalogues is the so-called Astrographic Catalogue which was started as a cooperative effort of 18 observatories in 1887. When completed the catalogue will contain positions of between 3 and 4 million stars measured on about 44,000 plates. As well as the positions of the stars, there will be also issued prints from the plates forming the atlas frequently referred to as the Carte du Ciel. At present the astrographic catalogue is somewhat more than 2/3 finished.

Many particular types of catalogues are issued for particular purposes, such as catalogues of **stellar magnitudes, spectral class, proper motions, double stars, variable stars,** etc. (W.K.G.)

STAR CONNECTION. This is the connection of the various phases of an a-c machine or circuit in which one end of all phases is connected to a common point, the other end of each phase going to a line. The **Y** is the three-phase star and is the most common example of this type connection. (L.R.Q.)

STAR COUNTS. Milky Way.

STAR FINDER. An instrument designed for the purpose of quickly determining the **horizontal coordinates** of a star, at a certain place and time, with an accuracy sufficient to locate it for observational purposes, is known as a star finder. A star finder may also be used for the reverse process of determining the name of an unknown star whose horizontal coordinates have been approximately measured.

Various mechanical types of star finders have been designed and placed on the market. The simplest of these types is a tube mounted in the same manner as an **equatorial telescope,** but having the altitude of the polar axis easily adjustable for **latitude.** The **declination** circle has the values for the 22 **navigator's stars** indicated, and has the hour circle arranged with various movable dials so that the **hour angle** of any navigator's star may be quickly set for local **time** in a given longitude. All types of mechanical star finders must be properly oriented and kept level while in use, hence they are far more practical for use on land than on a ship at sea or in the air.

For use on a moving ship several types of star finders have been devised which have a map of the celestial sphere, usually drawn on the **stereographic projection,** and with a set of transparent disks to be placed over the map. The disks have curves marked on them showing horizontal coordinates and the set covers a wide latitude range. To use such a star finder the disk most nearly corresponding to the latitude of the observer is placed over the star map and oriented in accordance with printed directions. The observer's local time and longitude govern the orientation in most cases. With the disk in proper position the horizontal coordinates of objects on the star map may be immediately determined. (W.K.G.)

STAR STREAMING. Moving Cluster.

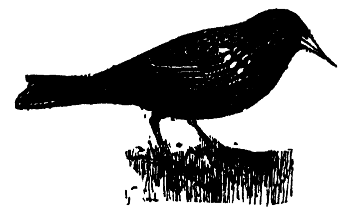
STARCH. Carbohydrates.

STARFISH. Asteroidea.

STARK EFFECT The effect of a strong, transverse electric field upon the **spectrum** lines of a gas subjected to its influence. In many respects it resembles the more complicated types of **Zeeman effect,** but is subject to different laws, and may change radically in character and in multiplicity of component lines with increasing field intensity. The phenomenon, first observed by Stark in 1913, is conveniently studied by means of a **canal-ray** tube having behind the cathode a third electrode which may be given a high positive potential, in order to impose the desired field upon the radiating canal-ray particles. (L.D.W.)

STARLING. Aves, Passeriformes. A bird (**Aves**) of any of several species native to Europe, Asia, and northern Africa. The African glossy starlings belong to a family containing also the Asiatic grackles or hill mynas, while the true starlings are placed in a closely related family.

The one species which concerns us in North America is the common European starling, *Sturnus vulgaris,* which was introduced into New York in 1890 and has



Starling. *Sternus vulgaris.*

since spread a third of the way across the continent. The males are black with green and blue iridescence and light tips on many of the smaller feathers, and the females are brownish-gray. The beak is rather large. In Europe the starlings are valued as destroyers of insects and for their song. They are able mimics. The same good qualities are worthy of consideration in America but the birds are also destructive of native species and in the fall they become a nuisance by gathering in great flocks to roost in countless thousands in the trees of residential districts. The net verdict is against them, and they are commonly regarded as another of our imported pests. (A.W.L.)

STARS. There is probably no one class of physical objects that has attracted more popular and scientific attention throughout the ages than have the stars. A small portion of the mass of mythological material that is associated with these bodies will be found in the various articles dealing with the individual **constellations** and a few of the brighter stars.

The methods for determining the physical characteristics of the stars will be found under such titles as: **Stellar Parallax, Stellar Magnitude, Spectral Classification, Binary Stars, Variable Stars, Cepheids, Giant and Dwarf Stars,** etc. The characteristics of a typical main sequence G-type star will be found in the articles dealing with the **Sun** and various solar characteristics. See table, p. 1370. (W.K.G.)

STARTER, ENGINE. The cycle of the **internal combustion engine** requires that the engine be initially revolved from an external source of power. The mechanism supplying this initial effort is known as the starter. Certain small semi-portable or stationary engines, also tractor engines, truck engines, etc., are frequently started by manual cranking, but a mechanical starter is standard equipment on automobile engines. **Diesel engines** are rarely hand cranked, although they are started by more varied types of starters than are employed with the gasoline engine. **Aeronautical engines** can be started by swinging the propeller by hand. However, many are now equipped with starters, the commercial plane because of the size of the engine and the inconvenient location of the propeller viewed from the standpoint of manual starting, the small plane for convenience of the private owner, or in emulation of the standard practice on automobiles.

Starters for automobile engines are electric motors of a series wound type, deriving their supply of electricity from a storage battery. The relation of motor output to battery capacity is such that the use of the motor must be restricted to short intervals of time, between which the battery is recharged. Normally, the starting motor is disengaged from the **engine.** During the starting cycle it is connected by a reduction gear which multiplies the **torque** produced by the motor. A small pinion on the motor engages with a large annular gear, usually placed on the circumference of the flywheel of the engine. The speed reduction is between 10:1 and 15:1. The method of engaging the pinion with the gear for starting used most frequently is the Bendix drive. This is shown in

PHYSICAL CHARACTERISTICS OF TYPICAL STARS *

* See article on **Stars**, p. 1369.

the accompanying figure. The motor shaft is extended to form support for an externally threaded sleeve and two collars. One collar is fixed to the shaft and to one end of a coil spring. The other end of the spring is attached to the remaining collar, as is also the threaded sleeve. When the shaft revolves, the sleeve and collar revolve as well, being driven by the spring. The pinion has an internal thread corresponding to that on the sleeve, and is unbalanced by having a weight cast on one side of the circumference. When the starter is connected to the battery, the armature immediately starts to revolve, but not so the pinion, due to its inertia and the effect of the unbalanced weight. Consequently, it moves endwise along the thread. The starting motor is so placed that this movement engages the pinion with its gear. When the end of the thread is reached, the pinion jams against a stop, and must then, perforce, turn with the armature. The shock of connecting a moving with a stationary body is eased by the spring connection between the pinion and the armature shaft.

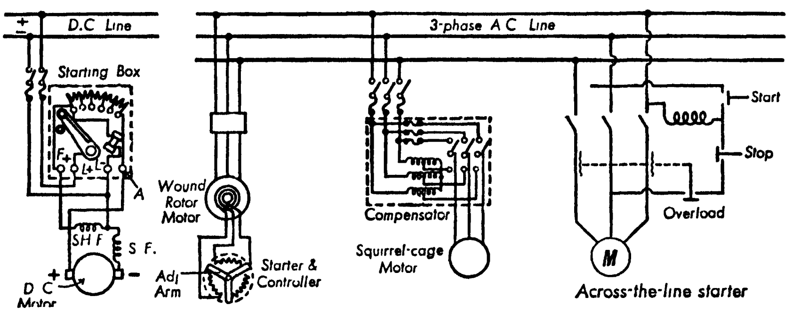
Starter rotor.

Small Diesel engines are started by electric starters, but this is not usual in the sizes in which these engines are usually built. Because of the high compression pressure, a heavy torque must be exerted to revolve the Diesel engine during starting. Some engines have small one- or two-cylinder gasoline engines as an integral auxiliary for starting. The gasoline engine is started by hand cranking, then mechanically clutched to the Diesel for the purpose of starting the latter. After the Diesel starts firing the starter engine is de-clutched and stopped. The largest Diesels generally use compressed air from storage tanks which are recharged after a start. Some manufacturers supply the compressed air to one cylinder, only, of the engine, and have the exhaust valves propped open on the other cylinders so as to reduce the torque required. Others suupply compressed air to all cylinders at the time of the normal power impulse by means of a rotary distributor valve.

Electric starters have been used on aeronautical engines, and it is probable that as starters continue to be applied in that field, the electrical starter will be the more important type. Its use was at one time restricted because of the aversion of manufacturers to including a wet storage battery in an airplane, and to the lack of suitable aircraft types of storage batteries. With the development of the latter, and the increasing desire for storage battery current to operate lights, radio, etc., there is a noticeable trend to the use of electric starters. (F.T.M.)

STARTER, MOTOR. The current in all types of electric **motors** is limited largely by the back voltage of the **armature.** Since this voltage is zero at starting, the current drawn by the machine under this condition may be many times that drawn when running at rated speed. For small motors this current may still not be too large for the system so such motors are frequently started by connecting them across the line without any auxiliary starting equipment. This method of line-starting is ordinarily used only for fractional horsepower d-c motors but a-c motors up to several hp. are started this way. Under these conditions it is necessary to provide only overload protection for the motor. The current drawn by large machines would impose too much of a strain on the supply system so such motors are provided with special starters. For d-c motors these starters

consist of some arrangement for starting with extra resistance in the armature circuit and then for cutting this out automatically or manually as the motor comes up to speed. The starter usually provides overload protection and under voltage release protection so if the voltage fails the motor is not connected directly to the line when power is restored. A four-point manual starting box is illustrated. Squirrel cage induction motors and synchronous motors (which usually start as induction motors) are commonly started on reduced voltage. Since these are a-c machines the **transformer** offers an efficient means of reducing the voltage. Auto-transformers are commonly used for this purpose, the motor being started on a tap position, then the voltage increased to full value in one or more steps as the machine comes up to speed. At the running position the transformer is disconnected and the motor is connected directly to the line. This operation may be manual or automatic. An example of this type starter is illustrated (the starter is frequently called a compensator). Wound rotor induction motors offer an additional method of reducing the starting current. This may be done by inserting resistance in the rotor circuit, the effect being analogous to the armature resistance of the d-c starter, and then cutting this out as the machine speeds up. This also offers a means of speed control of the motor. In large plants where many machines are used a special starting bus supplying reduced voltage may be used. The motors are connected to this for starting and switched to the full voltage bus as they come up to speed. (L.R.Q.)



Some methods of starting electric motors.

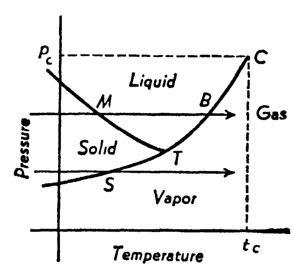
STARTING BOX. Starter, Motor.

STARVATION. A state of existence without food or with inadequate food. When animals are completely deprived of food their only source of energy for the essential processes of **metabolism** is the material already present in the body. The **carbohydrate** stored as glycogen is quickly used up, leaving only the stored fat, the circulating protein (see **Amino Acids**), and the protein of the tissues. Studies of the progress of starvation in mammals have shown that the fat is almost completely used up and that the greatest loss of tissue proteins is from the muscles, due to their great bulk. In percentages, however, the **liver, spleen,** and **gonads** lose more of their bulk than other parts of the body, and the **heart** and central **nervous system** are maintained at the expense of the other parts with very little loss of substance. Extensive observations of the details of metabolism and bodily changes during starvation allowed to continue to the death of the animal have been recorded.

A remarkable result of starvation in some of the lower invertebrates is a progressive shrinkage of the body as a whole, in contrast with the emaciation which results in vertebrates. Observations on the flatworm, *Planaria,* have shown that ultimately it even retraces its development to assume an embryonic form. (A.W.L.)

STATES OF MATTER. The term refers to the solid, liquid, and gaseous forms in which matter presents itself. If we started with any pure element at the lowest attainable temperature and, keeping it at some fixed pressure, as that of the atmosphere, raised the temperature gradually to the highest point known to the laboratory, the substance would be observed to pass through certain stages and to undergo changes from one stage to another at more or less definite transition points. If the pressure were different, similar changes would take place, but in general at somewhat altered transition temperatures. The same statements may be made concerning a pure compound, except that there are some compounds which are so unstable as to decompose before attaining all the states. (For example, if one attempts to melt nitrogen iodide, the result is an explosion, the products of which are nitrogen gas and iodine vapor.)

The stages referred to are the solid, the liquid, and the vapor states; which, for any pure substance, are determined by the two variables, temperature and pressure, with the density as a third, related variable. If the temperature and pressure are under complete control, it is possible to pass from any one to any other of the three states, either directly by a single transition, or by passing through the third state with two transitions. This will be clear from the accompanying phase diagram,



Temperature-pressure curves for substance like water. *C* represents the critical state, *T* the three-phase equilibrium point.

which represents the temperature-pressure equilibrium curves for a substance converging at the **three-phase equilibrium** or "triple point" *T*. (It is understood that each phase of the substance is to be strictly pure; for example, no air is to be mixed with the vapor.) Thus, if a mass of pure ice were kept completely enclosed by itself at a fixed pressure below 4.6 mm. (its "triple point"), and its temperature raised, it would turn directly into vapor at the **sublimation** point *S*; but if the pressure exceeded 4.6 mm., the ice would first become liquid at the **melting point** *M*, and the water would then vaporize at the **boiling point** *B*, corresponding to the existing pressure. The volume of the enclosure would, of course, have to be varied to keep the pressure constant during these changes.

When the temperature has exceeded the critical temperature t_c (see **Critical State**), neither the solid nor the liquid phase is longer possible, even with greatly in-

creased pressure. The liquid-vapor curve must be considered as terminating at C, since it pertains specifically to two phases in equilibrium, while beyond the point C the substance does not exhibit two phases. The one apparently homogeneous phase now remaining is said to be a true "gas." (L.D.W.)

STATIC. This is the name commonly applied to all the various random electrical disturbances which are picked up by a radio **receiver.** These can be divided into two general classes, natural and man-made static. The first is caused by various types of natural electrical discharges, the most pronounced being those of lightning. However, a static-producing discharge is not necessarily, or even usually, a visible lightning discharge. Various static charges are often continually building up and discharging in the atmosphere and hence inducing disturbances in the receiver. Cosmic radiations are also responsible for static. These types of natural static are often called atmospherics. The types of man-made static are almost as numerous as the electrical machines which man has developed. Any sparking contact or poor electrical connection will produce static which will be picked up by nearby receivers. Unfortunately many types of this interference may be fed back along the power lines and directly into the receiver. **X-ray** and diathermy machines are also sources of interference but cannot be properly classed as static.

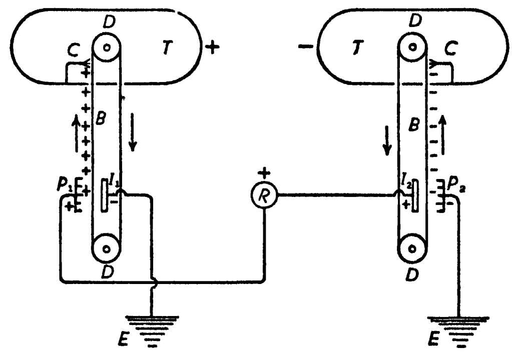
The elimination of static presents a particularly difficult problem since the frequencies in the static pulse cover a wide band, certain types being more prevalent in some frequency ranges than others. Man-made static is best eliminated by correcting the fault at the source although a **filter** in the power line often helps if the disturbance is coming into the set through the line. Natural static can be minimized, but not eliminated. For amplitude **modulation** systems limiting the **frequency band** to which the receiver responds will reduce the noise. Various types of limiters will also reduce the effect since the static signal is frequently greater than the desired one. Frequency modulation is inherently less susceptible to interfering noise and offers almost noise-free reception. (L.R.Q.)

STATIC EQUILIBRIUM. Equilibrium of Forces.

STATIC LENGTH. Relativity.

STATIC MACHINES. A variety of devices have been employed to furnish charges of electricity of considerable quantity at high voltage. Probably the simplest static machine is the **electrophorus,** operating on the principle of electric induction, but its output and voltage are quite limited. Some of the older machines generated charges by friction, but modern machines are of the induction type. Among the latter, the well known Toepler-Holtz and Wimshurst machines have rotating glass or mica plates bearing metal "carriers" on which the charges are induced as on the metal plate of the electrophorus. Recently some very powerful induction machines, embodying all the principles of the older types, have been developed by Van de Graaff and others and have come into use in nuclear research. One of the simplest of these is illustrated in the diagram.

Two endless belts, B, of silk or paper revolve on insulated drums D, the upper of which are mounted inside two hollow, rounded metal tanks T forming the terminals of the machine. R represents the positive terminal of an ordinary static machine or of a high-voltage rectifier-transformer, which keeps the system from the inductor plate to the "comb" of charging points P_1, positively charged at about 10,000 volts. The negative inductor plate I_1 and the charging comb P_2, opposite P_1 and I_2, respectively, are grounded at one end, their other ends being maintained negative by induction. As the belts revolve, the sharp teeth of the combs P, under the influence of the inductors I, discharge upon the belts, which carry the charge



Diagrammatic sketch of a modern electrostatic generator.

inside the hollow terminals T. Here the belts discharge themselves against the contact brushes C, the charges at once appearing on the outside of the respective terminals, in accordance with Faraday's law of electric distribution (see **Electrostatics**). Very large charges may thus accumulate on the terminals T, T, at potentials of many hundreds of kilovolts. The energy represented by these charges is supplied by the work required to drive the charged belts B toward the similarly charged terminals. Modifications of this design are in actual use in some research laboratories. (L.D.W.)

STATIC METAMORPHISM. A term proposed by Judd in 1889 and synonymous with the German, *Belastungmetemorphismus.* That form of regional metamorphism which may be considered as due to "load," and which is primarily induced by vertical or gravity pressure, as opposed to regional metamorphism which is caused by **orogenic** pressures. (R.M.F.)

STATICAL MOMENT. Moment.

STATICS. Statics is that branch of mechanics which deals with particles or bodies in **equilibrium** under the action of **forces** or of **torques.** It treats of the composition and resolution of forces, the equilibrium of bodies under balanced forces, and such properties of bodies as center of gravity and moment of inertia.

A set of forces may be exerted along lines which all lie in the same plane, in which case they are said to be coplanar. Again, the lines of action may all intersect at one point, so that the forces are "concurrent." A torque, or moment, is that which tends to produce rotation about some axis. The measure of the torque of a given force about an axis not parallel to its line of action is the product of the force, the perpendicular distance from its line of action to the axis, and the sine of the angle between the axis and the direction of the force. Two forces of equal magnitude, acting along parallel lines in opposite directions, constitute a couple, the torque of which, about any axis perpendicular to its plane, is the product of either force by the perpendicular distance between their lines of action. Such a pair of forces has no resultant and no equilibrant, since it can neither be replaced nor balanced by a single force. It is possible to have a system of more than two forces, not necessarily parallel or even coplanar, but which is equivalent to a couple in that it has a torque without having a resultant. Only another couple, or its equivalent, can balance such a system. One of the basic propositions of statics is that any system of forces is, in general, equivalent to a single force acting along a definite line and a couple whose torque axis is in a definite direction; and that for equilibrium, this force and this couple must both

become zero. These ideas are most conveniently expressed by means of the notation of vector analysis.

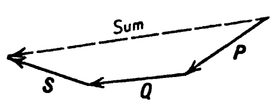
A force F, whose line of action lies at θ degrees to one of two mutually perpendicular axes, may be resolved into components of $F \cos \theta$ and $F \sin \theta$, parallel to the axes. When several forces are concurrent, and coplanar as well, the components of their resultant are found as the algebraic sums of the components of the separate forces. The resultant of two coplanar forces P and Q having an included angle θ, is expressed by the equation

$$R = \sqrt{P^2 + Q^2 + 2PQ \cos \theta}.$$

The angle between the resultant and the force P is

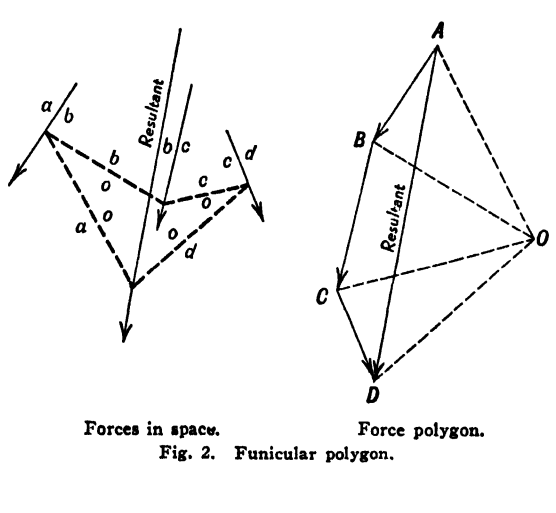
$$\text{arc tan} \frac{Q \sin \theta}{P + Q \cos \theta}.$$

If there are more than two forces whose resultant is to be found, any two may be combined to find the resultant which may then be combined with a third, and so on until the last resultant found is that for the complete array of forces. The same problem may be solved graphically by the vectorial addition of the forces. In vectorial addition, lines whose lengths are equal to the magnitudes of the forces are drawn in the directions of the forces so that the force representing one line follows another, forming part of a polygon, the arrows of which, as shown in Fig. 1, are in suc-



Vectorial Addition of Forces P, Q, & S
Fig. 1.

cession. The resultant is the line drawn from the beginning of the first force to the end of the last. This resultant force, with direction of arrow reversed, is the equilibrant, or neutralizing force. When forces are concurrent, the line of application of the resultant is known to pass through the point of concurrence of the forces; but with non-concurrent forces, neither the force polygon nor the analysis by components is sufficient to establish the line of application of the resultant force. To locate this line, another condition of statics must be introduced. It is that the moment of the resultant about any moment axis is equal to the algebraic sum of the moments of the forces about the same axis. The **funicular polygon** may also be used to establish the line of action of non-concurrent forces. Rays are drawn to the corners of the force polygon from some assumed pole, and the sides of the funicular polygon drawn parallel to these rays. The corners of the funicular polygon lie on the forces themselves, and the closing lines, *oa* and *od*, intersect on the line of action of the resultant. (See **Bow's Notation.**)



Forces in space. **Force polygon.**
Fig. 2. Funicular polygon.

When forces are not coplanar, the solution, in general, involves simultaneous solution of six equations, as follows:

Let F_x, F_y, and F_z be components parallel to x, y, and z axes, respectively.

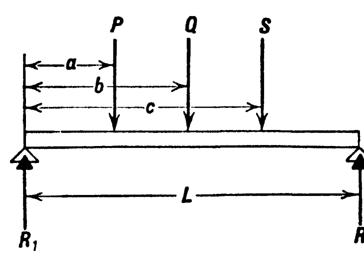
R_x, R_y, R_z are the corresponding components of the resultant.

$$\Sigma F_x = R_x,$$
$$\Sigma F_y = R_y,$$
$$\Sigma F_z = R_z,$$
$$\Sigma M_{Fx} = M_{Rx},$$
$$\Sigma M_{Fy} = M_{Ry},$$
$$\Sigma M_{Fz} = M_{Rz}$$ in which the M's

are the moments of the respective components about either axis perpendicular to them.

Static equilibrium exists if the algebraic sum of the components of the forces in any direction is zero, and if the algebraic sum of the moments of the forces about any axis is zero. When a body is in equilibrium under forces, some of which are unknown, an analysis may be made by applying these conditions of equilibrium, provided that, of the quantities required to specify the forces, the number which are unknown does not exceed the number of equations afforded by the given conditions. In the graphical analysis of static equilibrium, the conditions of equilibrium are that the force polygon and the funicular polygon close.

A common application of the laws of equilibrium of coplanar forces is the calculation of the reactions of a simply supported beam loaded with parallel forces which are perpendicular to the length of the beam. The reactions are determined by considering the whole system to be one in equilibrium, so that the moment equation may be applied by selecting the moment center on



Beam loaded with parallel forces
Fig. 3.

one of the unknown reactions. The moment of this reaction thus becomes zero, and the moment equation has only one unknown reaction. If a beam of span L (Fig. 3) is loaded with forces P, Q, and S, at distances, a, b, and c from R_1, the sum of the moments equals

$$R_2L - Pa - Qb - Sc.$$

For equilibrium, this quantity must equal zero; hence

$$R_2 = \frac{Pa + Qb + Sc}{L}.$$

Triangularly framed structures may be analyzed by algebraic resolution and composition of forces, or by the graphical method of funicular and force polygons. Since the latter is simpler and entirely as useful, it is the one most frequently employed. Consider a simple derrick, framed as shown in Fig. 4, loaded with weight W. This condition of static equilibrium may be analyzed for the forces acting in the structural members by drawing a force polygon for each joint, beginning with that which

has only two forces unknown in magnitude, then proceeding to some other joint, where the same condition exists. In the example given, it is plain that the joint

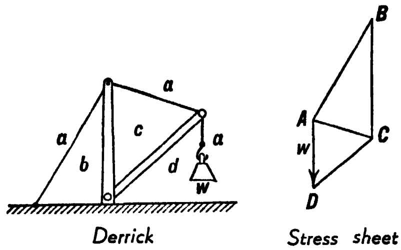


Fig. 4.

at the load must be analyzed first. The equilibrium polygon for this joint is CDA, and is drawn by laying off DA in the direction of W, and of the magnitude W, and locating point C as the intersection of lines DC and AC, drawn in the directions which those forces actually have in the derrick. Using the magnitude of CA thus determined, the joint at the top of the mast may next be analyzed, locating the point B. The magnitudes and character of the forces acting on triangularly framed structures are thus determined by the method of analysis of joints graphically by force polygons which close. These force polygons begin at a point where all corners of the polygon are known except one, and proceed from there in succession to other joints, which will offer the same conditions. Each joint has a separate force polygon, but it is usual to place these polygons in juxtaposition along the lines where they have lines in common, for convenience and simplification. The resulting diagram, which is a composite force polygon, is known as a stress diagram or stress sheet. (See **Graphical Statics.**)

Certain cases of **friction** lie properly in the realm of statics, since, though the friction may be that of moving bodies, the frictional surfaces themselves may not be in relative motion. Friction gearing, wedges, friction clutches, and the general problem of the inclined plane which includes the screw jack are typical examples. Friction is resistance offered by one body to the motion of another when the second body slides, or tends to slide, over the former. A normal force between two surfaces, which have a coefficient of friction f, results in a force fN opposing motion, where N is the normal force. This friction force is tangent to the surfaces of contact in a direction which would oppose motion. The resulting force, acting between a body and its supporting surface, takes the direction shown in Fig. 5. The horizontal component of the

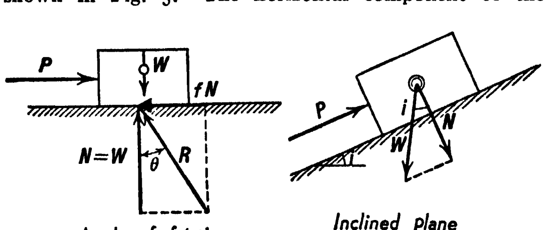

Fig. 5.

reaction R is equal to P. As P increases up to the point of sliding, the angle θ increases until its tangent equals the coefficient of friction of the surfaces in contact. When P exceeds fN there will be relative motion between the body and the supporting surface. Should a body having weight W rest on a plane inclined at angle i, the coefficient of friction between the surfaces being f, the force necessary to start the body up the plane must be greater than $W \sin i + fW \cos i$ where the force P is parallel to the plane. If the force P is inclined to the plane, only its component parallel to the plane will be available for starting the load, and its perpendicular component may either tend to increase or decrease the friction resistance.

The centers of gravity of areas and masses come under the head of statics, since they may be considered as made up of a number of elementary areas or masses, which could be treated as proportional to a set of parallel forces acting through their individual centers. (See **Centroid, Moment, Moment of Inertia, Friction, Equilibrium of Forces.**) (L.D.W., F.T.M.)

STATION. A wood stake or any other type of marker which is used to locate accurately a point on a **traverse** line or the intersection of traverse lines is called a station. The stake is driven flush with the ground. The exact point or the point of intersection is indicated by a tack.

Any station which is used for a transit setup is a transit station. Lines which connect transit stations are transit lines. The transit lines, taken collectively, form what is known as the horizontal control of the survey.

Open traverses are marked by stations every 100′ along the line. These are known as full stations. Intermediate stations, called plus stations, are placed wherever it is necessary to locate adjacent artificial or natural features with respect to the transit line.

A stake which is driven at an angle over a station for the purpose of indicating its location is a guard stake. (C.W.C.)

STATIONARY FRONT. **Fronts.**

STATIONARY WAVE. **Interference.**

STATISTIC. A statistic is a function of **sample** values such as the **mean** of a sample, the **variance** of a sample, the **coefficient of correlation** in a sample, etc (L.A.A.)

STATISTICAL MOMENT. **Moment.**

STATISTICAL PROBABILITY. Two modern theories of probability have been used in mathematical statistics, that of von Mises and that of Kolmogoroff. The theory of von Mises, usually called the "frequency" theory, depends upon the notion of a "kollektiv." A kollektiv x in one dimension consists of an endless sequence $x_1, x_2, x_3, \cdots$, of observations or experiments. Briefly a kollektiv corresponds to a **population** or universe. If x_i represents a success we replace x_i by 1, or a failure we replace it by 0. We may form the **relative frequency** of success in a finite sequence and in the case of a kollektiv the limiting value of the relative frequency is called the probability of the attribute in question within the kollektiv involved. The set of all limiting frequencies within one kollektiv is called its distribution. From a kollektiv x a new sequence x' may be formed by some transformation. Here the sequences x and x' must satisfy certain conditions and are called admissible numbers. Probability theory then is the study of transformations of admissible numbers, particularly the study of the change of distributions implied by such transformations. It should be noted that von Mises' theory emphasizes the importance of sequences and makes no use of notions such as "equally likely." The theory has been criticized as complicated. Its chief distinction is its clarification of the notion of "probability," emphasizing that probability does not depend on a single event, and its close conformity to reality.

The theory of Kolmogoroff, often called the "measure theory of probability," has been extensively used. Roughly speaking, the probability of an event is a definite number found by the theory of measure and the

axioms merely express the rules for operating with such numbers. Up to this point the general theories of probability have been discussed. It is important to define statistical probability. In case the probability of an event may not be determined by mathematical reasoning, then it is necessary to have a series of experiments or to record a series of observations. From this series we may by application of **Bernoulli's theorem** be practically certain that the value of the probability so found will differ little from the true probability. Great care must be exercised to see that the series of observations constitutes a random **sample** or, if properly planned, is a **stratified sample**. This method must be used in insurance and in the social, physical, and biological sciences. (L.A.A.)

STATISTICAL QUALITY CONTROL. A tool of industrial management comparable with production control and cost control. In the past it was usually a routine of inspections, investigations, corrections, and more inspections designed to insure the passage of only good products from one department to another or to the shipping room. At present the words "quality control" almost automatically imply "by statistical methods."

It is necessary to unlearn certain common misconceptions and to accept new views in order to understand how statistical methods can apply to manufacturing processes, assembly processes, typing of letters, writing of orders, and research in agriculture.

1. Inspection of manufactured products is performed not just to show whether these parts are acceptable; its more important function is to show whether the process, machine, or operator who made the parts is *capable* of working within tolerances and whether he is *actually* doing it.

2. No machine can make two articles exactly alike; all "identical" products or processes differ among themselves and tolerances must be allowed.

3. It is not necessary that a process be turning out thousands of parts a day in order to use statistical methods; these have been used where only one large assembly was completed in a day.

4. It does not require advanced mathematics to use these methods; tables in handbooks provide constants and formulae, and the arithmetic computations are simple.

All items or products fall into three classifications. There are (1) those items which have measurable characteristics or variables, (2) those items which are acceptable or rejectable because of either good or bad attributes, and (3) those which *can* have an infinite number of defects, but which *usually* have only a few observable ones.

As an example of the inspection for variables, consider an inspector who is weighing boxes of a powder. The specification states that the net weight must be 340 grams (about 12 oz.) plus 10 grams minus nothing. Each half-hour the inspector takes a sample of five boxes from the packaging machine, weighs the contents, and records the values. Then he computes the average of the five and notes the range of the sample (the difference between the lightest and the heaviest contents). Either from previous data or from six such samples, he computes the average range and multiplies by a constant to find the control limits within which the average weight of each sample must lie. He multiplies the average range by another constant and learns what extreme individual weights might be expected if he were to weigh several hundred boxes. If these lightest and heaviest anticipated weights lie within the specified figures, the machine is *capable* of doing its work and, if the average of each sample lies within the control limits, the machine is *actually* doing its work. In this example the grand average of all samples should remain very close to 345 grams.

When a process is not capable of working within the tolerances, either the process or the tolerances must be changed. If a machine or process does not work within its control limits, there is some assignable cause of variation which must be found and eliminated.

As an example of the inspection for attributes, consider an inspector who is checking small electrical devices for "grounds" or electrical paths between the windings and the metal frame. This defect could result from either faulty material or careless workmanship in assembly. During each 2-hour period, the inspector takes 100 units from the assembly line and makes a quick check on each to determine the presence or absence of a ground fault. He records the total number of items tested and the number of defectives found. This enables him to compute the average per cent defective for the process over a period when the rate of production is steady. By the application of statistics, he then computes control limits within which the per cent defective for each group of 100 items should lie. Any group showing more or less defective items must be investigated because it indicates an assignable cause of deviation. This cause should be discovered whether it makes the process better or worse.

The inspector may be checking only 1⁄10 of the total production but he learns more about the *process* by the use of control limits than he would learn by checking all items and avoiding the use of statistics. He learns precisely its capabilities.

As an example of the indeterminate sample size where the possible number of defects is large, consider the "squawk sheet" for a large airplane. The final inspectors of the finished plane fill out this sheet which lists all the faults that are observed. The statistical department analyzes these sheets to determine whether the over-all assembly process is getting better or worse. It also notes the frequency with which various faults occur. The total number of faults must follow a random fluctuation within certain limits which are computed by statistical methods. Lack of this random fluctuation may reveal improper performance of the inspectors. These limits may shift slowly with time if the quality of the assembly work changes.

In each of these examples which portray the elementary quality control operations, it can be seen that the use of an appropriate statistical method makes it possible for an inspector to learn more about the capabilities and the performance of the processes than he could learn by any other means. Usually this can be accomplished by using *less* inspection in a *more* efficient manner. (J. A. FIZZELL.)

STATISTICALLY SIGNIFICANT. A result is said to be statistically significant if the **null hypothesis** has been rejected. For example, if we say the difference in sample **means** is significant we imply we have rejected the hypothesis of the equality of the means in the two **populations** from which the two **samples** are drawn. While we have used sample means as an example, the theory is perfectly general and may be applied to **statistics** of any kind. Sample results should never be used unless statistical significance has been established, i.e., results have been determined for the populations from which the samples were drawn. Of course, sample statistics may differ statistically and yet from an engineering point of view the difference may be too small to be of any importance. (L.A.A.)

STATISTICS. Statistics is essentially a modern subject combining the mathematical theory of **probability** and the techniques of testing hypotheses. It is primarily concerned with the development of theories which have immediate applications and depends heavily on mathematics while deriving much of its inspiration from applied problems. Modern statistical methods arose from the classical theory of probability and the theory of

least squares. Formally statistics may be defined in various ways. Statistics is the subject concerned with the collection, tabulation, and analysis of data. This definition emphasizes **descriptive statistics.** Statistics is the study of variation. This definition implies the **analysis of variance.** At the higher level, statistics is that subject in which we make inferences concerning the whole **population** by use of a **sample,** usually a random sample. Statistics is of importance in the biological, physical, and social sciences as well as the fields of finance, business, industry, and insurance. Topics treated in statistics are descriptive statistics, analysis of variance, **Bernoulli's theorem, law of large numbers,** the **central limit theorem,** the **chi-square test, correlation, De Moivre-Laplace theorem, distribution functions, factor analysis,** design of experiments including **Latin squares,** and **randomized blocks, multiple correlation, normal probability function, Pearson system of probability functions, Gram-Charlier series, Bernoulli probability function, Poisson probability function, likelihood, Lexis distribution, partial correlation, Neyman-Pearson theory of testing hypotheses, periodogram analysis, serial correlation, sequential test of a statistical hypothesis, Fisher's *z* distribution, Snedecor's *F* distribution, Student's *t* distribution, hypergeometric probability function, consistent, efficient,** and **sufficient statistics, stratified samples, index numbers, confidence limits, quality control, industrial statistics,** the **test of independence in a contingency table,** and **tetrachoric correlation.** (L.A.A.)

STATOBLAST. Asexual reproductive bodies of fresh-water **Bryozoa.** They are disk-shaped buds formed in the parent colonies with a protective test to enclose them. When the colony dies in the winter the statoblasts remain alive and inactive, to produce new colonies in the spring. (A.W.L.)

STATOCYST. A form of sense organ found at the margin of **hydrozoan** medusae. It is a vesicular structure filled with a liquid containing small calcareous granules. The ectodermal lining is sensory and is apparently stimulated by the impacts of the granules as the animal moves. Varying stimuli in the eight statocysts around the margin of the animal bring about the proper movements to maintain its normal position in the water. **Lithocyst.** (A.W.L.)

STAUROLITE. The mineral staurolite is a complex **silicate** of **iron** and **aluminum** corresponding to the formula $HFeAl_5Si_2O_{13}$, but somewhat varying and may carry **magnesium** or **manganese.** It is orthorhombic, prismatic, twins common, often producing cruciform crystals. It is a brittle mineral; fracture, sub-conchoidal; hardness, 7–7.5; specific gravity, 3.6–3.7; luster, sub-vitreous to resinous; color, dark brown, sometimes reddish to nearly black; grayish streak; translucent to opaque. Staurolite is a metamorphic mineral usually the result of regional rather than contact metamorphism, and is common in schists, phyllites and gneisses together with **garnet, kyanite, tourmaline,** etc. Well-known foreign localities are in Switzerland and Brittany; and in the United States this mineral is common in the schists of New England, and those of the southern Alleghenies. Frequently the crystals are found loose in the soil after the disintegration of the country rock. The name staurolite is derived from the Greek meaning a cross, in reference to the twin crystals, the more nearly perfect crosses being somewhat in demand as curios. Quite frequently used as a baptismal stone, for according to early legend when the fairies heard of the crucifixion of Christ their falling tears when they reached the earth became crosses. (R.M.F.)

STAUROMEDUSAE. **Scyphozoa.**

STAY PLATE. **Compression Member.**

STAYBOLT. The surfaces of pressure vessels, such as **boiler** drums and **tanks,** which are not of a natural bulged shape, such as the cylinder or the sphere, must be stayed against bulging by special tension rods called staybolts. An example of a stayed surface will be found in the horizontal-return tubular boiler, which is simply a cylinder with flat ends having tubes extending from one end to the other, parallel to the axis of the cylinder. The tubes act to stay the flat surfaces, but the portion of the surface above the water line is free of tubes, and must therefore be supported by staybolts. Staybolts may be simple tie rods threaded on the ends to receive nuts which are screwed on the outside of the surface, or they may be hollow or flexible, the latter type having ball or socket joint at one or both ends of the staybolt. (F.T.M.)

STEADITE. A hard microconstituent found in **cast iron** consisting of a **eutectic mixture** rich in phosphorus. In high-phosphorus irons it may cause brittleness and impair machinability. (R.H.H.)

STEADYREST. **Lathe.**

STEAM. Steam is the vapor of water at or above its boiling temperature. The universal occurrence of water, its cheapness, its solvent properties, its suitability as a medium for a vapor cycle, and general familiarity with it and its properties, all have contributed to make of steam the most important vapor used by man. If a closed vessel is partially filled with water, and heat applied at a high temperature, the water will absorb the heat and rise in temperature until its molecular activity (which depends on its temperature) is so increased that the internal molecular attractions are no longer able to maintain it in the form of a liquid, and molecules leave the surface of the liquid and occupy the space above it in the rarefied condition of a **vapor.** Water has a definite vapor pressure at every temperature; when the vapor pressure becomes equal to the pressure above the liquid, the **boiling point** has been reached. If the steam is produced in a closed vessel, it is invisible. If it is released to the atmosphere, it partly condenses to form a cloud of mist (small drops of liquid water), which is visible. The temperature at which the boiling takes place is dependent upon the pressure which is maintained in the boiler. Steam which is in contact with the boiling water is known as saturated steam. If it is led away from the boiler, and subjected to further heating, it can become superheated, that is, its temperature may be raised above the saturation temperature. This elevation of temperature is known as superheat. (See **Quality; Saturated Vapor; Superheat.**)

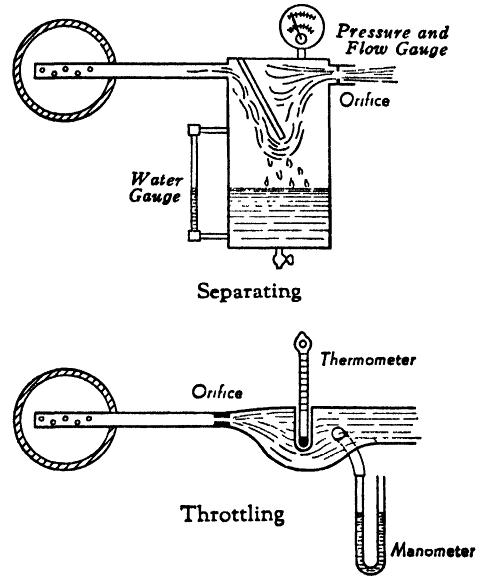
The saturation temperature of steam increases under pressure, at first rapidly, then more slowly, with uniform increments of pressure, until a temperature of 706.1° F. is reached, at a pressure of 3226 lbs. per sq. in. The heat required to boil off a pound of water at the saturation temperature into dry saturated steam is greater at the lower pressures, and decreases as pressures increase, until it disappears at 3226 lbs. per sq. in. This high pressure is the critical pressure at which steam and water are identical in physical properties. Steam at a temperature above 706.1° F. is certain to be superheated, no matter what the pressure. The heat contained in **saturated water** increases with increase of pressure until it becomes equal to the full enthalpy at the critical pressure. The rate of increase of heat of a liquid does not correspond with the rate of decrease of the heat of evaporation, and their sum, i.e., the

enthalpy of the dry steam, increases until it becomes maximum between 400 and 450 lbs. per sq. in., after which it decreases. At the critical pressure a pound of saturated steam contains less heat than at any other pressure. (See **Critical State.**) (F.T.M.)

STEAM CALORIMETERS. Dry saturated **steam** is rarely produced by a **boiler.** If unequipped with a **superheater,** the boiler will generate steam which contains droplets of moisture suspended in the steam. The per cent of steam in a unit quantity of steam and water is known as the **quality.** Steam exhausted from an **engine** or **turbine** has a considerable amount of moisture, the quality often being as low as 85%. It is not possible to judge the quality by inspection of steam, or of pipes in which steam is flowing. A thermometer is of no avail, and yet, there often arises the need for knowing the quality of steam flowing in a pipe line. To meet this need, there have been devised so-called steam calorimeters—devices for experimentally determining the quality of steam. Such calorimeters are made in two forms, each of which has its own particular sphere of usefulness. These instruments, which differ in principle, range of quality measurable, and technique of operation, are known as the *separating* and *throttling* calorimeters. (See **Calorimetry.**)

The separating calorimeter operates on a mechanical principle. It separates the water from the steam by centrifugal force, or difference of density of water and steam, and the principle is simply one of effecting the separation, and then separately measuring the water and dry steam. If A lbs. of water are separated from B lbs. of dry steam, the quality of the mixture is $\frac{B}{A+B}$. The calculations required in this calorimeter are thus seen to be simple, but the steam must be comparatively wet, because an extremely small amount of moisture cannot be effectively separated from the stream of dry steam. The calorimeter is provided with a catch chamber in which the separated water collects. The amount collected is measured by a graduated gauge glass connected to the calorimeter. The dry steam is measured by being passed through an orifice. A peculiar property of the orifice is that the weight of steam passed is proportional to the steam pressure. Using a fixed orifice, a scale of steam flow can be incorporated on the dial of an ordinary steam pressure gauge. However, the flow through the orifice is proportional to the calorimeter steam pressure only if the final pressure after passing the orifice is less than 58% of the initial pressure. This is equivalent to a requirement that the steam to be tested be at a pressure of over 10 lbs. gauge. For testing atmospheric exhaust steam, the calorimeter would have to discharge into a region of 12″ mercury vacuum or better.

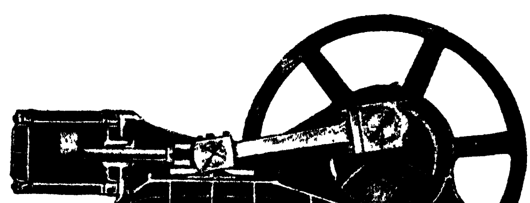
The throttling calorimeter is not suitable for other than the measurement of steam of very high quality. Its action depends upon the fact that the throttling of high-pressure steam through an orifice to a low pressure leaves the steam with the same heat content at the low pressure that it had at the high. Unless the high-pressure steam exceeds 1800 lbs. per sq. in. (a rare case), the heat it contains exceeds that of dry saturated steam at atmospheric pressure, so that it may be slightly wet, and yet have enough heat to produce superheated steam after being throttled. Now while the thermometer is of no avail in ascertaining the state of saturated steam, it does, in connection with pressure, definitely determine the state of superheated steam. That is, a temperature and a pressure together fix the state of steam and numerical data such as total heat, **entropy,** volume, etc., are readily obtained from compilations of steam data. Unless the steam is initially too wet to superheat the throttled product, the pressure and temperature readings of the low-pressure steam in the calorimeter are sufficient to determine its heat. Taking this, also, as the heat of the high-pressure steam, the quality is computed by the relationship: heat of wet steam = heat of liquid + quality × heat of evaporation. The quality



Steam calorimeters.

and heat of evaporation are taken from steam tables at the pressure of the pipe line. The accompanying diagrams are intended to be illustrative of the principle, rather than of the actual arrangement of the calorimeter equipment. A very different apparatus, also known as a steam calorimeter, and used for measuring *specific heats* of substances, is described under calorimetry. (F.T.M.)

STEAM ENGINE. A steam engine is a positive displacement piston and cylinder machine which, when supplied with **steam** at a pressure above its exhaust pressure, uses that steam expansively for the production of power which it makes available as a rotating **torque** at a crankshaft or flywheel. The steam engine is, with few exceptions, double acting, and at present is most



Ames automatic engine.

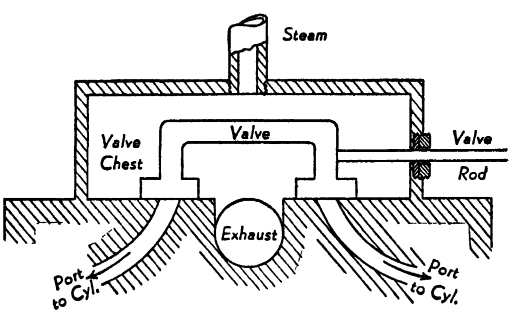
frequently built and used in sizes of less than 500 **hp.** Larger power units are generally installed as turbines. The steam engine is characterized by moderate or low speeds (100–500 rpm), the use of atmospheric exhaust (or a moderate vacuum), high starting torque, and ease of conversion to reversible operation if desired. The excellence of the **steam turbine** when a large amount of power is to be generated, especially where the exhaust is at a high vacuum, coupled with the high efficiency of the **Diesel engine** as a prime mover, has greatly restricted the field in which the steam engine is economically a superior prime mover. However, where a boiler must be supplied anyway, as for the generation

of heating steam, the steam engine is usually superior to the Diesel engine as a source of power, and where exhaust pressures are high (often the case in industry, where the exhaust is process steam), the steam engine offers advantages which are not seriously challenged by the other types of prime movers.

The principal parts of a steam engine are:

1. The frame or bedplate. In a multi-cylindered engine, this takes the form of a crankcase to which the cylinders are attached, but in a single-cylindered engine, the cylinder is often integral with the frame.
2. **Cylinder**, with valve chest.
3. **Piston**, piston rod, crosshead, connecting rod. This mechanical linkage receives a push from steam pressure at one end, and delivers it as a torque force on the crank.
4. **Crankshaft**, bearings, and flywheel. This part of the engine accomplishes the conversion of reciprocating to rotary motion, supports the shaft for power offtake, and steadies the speed.
5. **Valves** and **valve gear**. The device for admission and release of the steam to and from the cylinder, together with the means for actuating it from the crankshaft.
6. **Governor**. Stationary engines are automatically regulated for constant speed by means of a governor.
7. **Lubrication**. The piston and cylinder are lubricated by oil mixed with the steam. The bearings are lubricated with grease cups, oil rings, wicks, etc. The crosshead is often lubricated with a sight feed oil cup. On certain engines the totally enclosed crankcase permits the use of a splash system of oiling.

Unlike the gasoline engine, in which the valves have become standardized on the poppet type, the steam engine is built with many different valve types. The



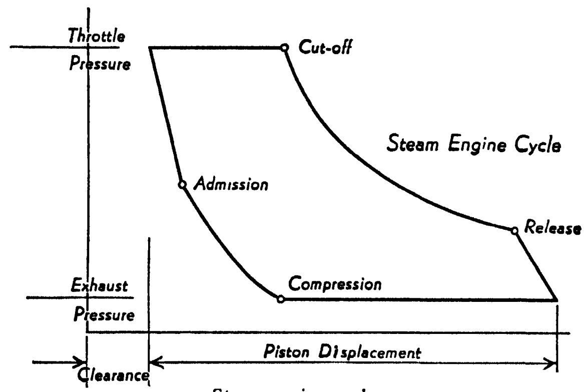
D Slide Valve

original valve was known as the D slide valve, because in cross-section it resembled the capital letter D. Only one valve was needed to admit and release the steam at both ends of the cylinder. This valve had definite disadvantages, to wit: the unbalanced steam pressure on it was difficult to handle except in low-pressure installations; its motion could be no faster than that of the piston, and consequently "wire drawing" of the steam existed during closure of the ports. Governing, by changing the point of cut-off, was possible only at the expense also of changing the other events of the cycle. The use of the D slide valve necessitated dual-flow engines, that is, steam entering and leaving by the same port. The alternate heating and cooling of the ports caused a large thermal loss known as **initial condensation**. To overcome some or all of these disadvantages, a century of engine development has evolved the following improvements:

1. The piston valve—no unbalanced pressure.
2. The Corliss—no wire drawing. Partially balanced pressure, partially reduced condensation. Cut-off independently controlled.
3. The poppet valve—balanced pressure, partially reduced condensation, and cut-off independently controlled.
4. Multi-port balanced valves—reduction of wire drawing. Balanced pressure.
5. **Uniflow** engine—elimination of initial condensation. Adaptable to any of the improved valves.

A steam engine converts from 5 to 15% of the heat supplied to it into work, depending on the state of the steam supplied, and on the exhaust pressure. The heat unconverted is composed: first, of heat remaining in the exhaust steam; second, initial condensation; third, incomplete expansion; fourth, wire drawing; fifth, friction; and sixth, radiation (negligible). The first of these is the largest, and is reducible only within certain limits. Incomplete expansion results from the release of the steam at the end of the stroke at a pressure higher than the exhaust. By using a longer stroke, this could be eliminated, but there is a point beyond which the increased cost of the engine more than offsets the gain derived by eliminating this loss.

The cycle upon which the engine operates is briefly described as follows: Slightly before the piston reaches the dead-center position corresponding to minimum cylinder volume, the valve connects the cylinder with the



Steam engine cycle.

steam line so that as the piston starts on its outward travel, the full steam pressure is acting on it. The beginning of this action is known as the event of *admission.* When some 20 to 30% of the stroke has been completed, the valve closes the port on the event known as *cut-off,* and during the remainder of the stroke, the steam is expanded **adiabatically** to the accompaniment of decreasing pressure. Near the end of its stroke, the valve again opens the port, this time connecting the cylinder with the exhaust line. This event is known as *release.* The cylinder remains connected with the exhaust during the return stroke of the piston, and the steam is expelled until approximately ⅔ of the return stroke has been completed. The valve then closes the port, and the remaining steam is trapped in the cylinder and compressed. The beginning of this process is known as the event of *compression.* The four events just described govern the form of the steam engine cycle. The engine using it will be able to develop a horsepower hour using from 10 to 25 lbs. of steam, depending upon the expansion permitted by the terminal conditions of the steam.

The steam engine may be mechanically controlled to give variable output so that when it is connected to a load which varies, it maintains nearly constant speed. There are two methods of accomplishing this result. In one, called cut-off governing, the per cent of the stroke during which the valve connects the cylinder with the boiler, is varied, and in this way different amounts of steam are admitted to the cylinder at one pressure. The mechanism to effect this type of control is incorporated in the valve drive. The other method, called throttling governing, consists of interposing an artificial resistance to create a pressure drop between the boiler

and the engine, so that although the same volume is admitted on each stroke (the cut-off being constant), the weight of steam admitted will vary because of the variation in density created by throttling. The governor, in this case, operates on a throttle valve located at the steam inlet. (F.T.M.)

STEAM ENGINE INDICATOR. Thermodynamics; Indicator.

STEAM PURIFIER. Steam purifiers are inserted in boiler drums to cleanse the steam of suspended moisture entrained in it during the process of generation. Boilers that steam slowly and have ample steam space in the drum do not need purifiers. At high rates of steaming, especially at high pressures, there are possibilities of wet steam generation and carry-over of entrained solids into the steam outlet. Clean steam is always desirable, especially when the steam is passed through turbines. Special cleaning equipment mounted inside the steam drum may be a simple *dry pipe* (a perforated pipe extending through the steam space to the outlet nozzle) or a more complex *washer.*

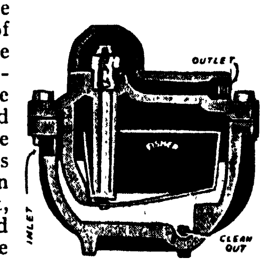
The steam washer is built into the steam drum so that incoming feed water will wash the entrained boiler water from the steam by bubble or spray action. If there is any moisture carry-over with the steam it is of the relatively pure feed water and not boiler water which is usually saturated with impurities. (F.T.M.)

STEAM RATE. The rate at which a **steam engine** or **turbine** consumes **steam** per unit power output is its steam rate. Originally, this quantity was called water rate, but since an enigne operates on steam, the term steam rate seems more appropriate. It is usually given in units of pounds of steam per horsepower hour, or per kilowatt hour in the case of a direct-connected or turbo-generator unit. The steam rate varies with the load, being minimum at a load known as the most economical load. This is the rated load in the turbine, and somewhat less than rated in the engine. Steam rate is affected by initial pressure and degree of superheat; also, by exhaust pressure. The higher the initial pressure, or temperature, and the lower the final pressure, the smaller the steam rate will be. Thermal efficiency is inversely proportional to steam rate. Steam rate, multiplied by load, is steam consumption, and when this product is plotted against load, the result is often nearly a straight line, up to the most economical load. This is the well-known **Willans Line.** (F.T.M.)

STEAM RECEIVER. The steam receiver is a tank or vessel providing a volume for the storage of **steam,** so that sources which use the steam in a fluctuating manner may be supplied from the storage in the receiver without causing a large fluctuation of pressure in whatever supplies the steam to the receiver. For example, the use of steam by an engine is pulsating, and where the boiler drum which supplied that steam had insufficient volume of steam storage, a cyclical variation of pressure was created, which, in some cases, caused excessive vibration of steam pipes and boilers. This was remedied by setting up between the **boiler** and the engine a receiver of suitable volume to augment the vapor storage of the boiler. Cross-compounded **steam engines** require a steam receiver intermediate between the exhaust of the high-pressure cylinder and the inlet of the low. The reason for this is that in this compounding arrangement, the low-pressure cylinder does not take in steam simultaneously with the exhaust of the high-pressure cylinder. A receiver of volume about equal to that of the high-pressure cylinder must be provided to prevent fluctuations of pressure on the inlet to the low-pressure cylinder. For much the same reason, receivers are used between the stages of multi-stage air compressors of the piston-cylinder type, though a cooling action is also incorporated in these receivers. (F.T.M.)

STEAM TRAP. A device which automatically operates to allow the discharge of water from a certain region, and prevent the escape of **steam** along with it, is known as a trap. The trap is used when condensate is to be drained from a vessel occupied by condensing steam, without the loss of steam. It traps the steam in the vessel and passes the water of condensation. Traps are used with steam heaters and cookers of all types, wherein a surface is interposed between the steam and that which is heated, to drain the condensation from steam lines, and for many similar services. A great deal of heat which is otherwise wasted by a partially opened drain valve will be saved by a trap if its discharge is connected to some point where the heat in the hot condensate can be used. The principal methods of operating a steam trap are expansion, float, tilting under the influence of accumulated condensate, and sinking bucket.

In an expansion trap, advantage is taken of the fact that condensate is usually a little cooler than the steam, and a metal expansion element is placed where it may be covered either with steam or condensate, depending on the amount of condensate in the trap. When it is covered with condensate it is cooler, and shrinks, opening a valve to pass the condensate from the trap. As the condensate is discharged, it uncovers the expansion element, and the hot steam causes it to expand and close the discharge valve. Such traps are frequently used on steam radiators. In a float-type trap, the float is attached to the end of a pivoted lever, from the other end of which a link bar extends to open or close a discharge valve, depending on the position of the float. These two types tend to produce a continuous discharge through a valve which is cracked open just sufficiently to maintain a condition of equilibrium in the water level of the trap. The tilting- and bucket-type traps are intermittent in operation, which is much better from the standpoint of wear on the discharge valve. In the tilting trap, water collects in a pivoted chamber until the weight of it overcomes the counterbalance and the whole chamber tilts until a valve is opened and the discharge of water through it relieves the trap so that the counterbalance can return it to the closed position. A pivoted bucket trap is shown in the accompanying diagram. As the condensate is collected in the trap, it fills the bucket, which otherwise would tend to float on the surface of the water in the bucket chamber. When the bucket is filled it sinks, thereby opening a discharge valve. The pressure of the steam forces the water out through the discharge valve, and as soon as the bucket is empty, it again floats on the water in the chamber, closing the discharge valve. (F.T.M.)



Steam trap.

STEAM TURBINE. Prime movers utilizing **steam** are the reciprocating engine and the turbine. One is essentially a pressure machine, the other a flow machine. The reciprocating parts of engines limit their speed to a comparatively low value, but turbine energy is obtained from a number of small forces working at high velocity. Smaller dimensions and freedom from vibration give the turbine an advantage in first cost, space, and foundation requirements. Both engine and turbine are reliable prime movers.

Probably the most significant factor bearing on the importance of the steam turbine is that it is the only prime mover available in the largest sizes desired. While

many of the larger turbines are specially made to the purchaser's specifications, manufacturers have developed the practice of arranging the blading within a number of standard sizes of casings so that turbines of almost any capacity can be built at reasonable cost and fairly good efficiency. Advantages of a turbo-generator are its (1) low first cost per kilowatt capacity, (2) low maintenance cost, (3) economy of foundation and building cubical content, (4) high efficiency when operated far into the low-pressure range, (5) uniform angular velocity with freedom from vibration, (6) oil-free character of the condensate.

The action in a steam turbine is the transfer of energy from the heat form first to kinetic energy of a high velocity steam jet, then to the energy in the rotating shaft. Its principal parts are:

1. Nozzles to change heat energy to work energy, and to direct the course of steam onto blades.
2. Blades, which change the kinetic energy of the jet of steam into shaft horsepower.
3. Rotating shaft, to which the blades are affixed.
4. A casing, which encloses the steam path and supports fixed parts.
5. Governor, bearings, lubrication, and other auxiliary devices.

When steam is expanded **adiabatically** through a stationary nozzle, it does not retain all the heat it originally had. The heat released during expansion does not disappear. According to the first law of thermodynamics, it must reappear as work energy in equivalent amounts (778 foot-pounds for every B.T.U.). In the case of steam expanding through a stationary nozzle, the moving steam must gain this mechanical energy, with the result that its speed is considerably increased. An ordinary expansion involving a heat drop of approximately 100 B.T.U. of steam has the capacity to increase its speed to the amazingly large magnitude of 30 miles per min.

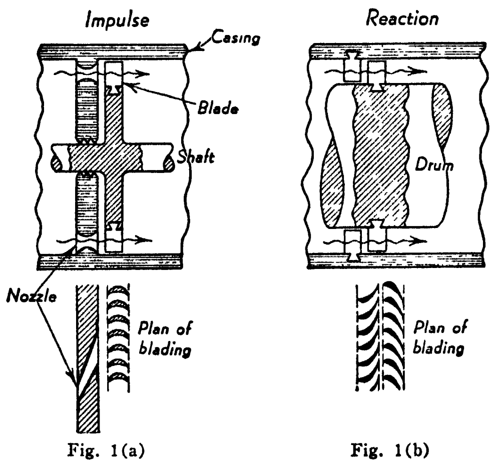


Fig. 1(a) Fig. 1(b)
One stage of steam turbines.

This may give some inkling as to the reason why so light a fluid medium as steam is capable of producing so much power in a machine of moderate dimensions. There are two principles of action employed in turbines, known as the impulse and reaction principles. The impulse principle involves stationary nozzles and moving blades which absorb the mechanical energy from the steam as it flows over the blades. In the reaction turbine the nozzles are themselves attached to the shaft. In one case the motivating force is one of impulse of a stream against a blade; the other, one of a reaction force created by the acceleration of the steam in the moving nozzles. A hydraulic analogy of the reaction turbine is the common revolving lawn sprinkler. The machines using these two principles exhibit some dissimilarity. For example, in the impulse turbine, the blades are rather heavy, of steel, attached to wheels which are mounted on the shaft. The nozzles have definite nozzle form, and are fixed in the casing. Reaction turbine blades are lighter, of bronze, and are directly affixed to a drum, which takes the place of the shaft. The moving nozzles themselves are made of blades so shaped as to give nozzle action. Further comparison of the impulse and reaction principles may be had by reference to the accompanying figure, which illustrates diagrammatically the nozzle and blade arrangement of both types. In each case one stage is represented. The nozzle of the impulse turbine speeds up the steam and guides it onto the blades which move past. The pressure drop is entirely consummated in the nozzle. The velocity increases in the nozzle and decreases on the blade. In the reaction stage, the row of fixed blades gives a nozzle effect which expands the steam and directs it onto a row of moving blades, also composed of nozzles. These, in turn, expand the steam, receiving thereby a reaction force from the acceleration of the expanding steam. The pressure drops in both fixed and moving nozzles. The fixed nozzles give the steam sufficient velocity to glide into the moving blades at their speed, or slightly faster. The expansion in the moving blades is sufficient to increase the relative velocity of the steam so that when it leaves them there will be no component of velocity in their direction.

Very high rotative speeds are necessary if the entire adiabatic heat drop for the turbine is released in one set of nozzles. For example, an impulse turbine with a conservative expansion would create a steam speed which, if absorbed on one row of blades revolving in an 18-in. circle, would require a rotative speed at the shaft of better than 10,000 rpm. This gives a clue to the desirability of staging a turbine by subdividing the heat drops, the energy being absorbed after each incremental heat liberation. Thus, in a five-stage impulse turbine, each stage may be called on to absorb only one-fifth of the total heat drop. The subdivision is even greater in the case of reaction turbines, where the B.T.U.'s liberated per stage rarely exceed 10. In consequence, the number of stages found in the reaction type turbine is greater than in the impulse. Except for areas of nozzles, size of blades, and blade angles, the stages resemble one another.

Large steam turbines fall into three classes:

1. Straight reaction.
2. Straight impulse.
3. Impulse reaction.

The straight reaction may have fifty or more stages, the straight impulse rarely more than twenty (half that number is more common). One or two impulse stages preceding a straight reaction section enable reduction of the number of reaction stages to about twenty.

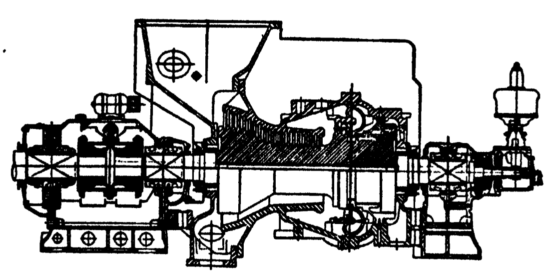

Fig. 2. High-pressure section of 110,000-kw. Westinghouse turbine.

An impulse turbine is pressure staged, i.e., the pressure drop is subdivided among a number of stages, any one stage of which may be, in addition, velocity staged. By this is meant that, following one set of nozzles there may be two rows of moving blades which, together, effect the reduction of velocity and the absorption of energy created in those nozzles. The two rows of moving

blades are separated by a row of fixed reversing blades, which receives the steam from the first row and directs it at the proper angle for the second row. A velocity stage within a pressure stage is known as a Curtis stage. A simple pressure stage is a Rateau stage, and the reaction stage often is called Parson's staging. As steam expands through a multi-stage turbine it increases in volume after each stage, making it necessary either that the diameter of the circle in which the blades travel be increased, or that the height of the blades be increased to provide sufficient area for the increased volume of flow. Usually both of these expedients are adopted, so that the turbine exhibits, roughly, a somewhat conical shape, being smallest at the high-pressure end, and largest at the exhaust.

Essential to the operation of a turbine are a number of auxiliary devices. The impulse turbine rotor receives a moderate end thrust, due to fluid friction on the blades. The reaction turbine has a large end thrust, arising from the drop of steam pressure, across the moving blades, acting on the blading annulus. While the end thrust of an impulse turbine can be accommodated by special thrust bearings, the large forces set up in a reaction turbine necessitate the use of a special device known as a dummy piston. The dummy piston is a circular plate mounted concentric with the axis of the turbine, and having, on one side, high, and on the other, low steam pressure. The pressures are so chosen that the direction of the resultant force on the plate is counter to the end thrust on the blades. A separate piston is used to balance each different diameter of the drum, so that although steam pressure and end thrusts may vary with different loads, the equalizing pressures also similarly vary. A thrust bearing is provided to absorb the small amount of unbalance which may still exist.

The moving parts of the turbine are few. Principally, there are two bearings, one at each end of the turbine, which support the rotor. These are rather heavily loaded so that plain babbitted bearings are usual. Oil is pumped to these bearings and wasted from them to a sump, from which it is withdrawn, filtered, and cooled before being again supplied to the bearings. An auxiliary pump maintains oil pressure during the starting and stopping cycle of the main unit. Where the shaft of the turbine projects through the casing, means are provided for packing against leakage of the steam outward at the high-pressure end, and infiltration of air at the low-pressure end. Packed **stuffing boxes** are used only on small turbines. This service is performed on large turbines by sealing **glands** which are built into the turbine, and which seal the shaft with steam or water. The outward leakage from the glands is minimized by labyrinths.

Governing of steam turbines is accomplished by three methods, viz.: (1) throttling at inlet, (2) varying number of inlet nozzles in action, (3) varying duration of full pressure puffs (blasts), of which there are several per second. In addition, some turbines are provided with hand-operated by-pass valves which, by admitting high-pressure steam to low-pressure stages, enable the turbine to carry more overload though, of course, at reduced economy. Of these methods, the first is widely used on small turbines. In the large turbine field, the second is applied to the Curtis type, and the third to the Parsons type.

The losses in a steam turbine, as is the case with the engine, are topped in magnitude by the heat in the exhaust. Unfortunately, this is difficult to reduce because of the troubles attending the use of steam of quality lower than about 85% in the turbine. Wet steam erodes turbine blades, due to the high velocity with which the particles of moisture strike them. The other losses which occur in steam turbines are:

1. Thermodynamic losses.
   - *a.* Leakage. Past shaft gland packings, dummy pistons, diaphragms and blade tips.
   - *b.* Blade and disk friction.
   - *c.* Throttling at the control valves.
   - *d.* Non-stream line flow at other than design conditions.
   - *e.* Leaving loss, and pressure losses in exhaust nozzle.
2. Mechanical losses.
   - *a.* Bearing and stuffing box friction.
   - *b.* Windage action of idle blades.
   - *c.* Gland water-seal power.
   - *d.* Oil pump and governor power.

All of the thermodynamic losses of one stage are returned to the steam as it enters the next lower stage, so that one definite advantage of multi-staging is to make available to the next stage the thermal losses of the preceding one. This is one factor in the superior performance of multi-stage turbines. To illustrates the point, consider the case of friction on the nozzles. If the turbine casing is well insulated, the heat that is generated by friction of the steam against the nozzles simply elevates the nozzle temperature until it returns, by conduction to the steam, as much heat as is generated by friction. The greater part of the stage loss is returned to the steam at the low pressure, and in turbine design it is considered that all of the reheat occurs at the low pressure of the stage. Fig. 3 shows how an adiabatic heat drop, as in nozzles, followed by a reheat, in which

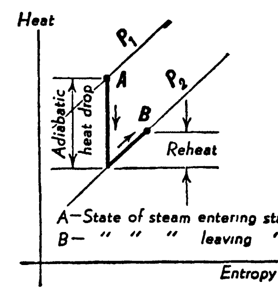

Fig. 3. Steam conditions in one stage of a turbine.

the stage losses are added at the low pressure, results in a steadily increasing **entropy** in a multi-stage turbine. This explains the typical expansion line of the steam turbine, which, as pressure is reduced, increases in entropy, whereas an ideal turbine would expand the steam at constant entropy. The increase of entropy corresponds to a decrease of energy availability, and that turbine which has the minimum entropy increase shows the best performance. (See **Stage Efficiency**.)

It is obvious from the foregoing analysis that all of the heat taken out of the steam during its passage from the throttle to the exhaust must have been put onto the rotating shaft as mechanical energy. This is true because of the negligible radiation loss from the casing. Friction and power required to drive the governor and oil pump take their toll of this energy, but they rarely amount to as much as 5% of the heat drop, so that practically all of the heat drop appears at the turbine shaft coupling as useful work. (F.T.M.)

STEARIC ACID AND STEARATES. Stearic acid ($H\cdot C_{18}H_{35}O_2$ or $C_{17}H_{35}\cdot COOH$ or $CH_3(CH_2)_{16}\cdot COOH$) is a white solid, melting point 69° C., boiling point 383° C., insoluble in water, slightly soluble in alcohol, soluble in ether. Stearic acid may be obtained from glyceryl tristearate, present in many solid **fats**, such as tallow, and in smaller percentage in semi-solid fats (lard) and liquid vegetable oils (cottonseed oil, corn oil), by **hydrolysis**. The crude stearic acid, after separation of the water solution of glycerol, is cooled to

fractionally crystallize the stearic and **palmitic acids**, which are then separated by **filtration** (oleic **acid** in the liquid), and fractional **distillation** under diminished pressure. With **sodium** hydroxide, stearic acid forms sodium stearate, a soap. Most soaps are mixtures of sodium stearate, palmitate and oleate.

The following are representative esters of stearic acid: Methyl stearate ($C_{17}H_{35}COOCH_3$), melting point 38° C., boiling point 215° C. at 15 mm. pressure; ethyl stearate ($C_{17}H_{35}COOC_2H_5$), melting point 35° C., boiling point 200° C. at 10 mm. pressure; glyceryl tristearate [tristearin ($C_3H_5(COOC_{17}H_{35})_3$)], melting point 70° C. approx.

Stearic acid is used (1) in the preparation of metallic stearates, such as aluminum stearate for thickening lubricating oils, for waterproofing materials, and for varnish driers, (2) in the manufacture of "stearin" candles, and is added in small amounts to paraffin wax candles. As the glyceryl **ester**, stearic acid is one of the constituents of many vegetable and **animal oils** and fats. (R.K.S.)

STEATITE. Talc.

STEEL. The essential elements in steel are iron and carbon, although manganese, silicon, copper, phosphorus, and sulfur may be present in greater amounts than carbon even in the so-called plain carbon or unalloyed steels. In alloy steels certain of these elements and many others including nickel, chromium, molybdenum, tungsten, and vanadium may be present in substantial amounts but carbon rarely exceeds 1.5% in either plain carbon or alloy steels.

Iron is not found in nature in elemental form because of its strong tendency to oxidize. The iron oxide ores are, however, readily reduced to iron by hot reducing gases formed by blowing air through burning charcoal, coke, and other carbonaceous materials. More or less carbon will be dissolved in the iron, depending on the length of time in contact with the hot reducing gases or the hot carbonaceous fuel itself, and the temperature attained. Thus the earliest iron products produced in primitive forges were often iron-carbon alloys or steels.

Because of the early limitations in producing a strong air blast it was not possible to melt the metal, but in the red-hot pasty condition in which it was withdrawn from the fire it could be readily welded together and shaped by hammering.

The art of hardening steel was undoubtedly discovered independently by many a smith who, by chance, cooled his red-hot "iron" by immersing it in water or other liquids. If the metal was too low in carbon, it did not respond to this treatment and some artisans apparently learned to increase the carbon content by methods similar to modern **carburizing.**

The irons and steels produced by direct reduction of iron ores inevitably contained as impurities some of the silica, clay, and other minerals present in the ore. Although considerable purification can be achieved by merely melting the steel and casting, it is doubtful if the required temperatures were attainable. However, in the course of development of improved bellows and of stack-type furnaces of increasing height in which the ores and fuels reached higher temperatures, a molten product of very high carbon content was finally obtained directly from the ore. The higher carbon content is the result of increased rate of absorption of carbon by solid iron at the higher temperatures. Since the melting point of iron-carbon alloys decreases progressively as the carbon content increases, it is possible to obtain molten metal without ever reaching the high temperatures necessary to melt pure iron or low-carbon steels. Castings from such a melt must have been disappointing in that they could not be welded or forged when heated to a red heat and were quite brittle at normal temperatures. While the new product found uses in cast form, only within the past century has it been used as the basis for making steel and other wrought or workable products. The indirect process of first making a high-carbon **pig iron** in a **blast furnace** and then refining it in a **Bessemer, open hearth,** or **electric furnace,** or by duplex processes involving more than one of these furnaces, is the basis of the modern steel industry. The most recent attempts to revert to the direct process of making steel from ore have not been economically successful.

The early history of the production of high-carbon **cast iron** from ore, the first stage in the indirect process for making steel, is not definitely known.

A cast-iron stove made at least 15 centuries ago has been discovered in China. Several other castings made in China before 1000 A.D. have been found, one weighing about 1500 lbs. The modern cast-iron period began in the 14th century when molten iron flowed from blast furnaces in the Rhine Valley. The process was used in England in about 1500, and in 1619 coke was first used instead of charcoal as the fuel and carburizing agent. Cast iron found many applications in the industrial revolution in England and later in America. Modern cast irons are made by remelting pig iron, the product of the blast furnace, in order to control its composition and adapt it to the product to be cast, often using alloying elements as in steel-making practice.

The principal developments in the second phase of the indirect process, the production of low-carbon iron and steel from pig iron, are of more recent occurrence. In 1766 a British patent was granted on a process for refining pig iron in a **reverberatory furnace** under oxidizing conditions which removed carbon and other readily oxidized elements. Improvements by Henry Cort in 1784 and Joseph Hall in 1830 virtually completed the development of the hand "puddling" process for making **wrought iron,** a low-carbon iron which could be welded and forged in the manner of the direct-process irons. Although this was a rather difficult product to make, requiring much arduous labor, wrought iron was produced in sufficient amounts to be used for many structural purposes in bridges and buildings and for machine parts, often replacing the relatively weak and brittle iron castings formerly used.

In 1856 the Bessemer process was introduced, making it possible for the first time to produce steel in relatively large quantities, thus introducing the age of steel. In 1864 the even more important open hearth steel-making furnace was invented by Siemens and Martin. The electric furnace followed in about 1890.

It will be recalled that small amounts of iron and steel have been made directly from the ore for many centuries. By means of Huntsman's "crucible process" (1740) it became possible to melt the crude "blister steel" made by cementation or carburization of direct-process irons, thereby liberating the slag and producing a casting of improved purity and uniformity which could then be forged into tools or weapons and heat treated to suitable hardness. The **crucible** process of melting steel is slow and very expensive compared with modern steel-making processes; however, until electric furnaces became well established the crucible process was used for melting high-quality tool and alloy steels from selected melting stock of high purity. In modern practice the electric induction furnace can be compared to the crucible process since both are ordinarily used to melt the charge without working or refining the metal.

The terminology of the iron-carbon alloys is, unfortunately, often confusing in that the term iron is applied to both very low and very high carbon materials. Thus wrought iron produced by direct reduction from ore under noncarburizing conditions or by the modern indirect methods has a very low carbon content. Of more industrial importance is open hearth iron, also widely known as Armco iron, produced in the open hearth furnace under highly oxidizing conditions in order to

remove practically all the carbon, manganese, silicon, and phosphorus present in the charge of pig iron and steel scrap. This material generally has 0.025% carbon or less and under 0.10% total of carbon, manganese, silicon, phosphorus, and sulfur. On the other hand, pig iron, the product of the blast furnace, and **cast iron,** generally made by remelting pig iron in a cupola, have high carbon contents, usually over 3.0%. Furthermore, **malleable cast iron,** the product of annealing white cast iron, has a carbon content usually between 2.0 and 3.0%. White-heat malleable iron, a product of British origin not generally made in this country, is a white cast iron whose carbon content has been practically all removed by an oxidizing heat treatment.

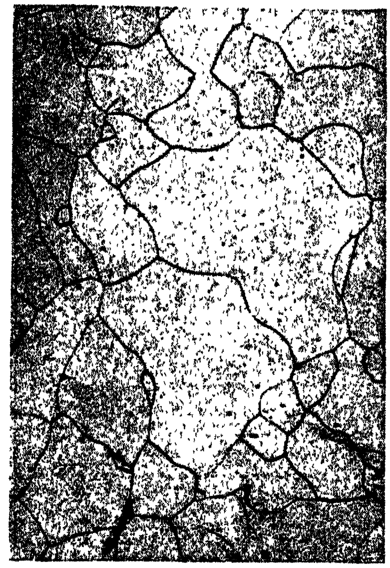
In many respects steels are intermediate between the very low carbon, and often very pure irons, such as wrought iron and open hearth iron, and the high-carbon cast irons which generally have high contents of silicon, phosphorus, sulfur, etc. The limits for carbon in steels are about 0.04% for low-carbon rimming steels such as are used for deep drawing sheets, and 2.25% in certain alloy die steels. Within this range there are certain fairly well-defined classifications as follows:

% Carbon	Representative Applications
.04– .12	Low-carbon rimming and killed steels for drawing and stamping sheets, wire, nails, rivets.
.08– .25	Low-carbon steel for structural purposes, boilers and fireboxes, pipe and tubing, machine parts to be surface carburized and heat-treated.
.25– .50	Medium-carbon steels for high-strength structural purposes, steel castings, forgings, machine parts to be hardened by heat treatment.
.45– .75	Intermediate-carbon steels for railroad car axles, hard-drawn spring wire, heat-treated alloy steel springs, rails, railroad car wheels, shock-resisting tools.
.75–1.25	High-carbon steels for cold-drawn music wire, drill rod, heat-treated carbon steel springs, cutting tools and dies, drills, reamers, ball bearings.
1.25–2.25	High-carbon tool steels for drawing dies, finishing tools, files, etc., in which high abrasion-resistance is more important than toughness.

Open hearth iron and the low-carbon drawing-grade steels consist, structurally, of crystals or grains of ferrite containing elements such as manganese, phosphorus, and copper in solid solution. (See **Metallography.**) A very small amount of carbon is also soluble in the ferrite and any excess will be present as particles of **cementite,** Fe_3C, embedded in the ferrite, or as patches of pearlite, an intimate mechanical mixture of ferrite and Fe_3C having a characteristic microstructure. Also present in iron and steels of all catagories are certain non-metallic particles such as iron and manganese sulfides, and various silicates and oxides. (See **Inclusions.**)

In the annealed or soft state the structures of all steels consist of various mixtures of ferrite, pearlite, and cementite. Ferrite is soft and ductile, with a tensile strength of about 40,000 lbs. per sq. in. Cementite is very hard and brittle. Pearlite has intermediate characteristics with a tensile strength of about 100,000–140,000 lbs. per sq. in., depending on the fineness of its structure. As the carbon content increases the proportion of ferrite decreases and the pearlite increases until at about 0.80% carbon the structure is completely pearlitic. This is also known as the **eutectoid** structure. Steels with higher carbon contents may consist of pearlite and cementite, the latter generally being present as massive particles embedded in the pearlite or as a continuous film around the pearlite grains. However, dead soft annealed high-carbon tool steels do not contain pearlite, all of the carbon being present as rounded cementite particles embedded in a matrix of ferrite.

When carbon steels are used in the annealed or normalized condition, their structures are essentially as described above and their properties change gradually



Ferrite grains in ingot iron at 100 times magnification. Etched in a solution of 3% nitric acid in alcohol (nital). (See Metallography.)

from those of ferrite to those of pearlite, with further increase in hardness and wear-resistance when massive cementite is present. However, for many applications steels are **heat-treated** by quenching in oil, water, or brine, which results in profound changes in their struc-

Ferrite (light) and pearlite (dark) in a 0.15% carbon steel at 100 times magnification. Etched in nital.

tures and properties. These changes are related to a property of iron-carbon alloys known as allotropy, or change in crystal structure with temperature. (See page 292.) When an annealed steel is heated above a certain temperature, e.g., 1400° F. for a 0.50%-carbon steel, its structure is changed from ferrite and pearlite

to austenite. Whereas the original ferrite had a **crystal structure** known as body-centered-cubic, austenite has a face-centered-cubic structure of somewhat higher density. Furthermore, all of the carbon present is soluble in the solid austenite at this and higher temperatures so that the material is homogeneous rather than a

mechanical mixture of ferrite and pearlite. Although the transformation is reversible under equilibrium conditions, upon rapid cooling the austenite does not revert to ferrite and pearlite. Instead, a new structure known as martensite is produced and some of the austenite may

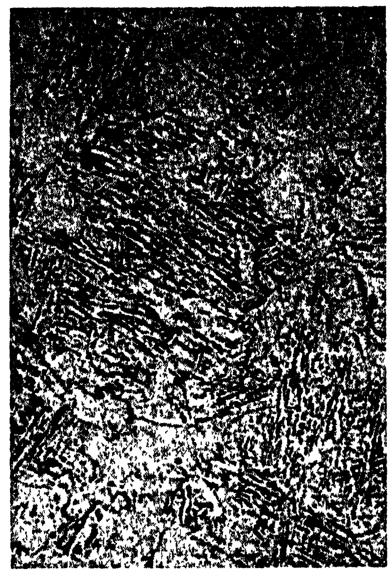
remain untransformed, especially in the case of certain alloy steels. Martensite has a body-centered-tetragonal crystal structure which is very similar to that of ferrite; however, it contains the carbon atoms in a state of supersaturated solid solution. Martensite is very hard and quite brittle.

For nearly all purposes hardened steel must be reheated or **tempered** to relieve internal stresses and reduce brittleness. (See **Heat Treating.**) This is accomplished at relatively low temperatures such as 400° F. If a greater measure of toughness and ductility is required at some sacrifice of hardness and strength, higher tempering or drawing temperatures up to about 1200° F. are used. The structural changes occurring during tempering include transformation of any retained austenite to martensite and the decomposition of martensite at the higher temperatures to a mixture of ferrite and cementite known as sorbite. The cementite particles are first precipitated in a very finely divided form throughout the matrix of ferrite, and as the tempering temperature in-



Martensitic structure in 0.15% carbon steel quenched in water from 1660° F. 500 times magnification. Etched in solution of picric acid in alcohol.

creases the particles grow by agglomeration until they become easily distinguishable in the microstructure as spheroids. Prolonged treatment at about 1300° F., known as spheroidizing, produces the largest cementite particles. Concentration of the hard cementite particles in this manner leaves a continuous matrix of soft ferrite. In this condition the indentation hardness and strength are at a minimum, and in the case of the higher carbon steels the machinability is very good, but not necessarily at a maximum.

In the foregoing discussion the direct quench and temper type of hardening treatment has been described. There are several alternative treatments, some of quite recent invention, for the heat-treatment of steel. These include time quenching, austempering, and martempering. All of these treatments are based on the fact that in the quenching of steel the cooling rate down to a black heat (about 900° F.) is very critical, but below this temperature a lower rate can be used. The actual transformation to the hard martensitic structure takes place in the lower temperature range, a few hundred degrees F. above room temperature. This transformation is accompanied by an increase in volume. In a large section or a piece having both large and small sections, temperature gradients will occur in any rapid-cooling process, thus the transformation and volume change will occur first in the small sections and the outer portions of large sections. Since the steel is at a black heat it has lost its high-temperature plasticity and the differential volume changes cause high internal stresses which can result in cracking. Special treatments have, therefore, been devised to avoid rapid cooling in the low-temperature range.

Time-quenching consists of withdrawing the piece from the quenching medium after a predetermined time while it is still hot and cooling it to room temperature in air or in a less drastic quenching medium. This method has been used to prevent cracking in the hardening of tools and dies.

Martempering, developed during the war, has the same purpose as time-quenching—full hardening without cracking or distortion. In the martempering process rapid cooling is interrupted at a temperature just above the martensite transformation temperature and the piece is held in a constant-temperature bath until the temperature is essentially equalized throughout the piece before final cooling to room temperature. This is followed by tempering in the usual manner.

Austempering consists of quenching into a bath of molten salt or metal held at a fixed temperature such as 750° F., and holding at this temperature until the hardening transformation is complete before cooling in air to room temperature. Martensite is not formed and no tempering treatment is required. The structure produced in this process by transformation at a constant elevated temperature is known as Bainite. Austempered steels develop a combination of strength, ductility, and toughness which is superior to that of conventionally quenched and tempered steels. Because of the necessity for rapid cooling down to the transformation temperature and the relatively poor cooling capacity of the elevated temperature bath, the process is applicable only to small sections and to steels having good **hardenability.**

The following list of steel compositions has been selected from hundreds now included in the specifications of the various technical societies, the government, and large users of steel. While the alloy and heat-treating grades far outnumber the non-heat treating grades, the latter make up the greatest tonnage. (See **Tool Steels, Steel Castings, Stainless Steel, Magnetic Materials.**)

STEEL CASTINGS. A relatively small proportion of the total domestic steel production is made into steel castings. (See **Casting, Steel.**) These range in size from small machine parts to hammer base foundation castings weighing 250,000 lbs. Most steel castings are a medium carbon (0.25–0.35% carbon) steel; however, the entire range of carbon and alloy contents ordinarily produced as wrought steels can be used for steel castings with slight modification to insure soundness. Steel castings are often heat-treated by normalizing or quenching, followed by a tempering or drawing treatment. The mechanical properties of heat-treated castings approach those of corresponding wrought steels and the ductility and toughness are much greater than that of cast iron.

Steel castings have many applications for railroad car and locomotive construction, including frames, trucks, couplings, and driving wheels. There are many other applications in rolling mills, machine tools, farm implements, automobiles, road-building machinery, cranes, valves and fittings, etc.

Although the rapidly increasing use of **welding** has made it possible to fabricate certain parts from wrought-steel shapes and forgings instead of using castings, the inherent ease of production of castings insures their continued use for parts having complicated shapes. (R.H.H.)

STEFAN-BOLTZMANN LAW. An important law of **thermal radiation,** discovered empirically by J. Stefan in 1879 and deduced theoretically 5 years later by L. Boltzmann. It states that the total emissive power of a **black body** is proportional to the fourth power of the absolute temperature of the black body:

$$E = \sigma T^4.$$

The constant of proportionality, σ, called the Stefan-Boltzmann constant, has been determined experimentally as 5.672×10^{-5} erg/sec. cm.^{2} deg.^{4}; but the measurements

(R.H.H.)

are difficult and the precision is doubtful. Boltzmann's deduction was based upon the thermodynamic theory of **radiation pressure.**

In accordance with this law and the principle of exchange of radiant energy, and since the emissivity and the absorptivity are equal, the net rate at which a black body of area a (sq. cm.) loses energy by radiation when placed in an enclosure of temperature T_m is

$$\frac{dw}{dt} = a\sigma(T^4 - T_m^4) \text{ (ergs per sec.)}.$$

Newton's law of cooling approximates the Stefan-Boltzmann law for small differences of temperature only. (See also **Heat Transfer.**) (L.D.W.)

STEGANOPODES, PELECANIFORMES. Birds with long legs, webbed feet, and long beaks and necks. The **pelicans** are typical of the group, which also contains the **cormorants** and some related marine forms. (A.W.L.)

STEGOCEPHALIA. Fossil Amphibia.

STEGODON. Fossil Mammals.

STEGOSAURUS. Fossil Reptiles.

STEGOTHERIUM. Miocene.

STEINBOK. Mammalia, Artiodactyla. A small African **antelope,** any member of several species. The group to which they belong includes several species named as steinboks, *Raphiceros,* and in addition the royal antelope, *Neotragus pygmaeus,* the grysbok, *Nototragus melanotus,* and the **oribi.** The name is also applied to the alpine **ibex.** (A.W.L.)

STELE. The **vascular** tissue of the axis of a plant is called the stele or central cylinder. The principal tissues composing it are the **xylem** and the **phloem.** Others are pith, pith rays, cambium, and pericycle. The most primitive type is the protostele, which consists of a solid central mass of xylem surrounded by a cylinder of phloem. There is no pith in a protostele. Protosteles are found in the roots of all plants and in the stems of some of the ferns. Many would set off the stele of the root as a separate type known as a radial stele, since the central mass of xylem is not a cylinder but has several arms projecting outward from its surface, with the phloem concentrated between these arms. In stems, only those of certain Pteridophytes like *Lycopodium,* have radial steles.

A siphonostele is composed of concentric cylinders of xylem and phloem enclosing a central pith. If the xylem cylinder is next the pith and is surrounded by the phloem, the stele is an ectophloic siphonostele; if there are two cylinders of phloem, one inside and one outside the xylem, it is an amphiphloic siphonostele. The most common type in **Gymnosperms** and **dicotyledon** stems is the ectophloic siphonostele. The amphiphloic siphonostele is found in members of the gourd family and in some ferns. Commonly there are many gaps in the siphonosteles, where vascular strands pass outward into a leaf. These gaps are called leaf gaps; the strand, a leaf trace.

A dictyostele is a siphonostele which is so broken up by numerous leaf gaps that it appears to be made up of a number of separate strands. It is really a very much dissected siphonostele. Dictyosteles are found in some **ferns** and in many **dicotyledons.** (R.M.W., B.S.M.)

STELLAR MAGNITUDE. In the first star catalogues issued by Hipparchus and Ptolemy the relative apparent brightness of the stars was designated by a system of six numbers referred to as the magnitudes of the stars. Twenty of the brightest stars were referred to as first magnitude, while those at the limit of visibility were called sixth magnitude. The stars with brightness intermediate between the two extremes were assigned to a magnitude number with the numbers increasing with faintness of the stars. With the application of the **telescope** to astronomy many faint stars were discovered and the need for additional magnitude numbers became evident. Unfortunately for modern astronomers, the attempt was made to amplify the ancient magnitude system not only to include the fainter stars, but also to indicate finer gradations of brightness by a decimal system. The result is that astronomers are now using a system which was started about 2000 years ago and has all of the clumsiness and inconvenience for modern observers which is characteristic of so many of the ancient scientific instruments.

There is no definite evidence that Hipparchus or Ptolemy had any idea in mind at the time that they first used the magnitude system other than to provide a rough descriptive term for the stars. In the early part of the 19th century Sir John Herschel found that the apparent brightness of a first magnitude star is about 100 times that of a sixth magnitude. In 1850 Pogson proposed a fixed scale of stellar magnitudes based upon the original scale of Hipparchus and Ptolemy, but so adjusted that it would agree at the sixth magnitude with the system employed by Argelander in his famous **Bonner Durchmusterung.** Adopting the announcement of Herschel that the ratio of brightness of a first and sixth magnitude star is approximately 100, Pogson proposed that the ratio between successive magnitudes should be $\sqrt[5]{100}$ or approximately 2.512. This leads to an analytical expression for the magnitude scale as follows:

Call B_1 the apparent brightness of a star of magnitude H and B_2 the apparent brightness of a star of magnitude J, then $B_1/B_2 = 2.512^{(J-H)}$ or, expressed in logarithmic form, $\log_{10} B_1 - \log_{10} B_2 = 0.4\ (J - H)$.

Since the magnitude scale is a scale of relative brightness, it is necessary to establish a system of standards. For this purpose a group of stars in the immediate vicinity of the north celestial pole has been selected. The magnitudes of the stars in this "north polar sequence" have been very carefully determined and agreed upon by the International Astronomical Union. All magnitudes determined at the present time should be referred, either directly or indirectly, to this standard sequence.

The magnitude scale as originally established referred to the relative apparent visual brightnesses of the stars. With the application of photography to astronomy difficulty with the magnitude scale immediately became evident. If we have two stars of the same visual magnitude, one of them blue and the other red, the photographic image of the blue star will be much stronger than the photographic image of the red star. The colors of the stars in the sky vary with the different spectral types, and the visual magnitude differences between a number of stars of different spectral types will differ considerably from the magnitude differences obtained by photographic means. Furthermore, the photographic magnitudes, so-called, will be different, depending upon the type of plate used and the characteristics of different telescopes, and it becomes necessary to be very explicit in defining the particular range of wavelengths of **spectral** energy that are to be used in any magnitude scale. The difference between the photographic and visual magnitude of a star is known as the **color index** of the star, the term arising from the fact that the color is the determining factor in the magnitude scale difference.

With the application of various other types of radiation measuring instruments, such as **bolometers** and **radiometers,** to the measurement of the apparent brightnesses, of the stars the necessity has arisen for various different magnitude scales such as bolometric magnitude, radiometric magnitude, etc. The problem of the intercorrelation of the different systems is at present in a

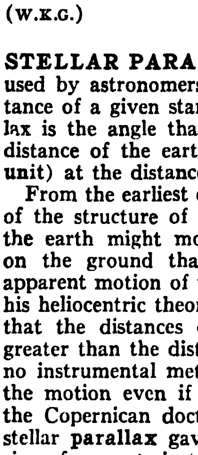
very confused state and much research is being carried on in this important field. It is devoutly to be hoped for that in the future some system of expressing the apparent brightnesses of the stars may be devised that will replace the present complicated inverse logarithmic scale of magnitudes.

For the purpose of expressing the intrinsic brightness of a star, independent of the distance of the star from the earth, a system of **absolute magnitudes** has been devised which will be discussed in more detail elsewhere. (W.K.G.)

STELLAR PARALLAX. The term stellar parallax is used by astronomers as a means for expressing the distance of a given star. Technically defined, stellar parallax is the angle that would be subtended by the mean distance of the earth from the sun (one **astronomical unit**) at the distance of the star from the sun.

From the earliest days of the Pythagoreans any theory of the structure of the **universe** which postulated that the earth might move about the sun was objected to on the ground that such motion should produce an apparent motion of the stars. **Copernicus**, in proposing his heliocentric theory, met this objection by postulating that the distances of the stars were so incomparably greater than the distance of the earth from the sun that no instrumental methods would be capable of detecting the motion even if it did exist. The attempts to test the Copernican doctrine by searching for this so-called stellar **parallax** gave a tremendous impetus to the design of accurate instruments, but even with the improvement in instrumental equipment the effect was not observed and the Copernican theory lost ground. It was not until 1838 that **Bessel** was able to definitely prove that the effect is present.

The type of effect to be looked for is illustrated in the figure. The type of curve which the stars should apparently follow due to the earth's motion about the sun varies from an ellipse with eccentricity equal to that of the earth's orbit for stars at the pole of the ecliptic, to oscillations back and forth along a straight line for stars in the plane of the ecliptic.



Parallaxes of the stars. Owing to the earth's revolution the nearer stars describe parallax orbits annually with respect to the remote stars.

The problem of determination of stellar parallax is theoretically very simple. All that is necessary is to make a series of observations of the positions of a star on any system of **spherical coordinates** (e.g., **right ascension** and **declination**) and from the observed changes in position throughout the year determine the stellar parallax. This so-called absolute method was attempted many times but failed to reveal any definite value because of the fact that the instrumental corrections were larger than the effect sought for. This is not surprising when we consider that the largest stellar parallax which has ever been found (for the star Proxima Centauri) has a value of 0".783, or equivalent to the angle subtended by a ten cent piece at a distance of approximately 3 miles.

With the failure of the absolute method to yield values for the parallaxes of the stars, Bessel and Struve decided upon an indirect or relative method for determining the desired quantity. This method is based upon the assumption that certain stars are at such a great distance that their parallaxes are too small for detection, but that there are other stars closer to the sun which should show motion relative to the distant background. Bessel selected the star 61 **Cygni**, which was assumed to be relatively close to the earth from a large **proper motion**, while Struve selected the star **Vega** which has an appreciable proper motion and is also so bright as to imply closeness to the earth. Proceeding by different methods, in 1838 both Bessel and Struve were able to show that the stars which they had selected showed parallactic motion relative to the background of stars.

Until the application of photography to astronomy the problem of determination of stellar parallaxes was very tedious and laborious and up to 1880 distances of less than 25 stars had been determined. With the application of photography the progress of parallax determination became very much more rapid, and at present many long programs of observations both in the northern and southern hemisphere are nearing completion.

The photographic method consists in first selecting stars which are suspected, either from proper motion, **spectral type**, or other characteristics, to be relatively close to the sun. Plates are taken of these stars, great care being exercised in the guiding, and the brightness of the "parallax star" is reduced until its photographic image compares favorably with the images of the fainter "background stars." The plates are all taken at the same **hour angle**, either east or west, to eliminate so far as possible atmospheric effects, and the dates on which the plates are taken are separated as much as possible to make the effect of the earth's motion as large as possible. Twenty or thirty plates, extending over several years, are taken and the position of the parallax star carefully measured with reference to half a dozen background stars. A **least squares** solution will yield the motion of the star relative to the background. This motion will consist both of the proper motion and the parallactic shift. The former may be separated from the latter because proper motion is linear in character while the parallactic shift is periodic. For stars within 5 million times the sun's distance from the earth (parallax 0".04) the mean of two or three determinations will be correct within 20%. For twice this distance the results are only accurate enough for statistical purposes, while beyond this distance the trigonometric method is practically valueless. Occasionally, due to an unfortunate choice of parallax star or of comparison stars, the value of the stellar parallax comes out to be a negative quantity. Such a "negative parallax" simply means that the star under observation is more distant than those selected for comparison purposes. For the more distant stars beyond the range of the trigonometric method certain other methods are available such as: parallaxes of members of **moving clusters, mean parallaxes, dynamical parallaxes** of double stars, and **spectroscopic parallaxes.**

The "General Catalogue of Stellar Parallaxes," published by Dr. Frank Schlesinger at the Yale University Observatory in 1935, lists 7534 parallaxes determined either by the relative trigonometric or spectroscopic methods, and 2482 parallaxes determined by the dynamical method. (W.K.G.)

STELLAR PHOTOMETRY. The problem of determining the **stellar magnitude,** or brightness, of a star is known as stellar **photometry.** Since the magnitude scale is a purely arbitrary one, all methods of stellar photometry consist fundamentally in the comparison of the brightness of one star with the brightness of a star of standard magnitude. The simplest method is to make direct visual comparison between the two stars and estimate directly the difference in magnitude. In the so-called "Argelander method" two stars of standard brightness are selected, one brighter and the other fainter than the star under consideration. The difference in magnitude between these "comparison stars" should not be greater than one magnitude. The observer then mentally divides the magnitude difference between the comparison stars into, say, ten, light steps and estimates the brightness of the unknown star in terms of these steps.

It is a well-known fact that the eye can more accurately determine when two objects are of equal bright-

ness than it can determine the difference of brightness of two unequal objects. A number of different devices, such, for example, as the **wedge photometer** and the **polarizing photometer,** are employed for equalizing the brightness either of an artificial star or a star of known magnitude with that of the star under consideration.

The above methods all employ the human eye as the instrument of measurement and the characteristics of different eyes vary not only between different observers, but also, to some extent, from day to day for an individual observer. In the attempt to remove the human element from the determination of stellar magnitudes various stellar photometers have been devised which measure directly the intensity of the radiation from star images formed by telescopes. Such photometers employ devices such as **photoelectric cells, selenium cells, thermopiles,** etc., by means of which the radiant energy is converted into a **galvanometer** deflection, with the deflection a complicated function of the amount of radiant energy. The technique of using such instruments is difficult to master and the process of obtaining results is slow and tedious, but in the hands of skilled observers the results with these physical photometers are more accurate than those obtained by any other method. These types of instruments are selective for particular wavelength bands of radiation, and great care must be taken in comparing results obtained with one instrument and telescope with the results obtained by others.

The determination of stellar magnitudes either by direct visual comparison, by the use of visual photometers, or by the use of physical photometers is slow and fatiguing for the observers, with ten magnitudes per hour being a fair average rate of measurement. With the photographic plate and modern astrographic **cameras,** images of several hundred stars may be obtained in one hour of observing with the telescope. The size and blackness of a star image are complicated functions of the magnitude of the star. A plate taken of a region of the sky for the determination of the magnitudes of the stars must be standardized in some manner. There are many different methods of plate standardization in use, for example, photographing a standard sequence of stars, such as the polar sequence, on the same plate, or exposing the plate to a number of small areas with light of different intensity in each area. The plates are measured in a **densitometer,** usually of the physical type of microdensitometer, and the photographic densities of the various star images and standarization images are obtained. From the densities of the standarization images a calibration curve for the plate may be obtained and the magnitudes of the stars obtained. In the photographic method, as in all methods of stellar photometry, color effects are very troublesome and the intercomparison of results obtained by different observers, using different photographic plates and cameras, is a difficult task.

In all methods of stellar photometry a great many precautions must be taken to insure results of any value. After all known corrections for observer, method, and telescope have been applied, there always remains the troublesome and uncertain error introduced by the effects of atmospheric absorption. (W.K.G.)

STELLITE. A non-ferrous alloy containing 25–40% chromium, 40–80% cobalt, 0–25% tungsten, 0.75–4% carbon, and smaller amounts of iron, manganese, and silicon. It is hard and unmachinable as case and must be finished by grinding. In addition to its high hardness and **red hardness** which make it useful as a cutting tool material, it has excellent corrosion-resistance which is a requirement for applications such as surgical instruments and polished mirrors in optical instruments. (See **Alloys.**) (R.H.H.)

STEM. The stem of a plant is that part which bears the **leaves** and **flowers** and later **fruits.** Commonly it grows erect, lifting these various organs up above the ground. It is readily distinguished from the root by being separated into joints or nodes and internodes, and by bearing leaves or by having on its surface scars left by the falling of leaves.

Stems may be classified in several ways. If one considers the duration of the stem, it becomes an annual lasting but one year, a biennial living 2 years, or a perennial stem which grows for several years. If one considers the internal structure of the stem, he finds it to be herbaceous or woody. An herbaceous stem is one which is largely made up of **parenchymatous** cells, without a great mass of woody tissue. In temperate regions such stems last but a single year, at the end of which they die. In annuals the entire plant dies, while in herbaceous perennials the top dies, but the basal portion including the root and the lower stem lives on. Woody plants are those in which the stem is predominantly composed of **vascular** tissues. Such plants are either trees or shrubs or vines. Trees are commonly distinguished by the existence of a single stem or trunk which does not branch at its base, whereas in shrubs no single trunk exists, but several of equal size result from basal branchings. Branching is either excurrent or deliquescent. When excurrent, the trunk is distinctly recognizable throughout its length, the branches coming from it being much smaller, as in many **conifers** such as spruce or fir. Usually such trees have a conical shape, due to the progressively smaller branches from bottom to top of the tree. In deliquescent branching, the main trunk branches into several large branches which in turn divide, as in the elm. Vines are distinguished by their long relatively slender stems which usually require external support. Another classification separates erect stems from those which are procumbent or trailing on the ground, from scandent stems which clamber over supports, and from twining stems, which wind tightly around any supporting object.

In many plants the stem is very much reduced in size, appearing as a small often flattened ball, as in the common Cyclamen or in certain Cactus plants. Other plants are said to be stemless, the stem existing only as a small object at the top of the root, the leaves arising from it seeming to come directly from the top of the root. A familiar example is the dandelion. The first year of growth in many biennials results in a similarly stemless plant; carrots, beets, and parsnips are common examples.

As previously noted, one of the functions of the stem is to elevate the leaves into a position where they may function most efficiently and the flowers to a position where they may become more conspicuous and where the resulting fruits may be better scattered. Not only does the stem perform this function, but it also permits a great increase in the number of leaves and flowers which may be borne. The stem is the organ through which sap ascends from the root to the leaves and through which organic materials elaborated in the leaves pass to the place of storage. The stem itself may be the place in which materials are stored.

The stem develops from a **bud.** In the **seeds,** the embryo has a terminal rudimentary bud, the plumule, from which the first stem develops. The tip of this stem bears a terminal bud, from which further increase in the stem is developed. In the axils of the leaves lateral buds are formed which develop into branches. Elongation of the stem takes place only in the tip, extending downward therefrom a few inches, and is caused by the cellular changes like those that occur also in the elongating root. In some plants, as in Grasses, intercalary growth also occurs. This is growth in the region of the older nodes of the stem. Increase in diameter of the stem results from the divisions of special cells called **cambium** cells.

When the extreme variations of stem are considered, with their range from tiny plants less than half an inch in height to forest giants towering 300' and over, and from vines with slender wiry stem less than 1/16" in diameter through succulent herbs to sturdy trunks 40' or more through, it is not surprising that stem structure should be very variable and often complex. Yet they are all composed of the same types of cells and are all arranged on two fundamental patterns, one found in **dicotyledonous** plants, the other characterizing the **monocotyledons.**

In dicotyledons, the growing tip of the young stem has cells which are all alike, having a dense cytoplasm, and large nuclei, which, if the stem is growing, will be dividing frequently. These cells comprise the promeristem, the region where active cell division occurs, but little change in cell form.

As these cells increase in number, some are carried ahead, while others remain unchanged in position. The latter gradually show very evident changes in size and shape, and in the nature of their walls. The outermost layer, called the dermatogen or protoderm, is made up of somewhat flattened cells which will become the epidermis, a protective covering against entrance of disease-producing organisms and against excessive loss of water. Within the body of the stem tip certain strands of cells become distinct by their elongate shape and dense protoplasmic content. These procambium strands are the beginnings of the vascular tissue presently to appear. In cross-sections of the stem the procambium appears as a ring of separate masses of cells. The remaining cells of the growing tip are parenchymatous cells, called the ground meristem, changed but little from the promeristem condition.

As the procambial cells grow older, they gradually change in form. Those cells which are nearest the center of the stem become xylem cells, those towards the circumference of the stem become phloem, with **cambium** cells separating the two types. In some stems the differentiation of cells continues until the procambial strands have united to form a continuous cylinder which gives place to concentric rings of xylem and phloem cells separated by a band of cambium cells. In other stems, the strands remain distinct, forming separate vascular bundles. The ground meristem or parenchyma in the center of the stem becomes the pith, that surrounding the strands becomes the cortex and pericycle, while the radiating masses of parenchyma cells between the separate strands make up the pith rays. All these tissues, derived indirectly from the differentiation of the promeristem cells, form the primary body, composed of primary tissues.

The epidermal cells are often somewhat elongated in the direction of the length of the stem. The outer wall of an epidermal cell is frequently much thickened and cutinized, so that it becomes impervious to water. Many **stomata** are found in the epidermis. As the diameter of the stem increases, the epidermal cells gradually become stretched until they finally break apart and are lost.

The cortex inside the epidermis is comprised of several kinds of cells. Those nearest the surface are the collenchyma cells. These are modified parenchyma cells, the walls of which are thickened in their angles. These cells usually contain chloroplasts. Because of their thickened walls, collenchyma cells give support to the stem, while at the same time they manufacture food. The parenchyma cells of the cortex are thin-walled, and

either rounded in shape or, through mutual pressure, more or less angular. Those near the surface of the stem often contain chloroplasts, and carry on photosynthesis. They give rigidity to the stem because of their turgor pressure, and also serve as storage tissue. In some stems there are also found in the cortex thick-walled sclerenchyma cells. These may be either long slender fibers or short stone cells. The innermost cells of the cortex, the endodermis, are rarely conspicuously filled with starch grains, which give to these cells collectively the name of starch sheath. In a few plants the innermost cells of the cortex form a definite endodermis, the walls of each cell being much thickened.

The tissues inside the cortex include the pericycle, the vascular bundles, pith rays, and the pith. This is the stele.

The cells of the pericycle are very similar to those of the cortex, so much so that it is often very difficult to distinguish one from the other. In the pericycle of stems, which usually is much thicker than that in roots, sclerenchyma cells, both fibers and stone cells, may be found along with the parenchyma, just as in the cortex.

The cells comprising the vascular system—xylem and phloem—are very much modified. The procambial cells towards the center of the stem first elongate greatly, without appreciably increasing in diameter. Soon changes appear in the wall, secondary deposits of cellulose being laid down against the primary wall. The manner in which the wall is thickened varies in different cells. In some the thick deposits are in rings: these are formed while the cell is still elongating and so are gradually separated. Such cells are called annular cells. In other cells of the first-formed xylem, which is called protoxylem, the wall thickenings are in the form of spirals, producing spiral cells, which allow a certain amount of growth even when the thick wall is formed. In cells which differentiate later, when elongation has been completed, the thickening of the wall will be much more extensive, only irregularly distributed, narrow slits being left unthickened. These slits extend transversely in the wall of the cell. Such cells are called scalariform or reticulate cells. Finally cells are formed in which special thin plates, often circular in outline, with overhanging walls are left. These are the pits which allow lateral communication from cell to cell. Cells having them are called pitted cells. Differentiation of the xylem cells continues until most of the inner part of the procambial strand has been changed to xylem cells. Those which form after the narrow protoxylem cells are called metaxylem cells. Protoxylem and metaxylem together make up the primary xylem. It should be understood that, as the xylem cells develop, the end walls are cut away forming long tubes, called vessels or tracheae. Water moves rapidly through such tubes.

The cells on the outside of the procambial strand become the primary phloem cells. These are the sieve tubes and companion cells. Early stages in the formation of these cells are much like those of xylem cells, elongation first occurring and then changes in the cell wall. In the formation of phloem cells, a single cell divides into two which become very unequal; the larger one continues to increase in size and loses its nucleus; the smaller one frequently divides again. The walls of these cells remain comparatively thin, with characteristic perforated thin places, called sieve plates, in the end walls of the larger cells, which form the sieve tubes. The smaller cells, called companion cells, are characterized by a dense cytoplasmic content, small vacuoles and prominent nucleus. They are connected with the sieve tubes by numerous small thin places, called simple pits, in their walls. Phloem cells are channels in which food passes through the stem. In addition to these various cells, the phloem contains parenchyma cells which are used for storage of materials and in some plants long thick-walled fibers, called phloem or bast fibers.

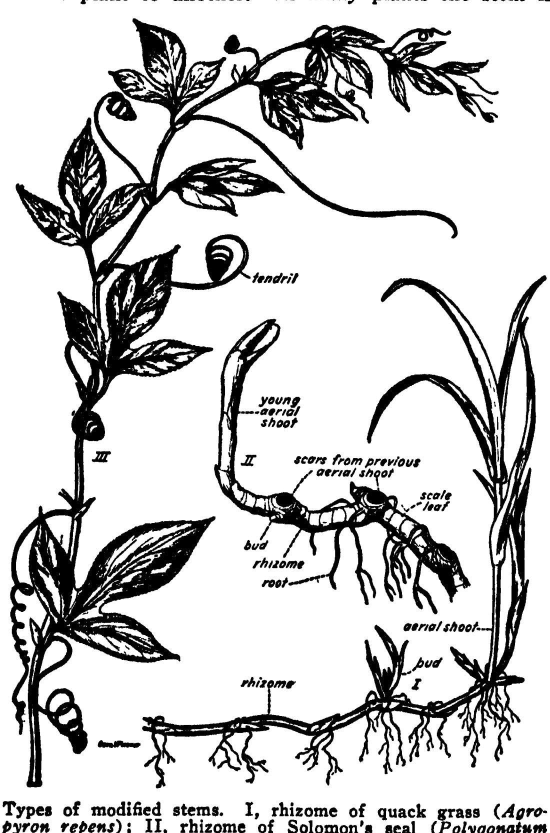
Parenchyma and fibers also occur in the xylem elements. Between the xylem and phloem elements there is a band of cells which remain unmodified and become an important tissue in many stems. This is the **cambium,** which by its divisions gives rise to the secondary tissues which compose the bulk of the stems of woody plants. These secondary tissues are the secondary xylem and phloem, and differ only slightly from the primary xylem and phloem, being unlike mainly in their origin. Secondary rays, which provide for lateral translocation of food, are also produced by the cambium.

In the center of the stem is the pith, composed of large, thin-walled cells arranged in irregular fashion. They function principally as places of storage of food.

In nearly all monocotyledons, no cambium is formed, therefore the monocot stem is composed entirely of primary tissues. The arrangement of these tissues is vastly different from that of the stems of dicotyledons. The vascular tissues occur in the form of separate small bundles which are scattered throughout the stem. It is impossible to distinguish any limit separating cortex from pericycle and pith. In many monocots the central portion of the stem is entirely free from bundles and recognized as a pith. Often the pith breaks up, forming a hollow stem.

All **Gymnosperms** have woody stems. The development and structure of these are quite similar to that of dicotyledons, but, except in a few uncommon species, the xylem is composed entirely of tracheids, distinguished from the tracheae of the angiosperms by the fact that they are elongated cells instead of long tubes formed from many cells, and no companion cells are formed in the phloem.

In most plants the function of the stem is to display the leaves and reproductive organs in the most favorable position and to carry materials from one part of the plant to another. In many plants the stem is

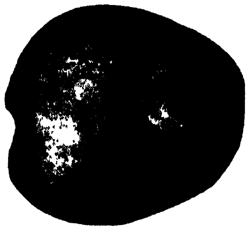


Types of modified stems. I, rhizome of quack grass (*Agropyron repens*); II, rhizome of Solomon's seal (*Polygonatum commutatum*); III, stem of passion flower (*Passiflora incarnata*) with tendrils which are modified stems.

a highly specialized structure with different functions. Often these specialized stems take over the function of one of the other organs of the plant.

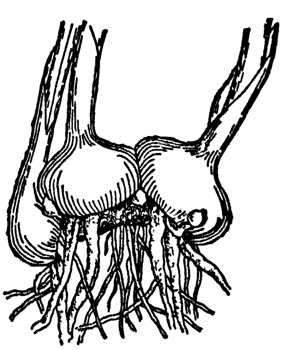
The outer tissues of the stems of nearly all plants are green. Therefore some **photosynthesis** takes place in these tissues. There are many plants in which the stem is the principal, if not the only, place where photosynthesis occurs. In many cases, as in some of the **spurges** and **cacti,** the appearance of the stem differs very little from that of any other plant; but leaves are very much reduced or entirely lacking, all photosynthesis occurring in the stem. In other species of cactus, such as the Prickly Pear and the widely cultivated crab or Christmas cactus, the stem is very much flattened, but still distinctly recognizable as a stem. In some plants, however, the modification has become extreme. The ultimate branches of the stem have become very much flattened and have a shape which gives them every appearance of a leaf. Only their position in the axil of a tiny scale, the real leaf, betrays their true nature. The dainty Smilax, *Asparagus asparagoides,* of the florist, has branches of this kind. So also does the Butcher's Broom, a marsh plant of Europe, which is widely cultivated and appears during the Christmas season, stained a brilliant scarlet. The inconspicuous greenish-white flowers of this plant occur in the center of that part which is commonly assumed to be a leaf. The tiny needle-like "leaves" of the garden asparagus are really branches.

In a few plants the stem becomes a very important reproductive part. Runners, long slender branches from the base of the stem, grow out horizontally over the surface of the ground, and root at their tip. There a new plant is formed. With death and disintegration of the connecting stem, the young plant becomes separate from its parent. This is a form of vegetative reproduction. A stolon differs very little from a runner; it is a prostrate branch which regularly roots at its nodes, and sends up new plants not only at its tip but also from the nodes. Rootstocks or **rhizomes** are spreading underground branches which produce **adventitious roots** at their nodes and often spread widely.



Potato tuber with scale-like leaf at "eye."

Many rhizomes become very fleshy because of an accumulation in them of food materials. Their principal function then is storage. Storage occurs in the stems of many different plants. If only a portion of the rhizome becomes enlarged, it is called a tuber. The common white potato is a very familiar tuber, which is formed at the tip of a slender rhizome. The "eyes" of the potato are really the nodes of the stem; from them buds will give rise to branches when the potato grows. More modified than the tuber is the corm.



Corms of *Gladiolus* consisting chiefly of fleshy stems.

This is a short thick erect rootstock. Often it is much broader than it is long. Buds are formed on the upper surface of the corm. Each of these buds grows into a new plant, exhausting the substance of the old corm. New corms form at the base of the old one. Corms known to all are those of *gladiolus* and *crocus.* These are usually incorrectly called bulbs. A bulb is a fleshy bud, composed of a short thick stem and many fleshy or scaly leaves or leaf bases. Onions form true bulbs, as do tulips, hyacinths and many lilies.

The materials stored in the stems so far considered are mainly reserve food. Other stems become swollen with stored water. Many cacti and Euphorbias have stems of this sort.

Thorns are usually stems or branches which have become stiff and pointed and serve to protect the plant Tendrils are organs which support a plant as it grows up through other plants. Not all tendrils are stems. Some, like those of the grape, are definitely so; others are leaves or parts of leaves. Usually plants which have tendrils have slender stems which lack sufficient strength to support themselves. Plants of this type are vines. There are several types of vines, or climbing plants. One of them supports itself by twining tightly around any available support. The direction of twining is very constant for any species, some invariably turning in a clockwise direction and others counterclockwise.

Other climbers support themselves by **adventitious roots** which form in abundance and cling tightly to any support. Other climbing plants are supported solely by the presence of many spines or prickles, often hooked, or pointed backwards so that the stem does not easily slide off any object on which it rests. Climbing roses illustrate this type of climber. But many tropical vines are much better illustrations. Often these grow to great lengths, hanging in long festoons from the tops of tall trees, or growing in tangled masses over low shrubby plants. In these tropical climbers, which are commonly called lianas, the stems often assume curious flattened or fluted or irregular shapes. In diameter they vary from a fraction of an inch to many inches; they may attain a length of 400 or 500 feet. They are one of the most characteristic and annoying features of the tropical rainforest. (See also **Cambium, Wood.**) (R.M.W., B.S.M.)

STENOPODIUM. The biramous appendage of crustaceans in its slender form. (A.W.L.)

STEPHANITE. The mineral stephanite, silver **antimony sulfide,** $5Ag_2S,Sb_2S_3$, is found in short prismatic or tabular **orthorhombic** crystals. It is a brittle mineral; hardness, 2–2.5; specific gravity, 6.2–6.3; metallic luster; color, black; **streak,** black; opaque.

Stephanite occurs associated with other silver minerals and is believed to be primary in character. Foreign localities are in Czechoslovakia, Saxony, the Harz Mountains, Sardinia; Cornwall, England; Chile and Mexico. In the United States it is found in Nevada, where it is an important silver ore. It was named for the Archduke Stephan of Austria, mining director of that country at the time this mineral was first described. (E.S.C.S.)

STEPHENSON GEAR. Valve Gear.

STEPTOE. A hill or mountain whose top projects above a lava flow which has surrounded its lower flanks. (R.M.F.)

STEREOGRAPHIC PROJECTION. This type of **map projection** is used to some extent by navigators, but more commonly for maps of the celestial **sphere,** particularly in constructing the basic map for **star finders.** This projection has a valuable property in that circles on the sphere appear as circles on the projected

map. Because of this property, several attempts have been made to use the stereographic projection for drawing **lines of position** obtained from celestial objects. In the proposed methods, the subastral point would be plotted on the chart and the circle of position drawn about this point with a radius equal to the observed **zenith distance** of the object. This method is proposed for use by aviators, where speed in drawing lines of position and obtaining a **fix** is particularly desirable, and where extreme accuracy is never possible because of errors inherent in measuring **altitude** with a bubble **sextant** in a moving plane. Thus far this use of the stereographic projection has not been developed for practical use, but it shows promise of success. (W.K.G.)

STEREOISOMERISM. **Isomerism and Stereoisomerism.**

STEREOPTICON. **Projection; Optical.**

STEREOSCOPE. **Binocular Vision.**

STEREOSCOPIC PHOTOGRAPHY. A stereoscopic photograph is one which reproduces in the mind of the observer the same sensation of three dimensions produced by observation of the object itself.

Students of optics have long been aware that the two eyes perceive dissimilar views of an object.

The two views received by the eyes differ in two significant respects. Since the angle of vision is different

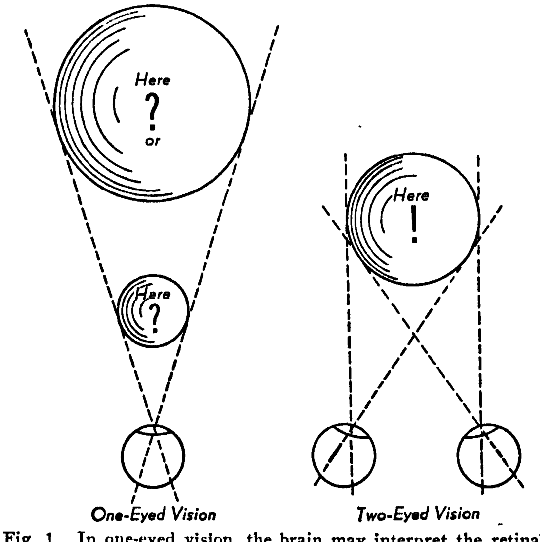


Fig. 1. In one-eyed vision, the brain may interpret the retinal image as a large object far away or a small object near by. In two-eyed vision, the object is fixed in direction, size, shape, and distance.

for each eye, the objects appear in a slightly different guise. If there are several objects in the field of vision, they appear in slightly altered relations to each other. Both the angles and distances of the objects in the scene are sufficiently changed to present a different picture to each eye.

A second important difference in the two views is a change in light distribution. As the angles of view change, highlights appear at different positions and with varying degrees of intensity.

The brain does not record a genuine sensation of depth unless the two eyes convey to it two complete and somewhat different pictures of the object seen. It is only by a rapid comparison and combination of both views that the brain is able to perceive depth directly.

All versions of the stereoscope are devices for duplicating the visual process of depth perception. They are all instruments that present two somewhat dissimilar 2-dimensional pictures, one to each eye of the observer. The brain reacts to these views as it would to the object itself and therefore "sees" a 3-dimensional image. The two pictures must be positioned so that the two eyes perceive mutually exclusive views.

In 1833 the British scientist, Sir Charles Wheatstone, stated the general theory of binocular vision, and in the course of his paper suggested a method of building a stereoscope. It is he who is generally credited with the invention of the device. A year later Professor Elliott of the Department of Logic at the University of Edinburgh decided to illustrate his theories on perception of distance with a practical demonstration. Since photography was unknown at that time Professor Elliott drew a pair of simple pictures containing a cross, a tree and a crescent moon. He placed these on transparent paper and designed a viewer.

Another investigator, Sir David Brewster, built a box-type stereoscope which he equipped with geometric drawings. In 1849 the Abbé Moigno equipped the Brewster stereoscope with daguerreotypes. A large variety of scenes could now be reproduced in pairs with ease and accuracy. By 1860 the stereoscope was a popular parlor amusement and a London stereoscope company was doing a thriving business.

In this country, Oliver Wendell Holmes became interested in the device and he designed a hand model for parlor use. He saw great possibilities in the device and predicted that the new invention would find many applications.

Since the original Wheatstone invention, stereoscopic photography has gone through a large number of improvements, most of which were developed for technical and scientific applications of the instrument.

The simplest method of providing a pair of stereoptic photographs is to take two successive pictures of the same object by shifting the camera a small distance laterally, generally equal to the distance between the two eyes. The camera may be mounted on a slide bar and the change of angle between the scenes controlled. The chief disadvantage to this method is that a period of time elapses between the two exposures. This difficulty limits the photographer to scenes of still life.

An improvement over the single-lens system is a specially constructed double-lens **camera.** Here the shutter

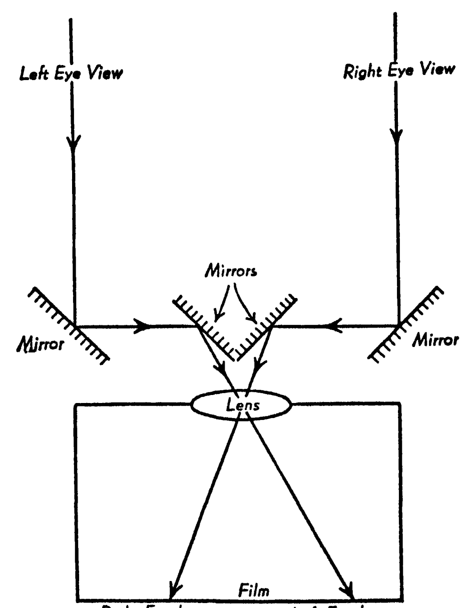

Fig. 2. A beam-splitter attachment converts any small single-lens camera into a one-shot camera for taking 3-dimensional views.

mechanism is synchronized for simultaneous exposures, and the pairs of scenes are recorded, one on each half of the film. After development the prints may be separated for stereoscopic use. A variation of this system is the use of mirrors which direct the two images through the single lens. In this manner two separate images may be obtained simultaneously with only one lens.

The problem of viewing stereoscopic pairs is more difficult. Ideally the two images should appear in the same location, yet each image must be seen only by the eye for which it is intended. Three general methods of image separation have been devised: geometric optics, color optics and polarization optics.

The earliest viewers of Wheatstone and Elliott used complicated systems of mirrors to achieve the proper picture separation. Brewster's model and its later development by Holmes use lenses to permit the eyes to look straight ahead in a normal manner with the focus relaxed as though viewing a distant scene. The modern stereoscopic viewer, permitting only one observer at a time, is a compact and inexpensive device. It can be used for viewing both transparencies and reflection-type prints.

A different approach to the problem of viewing was made in 1853 by Rollman and by D'Almeida a few years later. By their process, the two prints, called color anaglyphs, one reproduced in red, the other in blue-green or green, are superimposed. The system makes use of matching viewers. Since the red filter prevents the red reproduction from being seen by one eye, while the blue print is clearly visible, and the blue filter acts similarly, the effect is a stereoscopic presentation. The system has the great advantage of being capable of display to a large number of people at one time. However, the color filters greatly reduce contrast and brightness. They preclude any possibility of representation in natural colors. In addition, the strain caused by the conflicting colors restricts the viewing of color anaglyphs to short periods.

In 1901, F. E. Ives developed the parallax system of viewing which has the advantage of requiring no viewing devices. But the viewing positions are limited, there is a loss of detail, and the photographic technique required for the Ives system is complicated.

In 1891, the British scientist Anderton first experimented with polarized light as a means of image separation using tourmaline and other crystalline polarizing materials. But lack of an efficient and commercially practical light-polarizer prevented the development of these techniques. The invention of a practical sheet-polarizer by E. H. Land reopened the entire field of picture separation by means of polarizing filters.

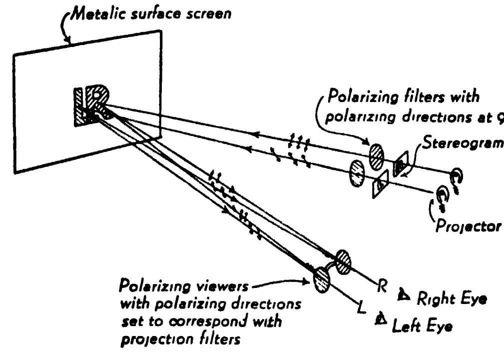

Fig. 3. The principle of 3-dimensional pictures in full color.

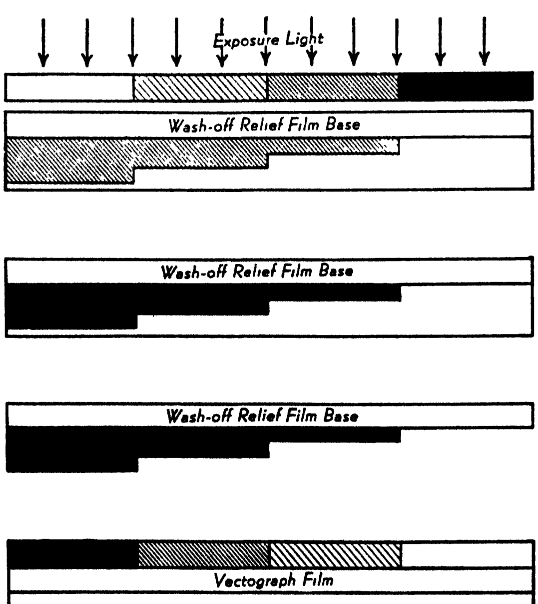
In 1934, J. Mahler invented the photo plasticon, a complicated device which permits only one observer at a time. It is the only instrument yet devised which presents a full-color stereoscopic image without loss of definition and yet requires no viewers of any kind.

The application of Polaroid sheet-polarizers to the problems of stereoscopic photography gave great impetus to the art of 3-dimensional representation. None of the foregoing procedures was suitable for presentation to a large audience without sacrificing much of the detail of the picture. None of the above methods could produce a satisfactory print that could be handled and observed as any other photographic print. In 1940, however, Land and Mahler developed the vectograph which met both these needs.

If two polarizing sheets are placed across each other, with their polarizing directions at right angles, no light will pass through them. If their polarizing directions are parallel, light will penetrate. If, however, one of the polarizers has only a partially polarizing effect, light



Exposure: Varying amounts of light transmitted through the light and dark areas of a stereo negative create latent image of varying depth in dyed relief film emulsion.

Development: Where latent image is developed the surrounding gelatin of emulsion is hardened by tanning developer.

Wash-off: Unhardened gelatin washes off, leaving relief image which soaks up varying quantities of printing solution.

Vectograph Printing: Varying densities of vectograph image set up by solution transferred from relief image. Similar image set up on other side of vectograph film.

Fig. 4. Vectograph process in diagram.

passing through it will appear gray to a polarizer placed across it. By controlling the degree of polarization, the observer can, through a crossed polarizer, see many shades or tones from very light, at zero polarization, to completely opaque for complete polarization. A polarizer parallel to the partially polarizing sheet will reveal no gradations whatsoever.

The vectograph reproduces the scene in terms of partial polarization, much as the halftone reproduces light and shade for printing. The light surfaces are not polarizing. The darker ones are more polarizing, reproducing varying shades of gray; the black portions are rendered in completely polarizing areas.

For stereoscopic effects two such pictures are placed one over the other on the same clear plastic sheet, but with their axes of polarization at 90° to each other. Viewers are similarly arranged with their polarizing directions at right angles to each other. The image intended for the right eye then appears in all the varying shades of the original photograph, while the picture intended for the left eye remains invisible. The left eye receives its exclusive image, and the brain combines the two to form a 3-dimensional scene.

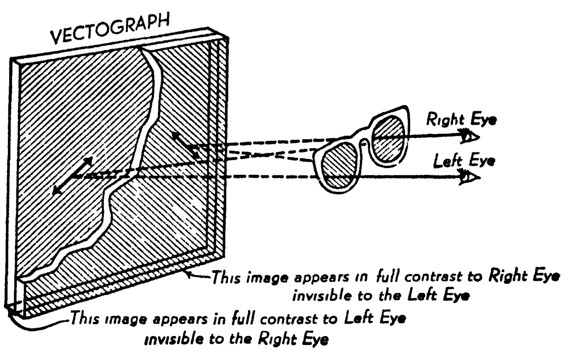


Fig. 5. Two-eyed vision. Three-dimensional vectographs have one image on each side of the film, each image being rendered in terms of degree of polarization, with their polarization directions at right angles. The front image appears in full contrast to the right eye because its vibration direction is crossed with the "optical slots" of the right eyepiece.

The applications of 3-dimensional photography vary from military and scientific uses to such recreational fields as motion pictures and the family snapshot album. In photomicrography, surface structures and minute objects can be observed in all the detail of their actual dimensions. Aerial photographs faithfully reproduce contour changes for relief maps. Instruction in solid geometry and celestial navigation no longer require an explanation of 3-dimensional phenomena from flat projections. The possibilities are far-reaching in all commercial fields where display is used. Museums and scientific exhibits can achieve far more effective representation of their materials by the use of depth perception. (Prepared by Polaroid Corporation, Cambridge, Mass.)

STERILITY. Inability to reproduce; barrenness. Sterility may be the fault of husband or wife or both. Sterility in either sex may be due to (1) anatomical defects, congenital or acquired, (2) disease or the results of disease in the reproductive organs, especially that due to **gonorrhea,** (3) glandular disturbances especially those concerning the **thyroid, pituitary, adrenal, ovarian** and **testicular** glands, (4) poor health, due either to chronic disease or deficiency in diet. (R.S.M., D.M.H.)

STERILIZATION. Any procedure by which an individual is made incapable of reproduction. Sterilization of the feeble minded, insane, or criminal insane, or for therapeutic measures, is a simple procedure. No mutilating operations are done and there is no loss of sexual urge, no change in appearance, behavior, or sensation. In the male a small incision is made in the upper part of the scrotum and a small piece of the vas deferens is removed, thereby preventing the passage of sperm cells to the outside. In the female, through an incision into the peritoneal cavity, small pieces of both fallopian tubes are removed. (R.S.M.)

STERLET. Pisces, Chondrostei. A **sturgeon,** ***Acipenser ruthenus,*** of moderate size found in the Black and Caspian seas and in rivers of Siberia and Europe. As a food fish it is one of the most desirable members of the group, both for its flesh and for its cavaiar. (A.W.L.)

STERN-GERLACH EXPERIMENT. An experimental test by O. Stern and W. Gerlach (Germany, 1924) of the magnetic moment of **atoms.** A stream of metallic atoms, issuing from a vaporizing furnace through a narrow slit, entered a strong magnetic field. The magnetic intensity was perpendicular to the atom stream, and had a strong gradient in its own direction. If magnetic moments of atoms are due to revolving electrons, the atoms should, according to classical theory, begin to precess at all angles about the field direction, and the atomic beam should simply broaden into a band. According to the quantum theory, they should precess at certain angles only, and the original stream should be divided into several distinct streams. Actually it proved to be divided into two, oppositely deflected streams. From this the experimenters concluded that the atoms tested have but one "magneton" each. (See **Magnetism** and **Precession.**) (L.D.W.)

STERNITE. **Skeletal System.**

STERNUM. The breast bone. **Skeletal System.** (A.W.L.)

STEROLS. **Alcohols and Ethers.**

STETHOSCOPE. An instrument used to transmit and to amplify various sounds produced by certain organs of the body. The stethoscope in its common form is composed of a cup-shaped device and two pieces of rubber tubing each running from this to an ear-piece which fits in the ear. This instrument is used particularly in listening to heart, lung, and pleural, arterial, venous, and intestinal sounds. (D.M.H.)

STIBIUM. **Antimony.**

STIBNITE. The mineral stibnite, **antimony sulfide,** Sb_2S_3, is found in radiated groups of acicular **orthorhombic** crystals or in other sorts of aggregates, as well as blades, also as columnar or granular masses. It shows a highly perfect pinacoidal cleavage; conchoidal fracture; hardness, 2; specific gravity, 4.5–4.6; luster, metallic and very brilliant on cleavage faces or freshly fractured surfaces. Its color is a steely gray; the streak very similar in color, may be covered with a black, sometimes iridescent tarnish.

Stibnite is the most common antimony mineral known and is the chief ore of that metal. It is believed to be a primary ore mineral and occurs with other antimony minerals and **galena, sphalerite,** silver ores, etc. It is found in Germany, Rumania, Czechoslovakia, Italy, Borneo, Peru, Japan, China, Mexico; and in the United States in California and Nevada.

The name stibnite is derived from the **Latin** word for antimony, *stibium.* (E.S.C.S.)

STICK INSECT. **Walking-Stick.**

STICKLEBACK. Pisces, Teleostei. Small marine and fresh-water fishes (**Pisces**) of the family Gasterosteidae, characterized by a series of strong spines along the back in front of the dorsal fin. (A.W.L.)

STIFF DIAGONAL. **Diagonal.**

STIFFENER. **Bridge, Monocoque.**

STIGMA. 1. A secondary sexual mark of **insects.** In many species of **butterflies** it consists of a patch on the wing of the male bearing modified scales on a more or less modified area of the wing membrane. 2. Used by some entomologists in place of **spiracle.** 3. In botany, the receptive part of the gynoecium or pistil of the **flower,** to which the pollen grain is carried in the act of **pollination.** In many flowers the surface of the stigma is sticky and so receives and holds the pollen grains more surely. (See **Flower.**) (A.W.L., R.M.W.)

STILBITE (DESMINE). The mineral stilbite, $(Na_2Ca)O \cdot Al_2O_3 \cdot 6SiO_2 \cdot 6H_2O$, is a **zeolite,** the compound **monoclinic** crystals of which are usually grouped in approximately parallel positions, forming sheaf-like aggregates, which have a soft pearly luster, whence the name stilbite from the Greek, meaning luster. The less commonly used term desmine is likewise from the Greek, meaning a bundle. Stilbite has one perfect cleavage; uneven fracture; is brittle; hardness, 3.5–4; specific gravity, 2–2.2; luster, vitreous to pearly; color, usually white but may be brownish, yellowish, red or pink. Its streak is white, and it is transparent to translucent. Like the other zeolites stilbite occurs in cavities in **basalts** and **traps,** rarely in **granites** and **gneisses.** Of the many foreign localities may be mentioned Trentino, Italy; the Harz Mountains; Valais, Switzerland; Arendal, Norway; the Ghats Mountains of India; and Mexico. The Triassic traps of New Jersey and Pennsylvania furnish specimens as do also rocks of the same age in Nova Scotia. (E.S.C.S.)

STILL-BIRTH. The birth of a dead fetus. (D.M.H.)

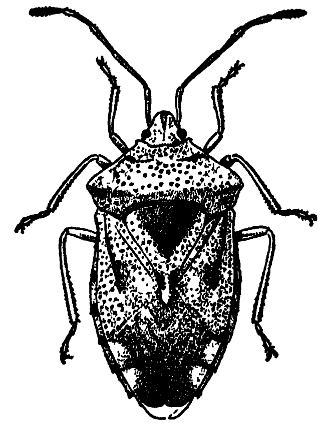
STILLSON WRENCH. **Wrenches.**

STILT. Aves, Charadriiformes. *Himantopus.* A bird (**Aves**) with unusually long legs, a long neck, and a long slender beak, slightly upcurved. Related to the avocets. In spite of their attenuated lines the stilts are beautiful and graceful birds. Their plumage is chiefly black or gray and white, but the beak and legs of some species are pink or red. There are only a few species but they are represented in all parts of the world. (A.W.L.)

STILT BUG. Insecta, Hemiptera. A **bug** with a slender body and very long slender antennae and legs. The few species make up the family Neididae. They are sluggish insects of no economic importance. (A.W.L.)

STIMULANT. Any agent or **drug** which increases the activity of an organ. Such drugs are **caffeine, strychnine, adrenaline, camphor, ammonia, digitalis** and its allies, etc. These drugs act principally on the nervous, respiratory or cardiac systems. Various remedial measures which are stimulating are cold air and water, contrast baths with hot, then cold water, and regulated exercise. (R.S.M., D.M.H.)

STINK BUG. Insecta, Hemiptera. A flattened **bug** of generally ovate form, in many species with an angular outline. Most species are moderately large, reaching a length of about ½". The many species, constituting the family Pentatomidae, are also characterized by the fetid odor of the secretion discharged from glands opening on the lower surface of the body.



Stink bug.

One species, the harlequin cabbage bug or calico-back, is a troublesome pest. It is best controlled by clean cultivation of fields, hand picking of bugs and their eggs, and the use of trap crops, planted early to attract the insects.

Some members of the group eat other insects and are probably beneficial in destroying pests, but unfortunately even the harmless species may contaminate berries with their unpleasant odors. (A.W.L.)

STINKSTEIN. **Limestone.**

STIPES. **Maxilla.**

STIPULES. **Leaf.**

STOAT. Mammalia, Carnivora. A slender short-legged animal, *Mustela erminea,* related to the weasels and sometimes called the greater weasel. It has been regarded by some zoologists as common to both hemispheres, living in northern latitudes, but authorities now consider the common North American weasel to be a distinct, although closely related, species. Except in the extreme southern parts of their range, both of these animals turn white in the winter, retaining a black tip on the tail. In this stage they are often called ermine. (A.W.L.)

STOCHASTIC VARIABLE. A stochastic variable is a chance variable or one whose value is determined by a **probability function.** Examples of chance **variables** are the height of a person, measurements of some kind in a laboratory, the number of defectives in a lot, and the intelligence of a person. Generally all variables in **statistics** are chance variables. If x and y are stochastic variables then $x + y$, $x - y$, xy, and x^2y^2 are chance variables also. If x and y are chance variables, so is x/y, provided $y \neq 0$.

Some well known theorems on stochastic variables follow. The **expected value** of the sum of two chance variables x and y equals the expected value of x plus the expected value of y; i.e., $E(x + y) = E(x) + E(y)$. The expected value of the product of two chance variables x and y is the expected value of x times the expected value of y if x and y are independent, i.e., $E(xy) = E(x) \cdot E(y)$. The expected value of a constant times a chance variable equals the constant times the expected value of the variable, i.e., $Ec(x) = cE(x)$. (L.A.A.)

STOCK. In geology, a mass of **igneous rock** not of great areal extent, generally with a circular or elliptical cross-section, which has been intruded vertically into previously existing formations.

In some cases stocks may represent the lower portions of volcanic conduits. (R.M.F.)

STOICHIOMETRY. Stoichiometry is a study of heat, energy, and material balances of a chemical system, commonly applied to the solution of problems in Chemical Engineering. It makes use of many of the laws and concepts of general and physical chemistry, and physics. (D.E.M.)

STOKER. The stoker is a machine for feeding **coal** into a **furnace**, and supporting it there during the period of **combustion**. It may also perform other functions, such as supply of air, control of **combustion**, distillation of the volatile matter. Stoker development has reached the point where stokers can offer substantial fuel savings over hand firing even under small and medium-sized boilers. Much depends upon suiting the stoker to the coal that is to be fired on it. The character of the volatile matter is studied and arrangement made for burning all of it through the introduction of over-fire air when necessary. The ash characteristics also influence stoker selection. The stoker ought to be responsive to variable load. Control of combustion necessitates a variable drive of the stoker. The power to drive stokers is usually furnished by electric motors or steam engines.

Modern stokers may be classified as overfeed, underfeed, and conveyor.

The sprinkler or spreader stoker is a type of overfeed, but with horizontal grates. A rotor is driven at high speed and so located that any coal dropped on it will be thrown onto the grates. A feeder delivers the coal at the proper rate from the hopper into the range of action of the rotor blades. Some sprinkler stokers have a pneumatic or steam jet delivery of the coal to the grates.

Stokers most in use nowadays are the conveyor (Fig. 1) and underfeed types. A chain grate stoker

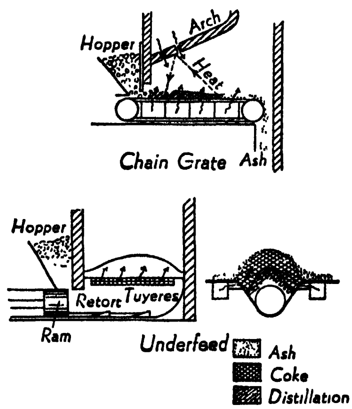


Fig. 1. Diagram of combustion in coal stokers.

(one type of conveyor) is a broad endless belt composed of short connected links. This belt passes over two sprockets so that it makes a flat upper surface upon which coal may rest. One of the sprockets is power driven, so that there is a very slow motion of the grate in a direction which will drag coal from the bottom of the hopper, carry it into the furnace, and finally dump the ash into a hopper. The rate of combustion is varied by simultaneous control of air pressure, velocity of the grates, and thickness of the fuel bed. Heat from the incandescent zone is radiated to the ignition arch and reflected back to the green fuel bed at its entry to the furnace. The volatile matter that is driven off is mixed with air admitted through and over the green fuel bed, and, being confined to the arch, is passed through the hottest zone of the furnace. The carbon left behind then reaches the ignition point and burns, giving up heat, part of which is radiated back to the incoming green coal. There is no means of breaking up a crust formed by a coal which will soften and fuse together, but the chain grate stoker will burn coals that would be too fine or easily packed for use in an underfeed stoker, as well as coals that clinker badly.

The natural draft chain grate stoker is adaptable to small or medium-sized boilers, operated at fairly steady loads. This type of stoker is being used less and less, more favor being given to the single retort underfeed stoker. At their best point they will use from 70% to 80% excess air. Coal of fine sizes sifts through between the grate bars and causes losses unless a system is installed for its recovery. However, they have burned lignite in a very successful manner. The chain grate type is applicable to burning fine coals of high ash content and clinkering characteristics. A large floor area is required. This stoker is hard to bank and is very sensitive to furnace design.

The efficient combustion of certain classes of coal requires that the coal be gasified under conditions which will prevent the coal from fusing into an air-tight crust. A coal that has a tendency to fuse together into a solid cake of coke must be burned in an underfeed stoker, in which the fresh coal is fed to the fire zone by being pushed up from underneath. This type of feed creates a heaving action at the fire line, which tends to prevent the formation of an air-blanketing crust. An underfeed stoker consists of a retort, usually trough-shaped in industrial stokers, but resembling a pot in the domestic type. The coal is forced into this retort by an endless screw or ram in such a way as to accomplish the feed action outlined above. Air is supplied at the sides of the retort under pressure sufficient to enable it to penetrate the zone of incandescence. Heat from an incandescent zone of burning carbon is radiated and conducted downwards into the green fuel which is being crowded up to the ignition line from below. The volatile matter which is given off is mixed with air supplied from tuyeres, also below the ignition line. The inflammable mixture then passes directly through the hottest zone of the furnace—the incandescent fuel bed—insuring that all parts of it reach the ignition point. The ever-upward motion of the fuel keeps the bed well broken up, allowing free passage of gases and oxygen to all parts of it.

The single retort underfeed stoker is well adapted to a wide range of coals and to all sizes up to 1000 boiler horsepower. As it sets low and requires no ash basement, it is easily applied to almost any existing boiler. For these reasons, and because of its inherent smokelessness, it is especially adaptable to industrial service. Good operation is secured in small as well as large sizes with everyday boiler efficiencies ranging from 65 to 70%. The most efficient types have auxiliary moving grates to break up the fuel bed that overflows the retort. The size of a retort is limited by the ability of the air to penetrate from the tuyeres to the zone of burning. Large underfeed stokers cannot be built with single large retorts, for this reason; rather, they must be built with a number of parallel retorts. However, the multiple retort underfeed stoker does not resemble a number of single retort stokers placed side by side. Instead, the retorts are sloped downwards slightly, and the coal emerges from the retort on to an overfeed section, where the residual carbon is burned.

The multiple retort underfeed and forced draft chain grate types are essentially large, high-capacity boiler types having large initial cost and installation expense. A basement ashpit is required for both types. Skilled

operators are needed, especially for the chain grate type, but they can readily obtain from 70 to 80% boiler efficiency, using about 50% excess air. From the fore-

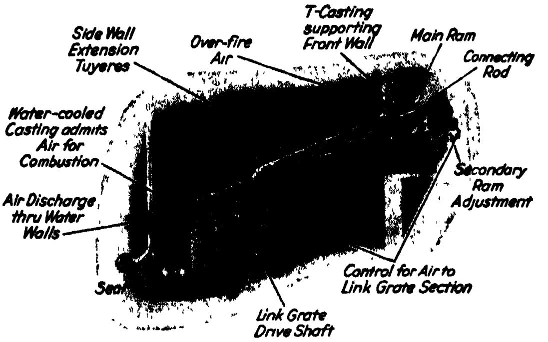

Fig. 2. Side view multiple retort underfeed stoker.

going remarks, it is evident that these stokers are central station types. The forced draft chain grate stoker is conceded to be the only type for anthracite or coke breeze. The ignition arches required increase the cost of the furnace. The complication of air zoning the plenum chamber must be accepted in order to control air in an efficient manner. Its flexibility and banking characteristics are better than the natural draft type but not so good as the underfeed.

Considerable similarity is apparent in multiple retort underfeed stokers as far as the underfeed portion is concerned, but examination of the overfeed portions discloses major differences. Ash is handled by dump plates or by clinker grinders. (See **Combustion; Combustion Control; Furnace.**) (F.T.M.)

STOKES' LAW. **Luminescence; Viscosity.**

STOKES' THEOREM. Stokes' theorem is an important mathematical result used in mathematical physics particularly. It transforms a **line integral** in space into a **surface integral** or vice versa. It was given by the great English mathematician and physicist Sir George Gabriel Stokes (1819–1903).

Let P, Q, R be **functions** of x, y, z, which, together with their first **partial derivatives**, are **continuous** in a region V of space, and let S be a **surface** lying in V and bounded by the curve C; let α, β, γ be the **direction angles** of the normal to S. Then Stokes' theorem is:

$$\int_C (P\,dx + Q\,dy + R\,dz) = \iint_S \left\{ \left(\frac{\partial R}{\partial y} - \frac{\partial Q}{\partial z}\right)\cos\alpha + \left(\frac{\partial P}{\partial z} - \frac{\partial R}{\partial x}\right)\cos\beta + \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}\right)\cos\gamma \right\} dS.$$

In **vector** language and vector notation, this theorem may be stated: The **surface integral** of the **curl** of a vector **function** F of position taken over any surface region S is equal to the **line integral** of $\mathbf{F}$ taken around the boundary C of the region:

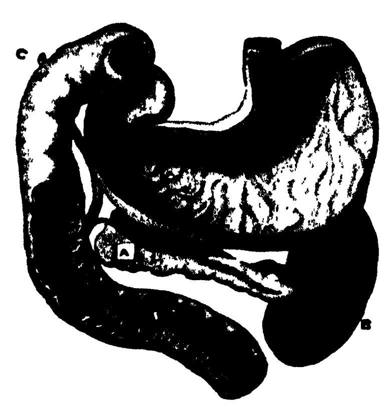
$$\iint_S (\Delta \times \mathbf{F})\cdot\hat{\mathbf{n}}\, d\mathrm{S} = \int_C \mathbf{F}\cdot d\mathbf{r}.$$

(L.L.S.)

STOLON. In botany, a stolon is a branch which grows out horizontally from the base of the **stem**, takes root and gives rise to a new plant at the **nodes** or at the tip.

In zoology, a shoot growing from the base of an **animal** or a **colony**, from which other individuals arise by **budding**. (R.M.W., A.W.L.)

STOMACH. The pouch-like structure, part of the **digestive system**, which serves as the temporary collecting place for the food as it leaves the **esophagus**. It lies high up on the left side of the abdomen just beneath the **diaphragm**. It lies obliquely extending from the extreme left side beneath the ribs across the midline of the abdomen about 3″ above the navel. The size of the stomach varies depending on the contraction of its muscular walls, the amount of food that it contains, and the pressure on its outside walls due to the adjacent small and large intestine. The entrance to the stomach from the esophagus is known as the cardiac orifice and the exit of the stomach is known as the **pylorus** or pyloric orifice. Both of these openings are closed by circular muscle fibers known as **sphincters**, except when food is passing through them. The walls of the stomach are made up of oblique longitudinal and circular smooth muscle fibers not under voluntary control. This arrangement in its walls allows for progressive wave-like movement of the food toward the pyloric opening, and also for a thorough mixing of the food. The glands of the stomach secrete mucus, **hydrochloric acid** and a substance which is converted into **pepsin** when it mixes with the acid.



View of stomach and duodenum with part of anterior portion removed. *A*, pancreas, *B*, spleen; *C*, common bile duct.

Functions of the stomach are to mix the food with the gastric juices, and to pass it into the **duodenum** in small portions at intervals. The movements of the stomach also serve to reduce the size of the swallowed food particles. Very little actual **digestion** takes place in the stomach. **Protein** digestion begins in the stomach but is incomplete. In general, the food is prepared for the digestive action in the small intestine. The acid of the stomach has further a definite germicidal action on the swallowed food.

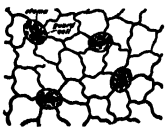
Since the secretion and movement of the stomach are controlled by the involuntary or sympathetic nervous system, anger, fear or worry interfere with or can alter the activity of the stomach. Exercise taken too soon after meals has a similar effect.

The common disorders affecting the stomach are (1) peptic ulcer, (2) cancer, (3) gastritis. (R.S.M., D.M.H.)

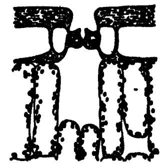
STOMACH ULCER. **Peptic Ulcer.**

STOMATE OR STOMA. The name applied to the minute pores which occur abundantly in the epidermis of leaves and, less abundantly, in the epidermis of young stems, flower parts and fruits. Each stomate is located between two distinctive epidermal cells called *guard cells*. The size and shape of the guard cells varies considerably from one species to another. Unlike other epidermal cells the guard cells contain chloroplasts. In many species of plants stomates occur in both the upper and lower epidermis of the leaf. In many other species, especially of woody plants, stomates occur only in the

lower epidermis. Even in those species in which the stomates are present in both epidermises there are commonly, although not invariably, more per unit area in the lower epidermis. In floating leaves such as those of the water lily stomates are present only in the upper epidermis. In many kinds of plants the stomates are restricted to grooves or furrows in the leaf.



A portion of the lower epidermis of a geranium leaf.



Sunken stoma of carnation.

The number of stomates per unit area varies with the kind of plant and also, within limits, with the conditions under which the plant has developed. The range is from a few thousand to about a hundred thousand per sq. cm. of leaf surface. A single corn plant has been estimated to bear from 140 to 240 million stomates and the number on a large tree could be represented only by a figure of astronomical dimensions. The size of the indi- vividual stomates also varies greatly from species to species, their dimensions being expressed in microns. In some species the fully open stomates may be as large as 8 to 10 x 30 to 40 microns, as measured along the two axes of the elliptical pore, but in most species they are smaller. Species in which the stomates are relatively small usually have more per unit area than those which have relatively large stomates.

The structure of the cell wall of a guard cell is quite complex, varying considerably in thickness and elasticity from one part of the cell to another. This wall structure is such that when the guard cells increase in turgidity their inner walls—those bounding the pore—bow away from each other causing a widening of the stomate. In general, therefore, when the guard cells are turgid the stomate is open; when the guard cells are flaccid the stomate is closed.

Shifts in the turgidity of the guard cells causing opening and closing of stomates are conditioned by a number of factors among which the most important are light, temperature, and the internal water supply of the leaf. In general stomates are open in the light and closed in the dark although there are many exceptions to this statement. Exposure of the guard cells to light appears to activate the conversion of starch (a secondary product of **photosynthesis**) in those cells to sugars. This results in an increase in the osmotic pressure of the cell sap of the guard cells which in turn causes osmotic movement of water into the guard cells from adjoining epidermal cells in which there has been no increase in osmotic pressure. The influx of water into the guard cells causes the increase in their turgidity which in turn results in stomatal opening. Concomitantly there is a reduction in the turgidity of the contiguous epidermal cells. With a failure of illumination the opposite train of events apparently takes place in the guard cells. In general, low temperatures are unfavorable to stomatal opening and when the temperature falls below the optimum for stomatal opening for a given species the stomates will remain closed or open only incompletely even if light conditions and water supply are favorable. Similarly drought conditions, by resulting in a reduction in the water content of the leaves, are usually unfavorable to stomatal opening even if light and temperature conditions are favorable. During prolonged droughts the stomates of many species remain nearly or completely closed most of the time. Night opening of the stomates is of regular occurrence in some species such as certain cacti, in which they are not usually open in the daytime, and may occur in some other species under certain conditions.

When the stomates are open they serve as the principal pathways through which gases diffuse into or out of the leaf; when the stomates are closed all gaseous exchanges between a leaf and its environment are greatly retarded. The gases of greatest physiological importance which enter or depart from a leaf principally through the stomates are oxygen, carbon dioxide, and water vapor. Loss of water vapor in the process of **transpiration** occurs principally through the stomates. Similarly the inward diffusion of carbon dioxide and outward diffusion of oxygen, the gaseous exchanges accompanying **photosynthesis**, occur principally through the stomates. (B.S.M.)

STOMATITIS. Inflammation and infection of the oral cavity—the gums, lips, cheeks. This may be due to poor oral hygiene, infection spreading from infected teeth, or it may be associated with a systemic disease such as **pellagra**. "Trench mouth," or Vincent's infection, is a common form due probably to a fusiform bacillus and a spirochete. It is recurrent and contagious and may occur in epidemics. Treatment with sodium perborate locally and nicotinic acid orally is usually effective, but the disease may be quite resistant. Penicillin has proved to be the most effective drug employed so far. (D.M.H.)

STOMATOPODA. Synonym of Hoplocarida. **Crustacea.** (A.W.L.)

STOMODAEUM. A tube lined with tissue derived from the surface of the body, associated with the alimentary tract (**Digestive System**). The tube forms as a depression in the outer surface and deepens until it meets the lining of the enteric cavity and breaks through into it. The gullet of sea anemones is one form of stomodaeum. In animals with a tubular alimentary tract it forms the anterior part of the tube, consisting of the oral cavity in **vertebrates** and of the entire fore gut of **insects**. This region of the insect alimentary tract includes the oral cavity, **pharynx, oesophagus, crop, and gizzard.** (A.W.L.)

STONE CANAL. **Water Vascular System.**

STONE FLY. **Plecoptera.**

STONE ROLLER. Pisces, Teleostei. A bottom-feeding fish, *Campostoma anomalum,* of moderate size found in small streams from Wyoming to New York and south to the Gulf. It lives on plant matter. (A.W.L.)

STONECHAT. Aves, Passeriformes. A bird (**Aves**), *Saxicola torquata,* of central and northern Europe. The male has a black head and back, a white collar, and reddish under parts; the female is more brownish. (A.W.L.)

STOP BATHS. The term stop bath is applied to solutions used to stop development. Stop baths may be divided into two classes: (1) acid stop and (2) hardening stop baths.

The acid stop bath in widest use is composed of

Water	64 oz.	1 liter
Acetic acid, 28% .	3 oz.	48.0 cc.

This is used most frequently in the processing of papers where it not only stops development but tends to prevent stains arising from the oxidation of the developer or the formation of reduced colloid silver from the continued action of the developer.

Other stop baths in less common use include:

Sodium bisulfite
Citric acid

Hardening stop baths are particularly useful when processing at high temperatures. A 2–3% solution of chrome alum is the most widely used hardening stop

bath. In using a solution of chrome-alum as a stop bath, the following precautions must be observed:

1. The solution must be fresh. Used solutions lose their hardening properties rapidly.

2. The film should be rinsed briefly, but thoroughly, before being placed in the stop bath.

3. The film must be kept in motion for 30 seconds to 1 minute after immersion in the stop bath.

If these precautions are not observed, a deposit of aluminum sulfite will be formed on the surface of the film and the hardening of the gelatin will be adversely affected. Stains of aluminum sulfite are readily removed when wet but very difficult to remove when dry.

The addition of a small quantity of acid makes the formation of aluminum sulfite stains less likely and increases the useful life of the solution but reduces its hardening properties.

Baths of chrome alum should be discarded when they turn green or turbid in appearance. At temperatures above 85° F., the efficiency of a chrome-alum stop bath may be increased by the addition of sodium sulfate (*not* sulfite). The sodium sulfate tends to prevent the swelling of the gelatin and thus increases the rate of hardening. The following formula is suggested.

(Kodak SB-4)

Water	32 oz.	1 liter
Potassium chrome alum	1 oz.	30 grams
Sodium sulfate (dess)	2 oz.	60 grams

This solution when fresh is a violet-blue by tungsten light, turning a yellow-green with use. When the blue-violet color disappears, the solution should be discarded as it will no longer harden the emulsion. (C.B.N.)

STORAGE BATTERY. The storage battery is one or more electric cells having a reaction which is reversible to a high degree. Not only is it necessary that the chemical reaction be reversible but the plates and products of the reaction must be insoluble in the electrolyte. There are two widely used commercial types of storage battery, the lead and the nickel-iron-alkaline (Edison) cells.

The lead cell consists of positive and negative plates, separated by wood, hard rubber, or fiberglass separators, and the electrolyte, the whole being in a hard rubber or glass container. The active material of the positive plates is lead peroxide either in a thin film on the supporting lead plate or as a filler in the holes of a cast lead-antimony alloy grid. The negative plate usually consists of a lead-antimony grid containing sponge lead as the active material. The electrolyte is sulfuric acid and water, producing chemical reactions as follows:

$$PbO_2 + Pb + 2H_2SO_4 \rightleftarrows 2PbSO_4 + 2H_2O.$$

The equation is read from left to right for discharge and the opposite for charge. It will be noted that the discharge converts the electrolyte to water so the state of charge may be determined by the specific gravity of the electrolyte. This is preferable to voltage readings which are very unreliable since the cell has a nearly constant voltage for a wide range of charge conditions. The specific gravity of a fully charged cell is about 1.300 and the voltage is approximately 2 volts.

Lead cells gradually lose their usefulness from a variety of causes. Loss of active material from the plates due to normal dislodging in service, excessive sulphation, local action in the plates, buckling of plates, deterioration of separators, etc., all contribute to the decay of the cell.

The nickel-iron-alkaline cell which was commercially perfected in this country by Edison and often called the Edison cell is composed of a nickel oxide positive plate, an iron negative plate, and potassium and lithium hydroxide solution as the electrolyte. The chemical reactions are considerably more involved than those in the lead cell and the structure of the plates is more complicated, the Edison plates usually consisting of perforated tubes of nickel containing the active ingredients, the tubes being supported in a grid structure. The state of charge of the Edison cell is usually determined by voltage readings, these varying from about 1.4 for fully charged to 1.0 for a practically discharged cell. The ability of this battery to withstand abuse makes it preferable to the lead type for many applications, especially in railroad signal service. The life is also considerably greater than for the lead cell.

In spite of the widespread availability of a-c power there are many applications of the storage battery. Among these may be listed automobile service, railway signalling, railway coach lighting, farm lighting, telephone service, industrial trucks and submarine service. (L.R.Q.)

STORK. Aves, Ciconiiformes. Birds of the Old World and South America. They are large, attaining a length of about 4′, and have long legs and a long straight beak. The common white stork of Europe, *Ciconia alba,* which nests on the tops of chimneys is the best-known species. Others occur in Europe, Asia, Africa, Australia and South America. Among the last are some of the giant storks, also called **jabirus.** The **adjutant** or marabou storks of Africa and India are peculiarly untidy-looking birds, due to the almost bare skin of the head and neck with its few straggling feathers.

The name stork is confused to a slight extent with that of the related herons, as in the case of the whale-headed or shoe-billed species, of the White Nile. This species, called both heron and stork, has an enormous and powerful beak, both broad and deep and provided with a strong hook at the tip. (A.W.L.)

STORM SEWER. Sewerage System.

STRABISMUS (SQUINT OR CROSS-EYE). The inability to fix the sight of both eyes on a given point at the same time; one eye or the other alone sees the object at any given moment, but never both at the same time. Strabismus can be corrected by non-operative measures such as glasses and training. The operative treatment is very successful and is done by the shortening and lengthening of certain eye muscles. (R.S.M., D.M.H.)

STRAIGHT LINE, IN A PLANE. The equation of any straight line is of the first degree, i.e., is a **linear equation,** in the **rectangular coordinates** x and y.

The **locus** of any linear equation (first degree equation) in rectangular coordinates x and y is a straight line.

A straight line parallel to the Y-axis has an equation of the form $x = a$, where a is the X-intercept; a line parallel to the X-axis has an equation of the form $y = b$, where b is the Y-intercept.

The fundamental type forms of the equation of a straight line in rectangular coordinates are the following:

The equation of a line with **slope** m and Y-intercept b is

$$y = mx + b \quad \text{(Slope-intercept form).}$$

The equation of a line with slope m and passing through the point (x_1, y_1) is

$$y - y_1 = m(x - x_1) \quad \text{(Point-slope form).}$$

The equation of a line passing through the two points (x_1, y_1) and (x_2, y_2) is

$$\frac{y - y_1}{y_2 - y_1} = \frac{x - x_1}{x_2 - x_1} \quad \text{(Two-point form).}$$

The two-point form may also be written in the determinant form:

$$\begin{vmatrix} x & y & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix} = 0.$$

The equation of the straight line with intercepts a and b is

$$\frac{x}{a} + \frac{y}{b} = 1 \quad \text{(Intercept form).}$$

The equation of the line whose normal (perpendicular) from the origin makes an angle ω with the X-axis and is of length p is

$$x \cos \omega + y \sin \omega - p = 0 \quad \text{(Normal form).}$$

To reduce an equation $ax + by + c = 0$ of a line to the normal form, divide all the terms of the given equation by $\sqrt{a^2 + b^2}$.

In **polar coordinates**, the equation of a line may be written

$$r \cos (\theta - \omega) = p,$$

where p is the length of the perpendicular to the line from the origin and ω is the angle which this perpendicular makes with the X-axis.

Special cases are: If $\omega = 0$, the line is perpendicular to the polar axis and the equation becomes $r \cos \theta = p$. If $\omega = \frac{\pi}{2}$, the line is parallel to the polar axis and the equation is $r \sin \theta = p$.

A straight line through the origin (pole) in polar coordinates has the equation $\theta = \alpha$, where α is its inclination angle.

The condition that the three lines whose equations in rectangular coordinates are $a_1x + b_1y + c_1 = 0$, $a_2x + b_2y + c_2 = 0$, $a_3x + b_3y + c_3 = 0$ shall intersect in a common point is

$$\begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} = 0.$$

The angle between two lines whose slopes are m_1 and m_2 is given by the formula

$$\tan \theta = \frac{m_1 - m_2}{1 + m_1 m_2}.$$

The perpendicular distance from a line whose equation is in the normal form $x \cos \omega + y \sin \omega - p = 0$ to the point (x_1, y_1) is given by the formula

$$d = x_1 \cos \omega + y_1 \sin \omega - p.$$

The perpendicular distance from the line whose equation is $ax + by + c = 0$ to the point (x_1, y_1) is given by

$$d = \frac{ax_1 + by_1 + c}{\pm\sqrt{a^2 + b^2}}.$$

If $L_1 = 0$ and $L_2 = 0$ are the equations of two given straight lines, then $L_1 + kL_2 = 0$ is the equation of the system of all straight lines passing through the intersection of the given lines, when k takes all positive and negative values (including 0).

If the equations of two given lines are $x \cos \omega_1 + y \sin \omega_1 - p_1 = 0$ and $x \cos \omega_2 + y \sin \omega_2 - p_2 = 0$, the equations of the bisectors of the angles between them are:

$$x \cos \omega_1 + y \sin \omega_1 - p_1 = \pm (x \cos \omega_2 + y \sin \omega_2 - p_2).$$

(L.L.S.)

STRAIGHT LINE, IN SPACE. Consider any line l in space. Through the origin O of a system of rectangular coordinate axes in space draw a line OP parallel to the given line l, and let the direction angles of the line OP be α, β, γ. Then the **direction cosines** of the line l are the cosines of these angles α, β, γ.

If α, β, γ are the direction angles of any line, then

$$\cos^2 \alpha + \cos^2 \beta + \cos^2 \gamma = 1.$$

If a, b, c are numbers proportional to the direction cosines of a line, then the direction cosines are given by

$$\cos \alpha = \frac{a}{\pm\sqrt{a^2 + b^2 + c^2}}, \quad \cos \beta = \frac{b}{\pm\sqrt{a^2 + b^2 + c^2}},$$

$$\cos \gamma = \frac{c}{\pm\sqrt{a^2 + b^2 + c^2}}.$$

If two lines have direction angles α, β, γ, and α', β', γ', then the angle θ between them is given by

$$\cos \theta = \cos \alpha \cos \alpha' + \cos \beta \cos \beta' + \cos \gamma \cos \gamma'.$$

Two lines are parallel when their corresponding direction angles (and direction cosines) are equal.

Two lines are perpendicular when the sum of the products of their corresponding direction cosines is 0.

The locus of two simultaneous **linear equations**

$$A_1x + B_1y + C_1z + D_1 = 0, \quad A_2x + B_2y + C_2z + D_2 = 0$$

is a straight line, unless the coefficients of x, y, z are proportional.

A parametric form of the equations of a straight line are:

$$x = x_1 + t \cos \alpha, \qquad y = y_1 + t \cos \beta, \qquad z = z_1 + t \cos \gamma$$

where P_1 is a point on the line, α, β, γ are direction angles of the line, and t is a variable parameter.

The symmetric form of the equations of a straight line is:

$$\frac{x - x_1}{\cos \alpha} = \frac{y - y_1}{\cos \beta} = \frac{z - z_1}{\cos \gamma},$$

where (x_1, y_1, z_1) is a point on the line, and $\cos \alpha$, $\cos \beta$, $\cos \gamma$ are the direction cosines of the line Another form of the symmetric equations is:

$$\frac{x - x_1}{a} = \frac{y - y_1}{b} = \frac{z - z_1}{c},$$

where a, b, c are numbers proportional to the direction cosines of the line.

The two-point form of the equations of a straight line is:

$$\frac{x - x_1}{x_2 - x_1} = \frac{y - y_1}{y_2 - y_1} = \frac{z - z_1}{z_2 - z_1}.$$

The plane $Ax + By + Cz + D = 0$ and the line

$$\frac{x - x_1}{a} = \frac{y - y_1}{b} = \frac{z - z_1}{c}$$

are perpendicular if

$$\frac{a}{A} = \frac{b}{B} = \frac{c}{C},$$

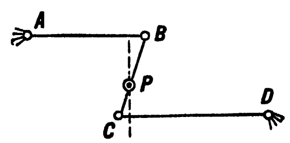
and are parallel if $aA + bB + cC = 0$.

A plane passing through a given line and perpendicular to one of the coordinate planes is called a projecting plane of the given line. (L.L.S.)

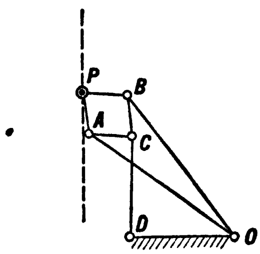
STRAIGHT LINE MOTION. If a **mechanism** has links designed so that a point on one of them moves in a straight line, that mechanism is one of a particular class known as the straight line mechanism if it is devoid of sliding links. The accompanying figure shows the Watt motion, an approximate straight-line mechanism, and the Peaucellier, an exact straight-line motion. The point P, which is located on the intermediate length BC in the Watt straight-line mechanism, moves, within limits set by the mechanism, in what is nearly a straight line. For best results, this point P should be located by the ratio

$$\frac{AB}{CD} = \frac{PC}{PB}.$$

In the Peaucellier mechanism, line OD is fixed, links OA and OB are equal, link CD equals OD, and links PB,



Watt



Peaucellier
Straight line mechanism.

BC, CA, and AP are equal. Within the limits of its motion, this mechanism traces at point P a straight line perpendicular to the line OD. (F.T.M.)

STRAIN. **Deformation.**

STRAIN AXES. **Elasticity.**

STRAIN-HARDENING. **Cold Working.**

STRAMONIUM. **Potato Family.**

STRAND. **Wire Rope.**

STRANGLING FIG. **Fig.** Moraceae.

STRAIGHT-EDGE. One of three, any two of which when placed together, coincide throughout their length. (See also **Lapping, Origination.**) (H.C.H.)

STRAIN. **Deformation** and **Elasticity.**

STRATH. Geographically defined as a broad alluviated valley. Geomorphologically defined as a valley or confluent valleys which represent a local base level of erosion or local and incipient **Peneplain.** (R.M.F.)

STRATIFICATION. **Bedding.**

STRATIFIED DRIFT. **Glacial Deposits.**

STRATIGRAPHIC THROW. **Fault.**

STRATIFIED SAMPLE. Consider a **population** which may be divided into mutually exclusive portions, each part called a stratum, and from each stratum a random **sample** of **variates** is chosen. The resulting sample is called a stratified sample. The stratification may be determined by some logical classification such as geographical location, income group, political affiliation, racial origin, or any other characteristic. Stratified sampling is usually more precise with fewer items needed in the sample, and if it is possible to achieve the stratification with sufficient ease so as not to make the process too expensive, it is quite advantageous. The theory of stratified sampling has been developed chiefly by J. Neyman. Let $\bar{X}$ be an estimate of the **mean,** m of the population, then

$$\bar{X} = \frac{n_1\bar{X}_1 + n_2\bar{X}_2 + \cdots + n_r\bar{X}_r}{n},$$

where $\bar{X}_i$ is the sample mean of the ith stratum, $n = \sum_{i=1}^{r} n_i$, n_i = number of variates in the sample from the ith stratum, when we know T_i = number of variates in the ith stratum, and $T = \Sigma T_i$, σ_i^2 = **variance** in the ith stratum and

$$\sigma_{\bar{X}}^2 = \sum_{i=1}^{r} \frac{T_i - n_i}{T_i - 1} \cdot \frac{\sigma_i^2}{n_i}.$$

It is readily proved that $\sigma_{\bar{X}}^2$ is always less than the variance of the mean when using random sampling provided that not all the means of the strata are equal. In all these results it is assumed that T_i and ΣT_i are known or may be very accurately estimated. If this cannot be done it is advisable not to use stratified sampling. To estimate the σ_i^2 in the formula for $\sigma_{\bar{X}}^2$ we may use

$$\sigma_{S.i}^2 \frac{n_i}{n_i - 1} \cdot \frac{T_i - 1}{T_i},$$

where $\sigma_{S.i}^2$ is the sample variance

An important question is the size of n_i. In general to obtain the optimum precision for $\bar{X}$, it is advisable to make n_i proportional to the standard deviation σ_i and to the number of variates T_i. The advantage of stratified sampling is that $\bar{X}$ is unbiased and possesses a minimum variance. On the whole stratified sampling is readily adapted to many purposes. (L.A.A.)

STRATIGRAPHY. The study of the origin and chronological successions of the observable rocks of the **lithosphere,** in which each lithologic unit is considered to be a formation. The term formation is usually confined to bedded or stratified rocks, including lava flows and volcanic ashes. The major principles involved in the correlation (dating) of formations are: 1. The law of superposition, or that the chronological sequence of any stratigraphic section depends upon the original order in which the formations were laid down; thus the fundamental basis of Stratigraphy is **Structural Geology.** 2. Index Fossils, or those species of fossils whose stratigraphic age are already known. 3. **Lithology.** Igneous rocks may be dated by the age of the sedimentary rocks which they intrude, or overlie; or by **radioactive minerals.** (R.M.F.)

STRATOCUMULUS. **Clouds.**

STRATOSPHERE. That portion of the earth's atmosphere above the tropopause. This air is free of all weather phenomena being practically without moisture and having in general an isothermal structure. (See **Atmosphere.**) (P.E.K.)

STRATOSTAT. **Balloon.**

STRATUS. **Clouds.**

STRAWBERRY. **Rose Family.**

STREAK. This term, as used by the mineralogist, denotes the color of a powdered **mineral.** Usually determined by rubbing the mineral on a piece of unglazed porcelain, called a streak plate. All metals, and most minerals showing a metallic **luster,** show the same color whether in the solid or powdered form. The **silicates** and most of the minerals having a non-metallic luster, show different colors according to whether each is viewed in mass or as a powder. (R.M.F.)

STREAMLINE. If a fluid has steady flow without large-scale turbulence the paths of elements of the fluid are streamlines. If a body is "streamlined" its shape allows the streamline pattern to follow the surface

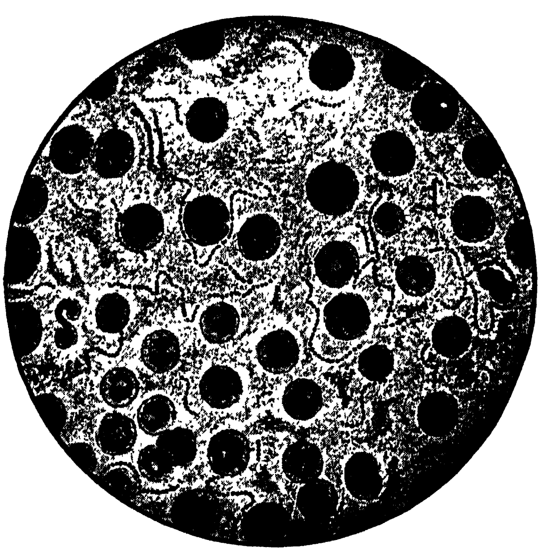
closely, in contrast to a "bluff body" where the streamlines break away from the rear portions of the body. The more nearly a body conforms to the pattern of natural streamline flow, the less will be its drag. As low drag is usually an asset, streamlining is a mark of excellence in shape design for aeronautics.

Through popular interest in aviation, 'streamlined" was appropriated to mean, broadly, excellence in design, smoothness in organization, elimination of uneconomical appendages, and similar ideas. (See **Drag; Fluid Flow.**) (F.T.M.)

STREAMLINES IN THE ATMOSPHERE. Lines drawn everywhere tangent to wind vectors. They show the instantaneous flow-pattern of the air at a given time only and do not indicate trajectories of air parcels. Streamlines are used for 2-dimensional flows (horizontal plane), although actually they are a 3-dimensional function. The vertical velocity is usually considered insignificant in comparison with the horizontal flow. Streamline charts are useful and quickly prepared forecast tools for obtaining wind forecasts at a given flight altitude. Trajectory charts, however, are more useful for projecting atmospheric phenomena. (P.E.K.)

STREPSIPTERA. An order of peculiar parasitic insects called stylopids by entomologists. They live in the bodies of other insects, including **wasps** and **Homoptera**, and are not likely to be seen without special efforts to find them. The female remains in the host as a grub-like individual but the male becomes a winged adult whose hind wings alone are developed for flight. The **metamorphosis** begins with an active **larval** form which seeks and enters a host and undergoes a gradual transformation through several molts leading to the ultimate grub-like form. (A.W.L.)

STREPTOCOCCI. A group of small, round, bacterial organisms of many strains, differing widely in pathogenicity. They are frequently the cause of many acute,



Streptococci from a case of empyema (Jakob). The *streptococci* appear in chain formation lying among pus cells. (*Todd and Sanford, Clinical Diagnosis by Laboratory Methods, W. B. Saunders Co.*)

chronic and often fatal diseases. This group of cocci is characterized by multiplying by division in one plane of space only. Therefore, in the stained preparation on a slide the cocci appear in chain-formation.

Pasteur recognized the *Streptococcus* in 1878 in studies on sepsis following childbirth. Koch saw the organisms in pus from wound infections about the same time.

The classification of streptococci is based on their ability to break up or hemolyze red blood cells. Strains producing a hemolytic **toxin** are thus spoken of as *hemolytic streptococci* in contrast to the non-hemolytic type, and the green-producing *streptococcus viridans*. The pathogenicity of the organisms is correlated with the presence of the hemotoxin. Hemolytic streptococci are the chief disease-producers; *streptococcus viridans* occasionally may produce disease (e.g., subacute bacterial **endocarditis**), and non-hemolytic or indifferent streptococci are harmless. The green and indifferent varieties are normal inhabitants of the skin, throat and other **mucous membranes.**

Among the disease-producing hemolytic streptococci, several groups are recognized. To *group A* belong most of the organisms pathogenic to man, and within this group approximately forty specific types have been identified on the basis of immunological characteristics. Any type can, under favorable circumstances, produce any one of the streptococcal diseases. Group-A hemolytic streptococci produce **scarlet fever, erysipelas,** and acute **tonsillitis.** Diseases which may be caused by these organisms as well as other bacteria include **osteomyelitis, puerperal sepsis, meningitis, pneumonia, otitis media, impetigo** and any skin or tissue infection. **Rheumatic fever** and **nephritis** are closely related to group-A hemolytic streptococcal infections but the mechanism of this relationship is obscure.

Hemolytic streptococci are very sensitive to **sulfonamides** and **penicillin.** These chemotherapeutic agents have been highly effective in controlling streptococcal disease and curing infections which formerly would have resulted fatally. In the treatment of scarlet fever antitoxic **serum** is available to combat the effects of the potent rash-producing toxin. (R.S.M., D.M.H.)

STREPTOMYCIN. An **antibiotic** produced by the ray **fungus,** *Actinomyces griseus.* As this organism grows in culture media, it liberates a substance which inhibits the growth of certain bacteria. This substance, isolated from the culture filtrate, purified, and concentrated, is streptomycin. It has a low degree of toxicity and, while less effective against the coccal organisms than **Penicillin,** is effective against some organisms against which penicillin is inactive. These include H. influenza, Friedländer's bacillus, B. tularensis, and some gram negative (see **Bacteria**) bacilli. Clinical trial has been limited, but results so far indicate that streptomycin exerts a therapeutic effect in influenzal **meningitis, tularemia,** Friedländer's bacillus **pneumonia,** and **peritonitis,** and urinary tract infections due to gram negative rods. **Tuberculosis** in the experimental animal (guinea pig) improves strikingly with streptomycin therapy. Use of the drug in human tuberculosis suggests that certain forms of the disease may respond, but investigations must be carried much further before its value in tuberculosis can be determined. Further investigation is necessary also to determine its usefulness in typhoid fever, undulant fever, and intestinal infections.

STREPTONEURA. Gasteropoda.

STRESS. A stress is the quantitative expression of a condition within an elastic material due to deformation, or strain, brought about by external forces, inequalities of temperature, or otherwise. Its measure is always the ratio of a force to an area. By some, stress is interpreted as a force distributed over an area, and the above ratio is called the "unit stress." Central, torsional and bending **loads** cause stress. The total resisting force acting at any section of the body divided by the area of the section is the average stress, commonly expressed in points per sq. in. The unit stress is the resisting force on a unit of area. The component of a stress which acts at right angles to a surface is known as the normal stress. If this stress is produced by a load

whose **resultant** passes through the **center of gravity** of the area, it is called an axial or direct stress and is always uniformly distributed over the area. A normal resisting force which causes the fibers to increase in length is a tensile stress, while one which shortens the fibers is a compressive stress. The latter is often called a bearing stress. The component of any stress which lies in the plane of the area is a shearing stress. (See **Elasticity.**)

Direct tensile or compressive stresses are known as primary stresses. The bending stress, resulting from deflection, is called a secondary stress. The stresses developed in a column due to the lateral deflections are of a secondary nature. The rigidity of the riveted or welded joints of a truss which has deflected due to the axial **deformation** of its members causes bending stresses in the members which are classified as secondary stresses. The resistance offered by a body to a combination of direct and bending loads is frequently called a combined stress. A normal stress which occurs at a point in a plane on which the shearing stress is zero is known as a principal stress. If this normal stress is tensile it is often called a diagonal tension stress; if compressive it is known as a diagonal compression stress.

The internal resisting force which arises in a restrained body due to temperature changes is a thermal stress. The adhesive resistance which is developed in the concrete surrounding the steel reinforcing rods when a reinforced concrete member is subjected to load is known as **bond** stress. Safe unit resisting forces which are used in design are called working stresses. These are usually taken as a percentage of the **ultimate stress** or the elastic limit of the material.

The stress developed in **bridge** members as a result of **traction** between the wheels of the **live load** and the supporting surface is called a traction stress. The effect of these stresses is usually neglected in highway bridge design but must be considered in railway bridges.

Any stress which is developed in a body before the application of an initial external load is an initial stress. These stresses are usually the result of a manufacturing process or a manufacturing and erection procedure. Shrinkage of concrete or other cast materials produce initial stresses. Initial **tension** is a term frequently used to denote the following initial stress conditions:

1. The stress in the shank of a hot-driven **rivet** after it has cooled. Contraction causes compression in the connected materials which, in turn, produces tension in the rivet.

2. The stress in the shank of a **bolt**, used to connect two or more parts, after the nut has been tightened.

3. The stress in riveted or bolted diagonals of bracing systems of bridges and buildings as the result of pulling them into position with **drift pins**. These diagonals are usually fabricated slightly shorter than the theoretical length in order to produce a rigid bracing system after being pulled into their proper place.

4. The stress in **tie rods** of bracing systems caused by tightening the nuts at the end connections. If the tie rod is equipped with a turnbuckle, initial tension is produced by tightening the turnbuckle. (C.W.C.)

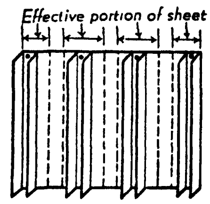
STRESS CONCENTRATION. **Fatigue.**

STRESS CONCENTRATION FACTOR. Laboratory tests and field experience as well as theoretical analysis indicate large concentrations of **stress** at those points where the cross-section of a member changes abruptly. This condition is not particularly serious except for **repeated loads** because the material will yield, if stressed beyond the **elastic limit**. The yielding causes a redistribution of stress in the vicinity of the discontinuity which will not affect the member as a whole.

In the case of repeated loads a factor is introduced to evaluate the effect of the abrupt change or other discontinuity. This factor, which is called the stress concentration factor, is the ratio between the **endurance limit** of the member without the abrupt change (the same as the endurance limit of the material) and the endurance limit of the member with the abrupt change. Both of these may be found by experimental means. The magnitude of the localized stress may be predicted by multiplying the stress obtained from the conventional formulae by the stress concentration **factor.** (C.W.C.)

STRESS DIAGRAM. **Graphical Statics.**

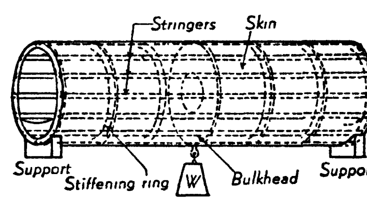
STRESSED-SKIN CONSTRUCTION. This term refers to a type of load-carrying structure whose covering, casing, or "skin," carries all or part of internal stresses resisting some applied external load. It is an alternative to a **truss** as a load-carrying structure. Stressed-skin construction may be advantageously employed where a skin or covering must be supplied for reasons other than structural, for by giving appropriate consideration to load-carrying qualities, the skin will serve a dual purpose. An an example, several components of airplanes must have a surface covering for aerodynamic reasons. If this covering can, by proper design, take some of the tension, compression, or shear stress that would otherwise be borne by a structure supporting the skin, then some of that structure may be eliminated with a corresponding saving in weight.



Sample Specimen of Flat Stiffened Sheet

In no other field of construction has stressing of the covering been so widely employed as in the construction of the *airframe* of airplanes. Here costly construction that saves some weight is more readily justified than in most other fields.

In practice, the gauge of metal sheets used as the skin is liable to be so thin that a light network or grid of stiffening members will be employed to give the skin support, shape, and stability. In long tube-like structures (i.e., an airplane fuselage) this grid is composed of longitudinal stringers and transverse stiffening rings or bulkheads. The relative position of these is illustrated in the figure, which shows a simple beam created by a tube whose covering is reinforced by a network of stiffeners.



Stiffened Stressed Skin

Stressed skin will resist tension very well, up to the ultimate strength of the material, but shear and compression limits are met at considerably reduced values because of the early failure, under such stresses, due to local instability, wrinkling between stiffeners, etc. The presence of wrinkles under compression does not necessarily mean structural failure in the case of thin ductile material such as aluminum alloy. It has been found that a stiffened sheet will carry some additional load even after buckling starts. However, even where some wrinkling would be safe structurally, it is not considered feasible in aeronautic design to permit it because of the loss of optimum aerodynamic shape of the covering, the misalignment of parts which may be attached to the covering, and the psychological effect upon passengers.

The design of stiffened stressed-skin structures **has**

developed in both theoretical and research phases of structural investigation. The irregular behavior of structural elements subject to local instability has prevented correlation of theory and test, as has also the dependence of test results upon dimensions, support, etc., of the specimens. However, general methods of attack have been devised which are effective if supplemented by strength tests of specimens whose construction is similar to that which it is proposed to use in the completed design.

A common method of estimating the compressive strength of a stiffened sheet is to consider only part of the sheet as working with the stiffener, but that part to carry a stress equal to that of the stiffener. There have been several research investigations of this problem and reasonably reliable equations have been developed for computing the effective width of the sheet. The strength of the stiffener depends greatly on its gauge, size, and shape; consequently it is well to construct specimens and test to determine the critical buckling stress.

One of the most difficult problems faced by the designer is the transfer of load around cutouts such as windows, doors, hatches, attachments, etc. These are particularly numerous in the fuselage and wing of all-metal multi-engined airplanes and account for the principal departure from rational and definite structural design of stressed-skin airplanes. (F.T.M.)

STRESS-STRAIN CURVE. A stress-strain curve is a graphical representation of the relation between unit **stress** and unit **deformation** in a stressed body as a gradually increasing **load** is applied. (See **Tension Test.**) (C.W.C.)

STRETCHER. **Masonry.**

STRETCHER LEVELING. Flattening of sheet metals by stretching. A stretcher leveler consists primarily of a set of stationary jaws to hold one end of a sheet and a set of movable jaws attached to a hydraulic piston to hold the other end of the sheet. By means of hydraulic pressure the sheet is stretched gradually, taking up all of the slack that may exist in the form of waves or buckles and continuing until the sheet is stretched very taut and flat. The stretching proceeds, theoretically, past the elastic limit of the steel, in the neighborhood of 1–2% elongation, so that the sheet will not spring back to its original shape but will spring back uniformly across its full width and remain flat. Stretcher-leveled sheets are used primarily for applications where the finished product must be perfectly flat, i.e., table tops, wall panels, and furniture. (See **Roller Leveling.**) (R. S. BURNS)

STRETCHER STRAINS. **Temper Rolling.**

STRIAE. The scratches on bedrock or on pebbles and boulders which are the result of glaciation. These are called glacial striae to distinguish them from the striae which occur on the surfaces of fault planes. (R.M.F.)

STRIDULATION. **Sound Production.**

STRIGIFORMES. The owls. An order of birds with the hooked beak and talons of birds of prey but differing from the hawks and related forms in having the eyes directed forward and in their nocturnal habits. (A.W.L.)

STRIKE. For the use of this term in geology, see **Anticline.**

STRIKE-FAULT. **Fault.**

STRING PLANING. **Planer.**

STRINGER. **Bridge.**

STRIPPING. **Gas Absorption.**

STROBILATION. An asexual process of reproduction by terminal budding. Some of the **annelid** worms reproduce in this manner and the proglottids of tapeworms (**Cestoda**) are formed by a similar process, leading to the application of the term strobila to the segmented portion of the body. The production of jellyfishes by their scyphistoma larvae is another example. (A.W.L.)

STROBILUS. A strobilus is a group of **sporophylls** or **spore-bearing leaves** aggregated together to form a compact cone-like structure. (R.M.W.)

STROBOSCOPE. The stroboscope is an instrument for viewing moving objects so they appear stationary. In its simplest form it may consist of a revolving disk with holes spaced around the edge, the moving object being observed through these holes. Since the object can be seen only when a hole is opposite the eye, a cyclic motion can be made to appear stationary if the speed of the disk is adjusted so a hole comes opposite the eye only when the moving object reaches the same point in each cycle; at other times the disk blocks out the view. As the object is thus always seen in the same position the persistence of vision makes it appear to be still. The principal drawback to this type stroboscope is the blurring of rapidly moving objects since they can be seen for a short time while the disk hole is moving before the eye. Much more accurate stroboscopes utilize a flashing light to illuminate the moving machine. Again, if the light flashes once for each cycle of the motion the eye sees it only in one position, i.e., that at which the flash occurs. Even though the machine may have general illumination so the observer sees the usual blur of a rapidly moving machine, the flash of stroboscopic light causes it to appear stationary. Since the flash can be made of extremely short duration by using gaseous discharge lamps the machine being observed moves a negligible distance while the light is on and thus appears sharply defined. If the light is not quite synchronized the machine appears to move slowly in one direction or the other depending upon whether the light is fast or slow. The greatest value of the stroboscope is in the study of machine parts while they are under the stresses due to motion. As an example, a part may be badly distorted by its motion. If the stroboscope is synchronized with this part's motion, the part will appear stationary, but any distortion will be clearly visible. In the study of wear, distortion, vibration, etc., of rapidly moving machine parts the stroboscope has been an invaluable aid and has enabled investigators to solve experimentally many difficult problems. (L.R.Q.)

STROKE. **Apoplexy.**

STROMATOLITH. A term proposed by Foye, in 1916, for banded **gneisses** composed of alternate layers of igneous and metamorphic (**schistose**) rocks. Compare with lit-par-lit. (R.M.F.)

STROMEYERITE. A mineral sulfide of silver and copper, AgCuS. Crystallizes in the orthorhombic system. Hardness, 2.5–3; specific gravity, 6.2–6.3; color, gray to blue with metallic luster; opaque. Named after Fr. Stromeyer (1776–1835), Göttingen. (R.M.F.)

STRONTIANITE. The mineral strontianite is **strontium carbonate**, $SrCO_3$, usually occurring in whitish-yellow or whitish-green masses of radiated acicular crystals, or in fibrous or granular form. When distinctly crystallized it is obviously **orthorhombic**, but such crystals are rare. It has a nearly perfect **prismatic cleavage**;

uneven fracture; brittle; hardness, 3–3.5; specific gravity, 3.68–3.72; luster, vitreous; color, as above, also green, gray and colorless; streak, white; transparent to translucent. Strontianite occurs in veins chiefly in limestones, occasionally in the crystalline rocks, and usually associated with **calcite** and **celestite.** It is found in the metalliferous veins in the Harz Mountains and Saxony. It is commercially important in Westphalia where it is mined for use in the beet sugar industry. In the United States, crystalline masses and geodes of strontianite are found in Schoharie County, New York, long a famous locality for this mineral. (E.S.C.S.)

STRONTIUM. Symbol: Sr. Atomic number: 38. Atomic weight: 87.63. Density: 2.6. Melting point: 800° C. Boiling point: 1150° C. (**Isotopes:** page 290.)

Strontium is a silver-white metal, soft as lead, malleable, ductile, oxidizes rapidly on exposure to air, burns when heated in air emitting a brilliant light and forming oxide and nitride, reacts with water yielding strontium hydroxide and **hydrogen** gas. Discovered by Hope and by Klaproth in 1793, and isolated by Davy in 1808.

Strontium occurs chiefly as sulfate (**celestite,** $SrSO_4$) and carbonate (**strontianite,** $SrCO_3$), although widely distributed in small concentration. The commercially exploited deposits are mainly in England. The sulfate or carbonate is transformed into chloride, and the electrolysis of the fused chloride yields strontium metal.

Acetate: Strontium acetate ($Sr(C_2H_3O_2)_2$), white crystals, soluble, by reaction of strontium carbonate or hydroxide and **acetic acid,** and then crystallizing.

Carbide· Strontium carbide (SrC_2), black solid, by reaction of strontium oxide and **carbon** at electric furnace temperature, decomposes water yielding **acetylene** gas and strontium hydroxide.

Carbonates: Strontium carbonate ($SrCO_3$), white solid, insoluble, (1) by reaction of strontium salt solution and **sodium** carbonate or bicarbonate solution, (2) by reaction of strontium hydroxide solution and **carbon dioxide,** decomposes at 1200° C. to form strontium oxide and carbon dioxide, is dissolved by excess carbon dioxide, forming strontium bicarbonate; strontium bicarbonate ($Sr(HCO_3)_2$), solution, by excess carbon dioxide and strontium hydroxide solution.

Chloride: Strontium chloride ($SrCl_2 \cdot 6H_2O$), white crystals, soluble, by reaction of strontium carbonate or hydroxide and **hydrochloric acid,** and then crystallizing. Anhydrous strontium chloride ($SrCl_2$) absorbs dry **ammonia** gas.

Chromate: Strontium chromate ($SrCrO_4$), yellow precipitate, by reaction of strontium salt solution and **potassium** chromate solution.

Cyanamide: Strontium **cyanamide** ($SrCN_2$), mixed with cyanide ($Sr(CN)_2$), by heating strontium carbide at 1200° C. with **nitrogen** gas.

Hydride: Strontium hydride (SrH_2), white solid, by heating strontium metal or amalgam in **hydrogen** gas at 250° C., reactive with water, yielding strontium hydroxide and hydrogen gas.

Hydroxide: Strontium hydroxide ($Sr(OH)_2$), white solid, (1) by reaction of strontium oxide and water, (2) by precipitation of strontium salt solution with **sodium** hydroxide solution, yields hydrate ($Sr(OH)_2 \cdot 8H_2O$) on crystallizing, decomposes upon heating at about 850° C. to form oxide (SrO) and water.

Nitrate: Strontium nitrate ($Sr(NO_3)_2$), white crystals, soluble, by reaction of strontium carbonate or hydroxide and **nitric acid,** and then crystallizing, used in pyrotechnics for the production of red light.

Oxides: Strontium oxide (SrO), white solid, melting point about 2400° C., reactive with water to form strontium hydroxide; strontium peroxide ($SrO_2 \cdot 8H_2O$), white precipitate, by reaction of strontium salt solution and **hydrogen** or sodium peroxide yields anhydrous strontium peroxide (SrO_2) upon heating at 130° C. in a current of dry air.

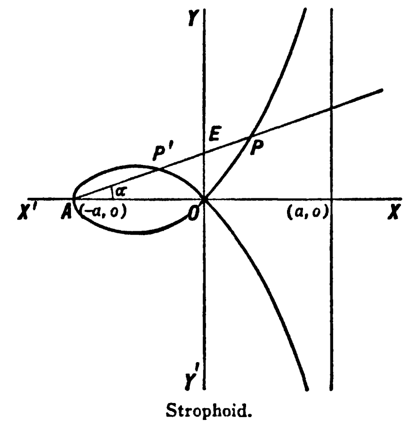
Oxalate: Strontium oxalate (SrC_2O_4), white precipitate, by reaction of strontium salt solution and **ammonium** oxalate solution.

Sulfate: Strontium sulfate ($SrSO_4$), white precipitate by reaction of strontium salt solution and **sulfuric acid** or **sodium** sulfate solution, insoluble in acids, by heating with carbon yields strontium sulfide, by boiling with sodium carbonate solution yields strontium carbonate.

Sulfides: Strontium sulfide (SrS), grayish-white solid, by heating strontium sulfate and **carbon,** reactive with water to form strontium hydrosulfide solution; strontium hydrosulfide ($Sr(SH)_2$) solution, (1) by reaction of strontium sulfide and water, (2) by saturation of strontium hydroxide solution with **hydrogen sulfide;** strontium polysulfides are formed by boiling strontium hydrosulfide with **sulfur.**

Volatile compounds of strontium, such as the chloride, color the bunsen flame a brilliant red. (R.K.S.)

STROPHOID. The strophoid is a plane curve which may be defined geometrically as follows: Through a



Strophoid.

fixed point $A(-a,o)$ on a set of rectangular axes draw any line AE and on this line locate points P and P' such that $OE = EP = EP'$. As AE rotates about A, points P and P' describe the strophoid.

The **parametric equations** of the curve are:

$$x = a \sin \alpha, \quad y = a \tan \alpha(1 + \sin \alpha).$$

The equation in **rectangular coordinates** is

$$x^3 + xy^2 + ax^2 - ay^2 = 0.$$

(L.L.S.)

STRUCTURAL COLOR. **Interference.**

STRUCTURAL CONTOURS. Sub-surface **contours** which represent the structure-in-depth of **orogenic** belts of the lithosphere. Compare with **isopach** and **isobath.** (R.M.F.)

STRUCTURAL GEOLOGY. The study of the arrangement, or rearrangement, of the materials which form the **lithosphere** or outer rocky portion of the earth. The general subject of structural geology is related to a number of other phases of geology, including **metamorphism** and the structure of the earth as a whole. Ordinarily the term is confined to the study of the deformational or structural features of the observable portion of the lithosphere, including the making of geologic maps (geologic surveying). Structural geology is, therefore, intimately related to stratigraphic geology (**Stratigraphy**). While the primary object in a problem in structural geology is to determine the character as well as the space, time relationship of the deformations, the primary object in stratigraphy is to

determine the order of geological events. From a practical point of view there is a close relation between structural and stratigraphic geology. In **petrology**, the structure of a rock refers to the arrangement of the mineral constituents. A number of different types of folds and faults are described under the subject of structural geology. During recent years the science of **geophysics** has supplied a number of methods and techniques which are highly essential to modern research in structural geology. (R.M.F.)

STRUCTURAL MOUNTAINS. Mountains.

STRUT. A strut is a structural member subjected to **compression.** Its conditions of loading and analysis are the same as for a **column.** If there is any difference between strut and column, it rests on the following points. A column is usually thought of as being a fairly large compression member, vertical in position. Small columns are frequently called struts; also, struts are compression members which are incorporated into structures in many positions besides vertical. (F.T.M.)

STRUTHIDEA. Aves, Passeriformes. An Australian bird (**Aves**), probably related to the shrikes. Its colors are gray, black and brown and the beak is short and curved. (A.W.L.)

STRUTHIONIFORMES. The true **ostriches.** An order of birds with long legs and necks, and vestigal wings. They are native to Africa, ranging as far as Syria and Mesopotamia. (A.W.L.)

STRYCHNINE. *Nux Vomica.* Strychnine is the principal **alkaloid** obtained from the seeds of a tree native to India and the East Indies, *Strychnos Nux Vomica.* This tree is often cultivated in the tropics. It has opposite simple leaves with a glossy surface, and small yellowish flowers. The fruit is an orange-colored berry. From the coats of the seeds is obtained the alkaloid strychnine, one of the most bitter substances known. Strychnine is used as a poison for rodents and vermin; it has long had wide use in medicine but without sound pharmacological reason. Its chief action is stimulation of the nervous system. All parts are affected, but the **spinal cord** is the site of the most striking alterations. Strychnine produces "spinal convulsions," i.e., tonic contractions of all the muscles in response to the slightest stimuli. In therapeutic doses it has no effect on the heart, or on the gastrointestinal tract, and it is not a "tonic," contrary to popular belief. Its only rational use is as a respiratory stimulant when the central nervous system is so depressed that effective doses can be used with safety. This occurs in poisoning with **barbital** and its derivatives.

Strychnine poisoning, either through accident or with suicidal intent, is not uncommon; death from this poisoning is particularly violent and agonizing. Following a poisonous dose of strychnine the muscles twitch, muscular spasms appear and are soon followed by convulsion. During the convulsions, the mind remains acutely clear and there is great apprehension on the part of the patient. The convulsions increase in rapidity and degree and are initiated by any slight stimulus such as turning on a light, or any sudden sound. Death takes place from asphyxia due to paralysis of respiratory centers in the brain and **anoxemia** as a result of continuous spasm of the respiratory muscles.

Immediate treatment for this poisoning is the intravenous administration of a depressant drug, particularly one of the rapid-acting barbital derivatives such as amytal. As soon as the patient is quieted, gastric lavage with tannic acid or strong tea, or **potassium** permanganate can be carried out without danger of setting off another convulsion.

A related South American tree, *Strychnos toxifera,* is a source of **curare,** used by the native Indians as an arrow poison. To obtain the poison the bark is scraped off and macerated in water. (D.M.H.)

STUB SWITCH. Railway Track.

STUB TOOTH. Spur Gearing.

STUBS. Gauge Number.

STUBS, LINE. Line stubs are relatively short lengths of **line,** either open or closed at the end, which are connected across the main line. In telephone practice stubs are usually short lengths of **cable** which are connected at cable junctions to build out the line capacitance to the desired value so a better match (see **Impedance, Match**) can be obtained at the junction. In radio frequency work, particularly at the very high and ultra high frequencies, the stub line serves as a valuable matching aid. In these applications the stub is an appreciable fraction of a wavelength long (order of ¼ to ½ wavelength). Such stubs are frequently used to match a transmission line to an **antenna.** By proper location of an open or shorted stub near the junction of the line and load a match can be obtained, the location and length of the stub depending upon the characteristics of the line and load but being subject to calculation in any given case. For many such problems curves or tables are available to aid in the solution. In microwave work where lines are coaxial or **wave guides** the matching stub is widely used to match the various junctions since the dimensions at these frequencies make them entirely feasible and other more conventional matching means are not satisfactory. (L.R.Q.)

STUD. Screw Fastenings.

STUDENT'S *t* DISTRIBUTION. Student's *t* distribution is given by

$$P_t dt = \frac{\Gamma\left(\frac{n}{2}\right)}{\sqrt{n\pi}\,\Gamma\left(\frac{n}{2} - 1\right)} \left(1 + \frac{t^2}{n}\right)^{-\frac{n+1}{2}} dt.$$

$-\infty < t < \infty$, n = the **degrees of freedom.** Student's *t* distribution is needed in testing the significance of a **sample mean,** the difference of two sample means, the significance of a **coefficient of correlation,** the significance of regression coefficients and **confidence limits** in these cases. Most of these results are due to R. A. Fisher who gave a rigorous proof of the distribution in 1925, although Student gave the result after an empirical demonstration in 1908. In all cases it is assumed that the variates are **normally distributed** with the same **population variance.**

To test the hypothesis that the population mean is m we use

$$t = \frac{\bar{X} - m}{s} \sqrt{N}$$

with $N - 1$ degrees of freedom, where $\bar{X}$ is the mean of the sample and s^2 is

$$\frac{\sum_{i=1}^{N} (x_i - \bar{X})^2}{N - 1}.$$

N = number of **variates** in the sample

To test the hypothesis $m_1 = m_2$ we use

$$t = \frac{\bar{X}_1 - \bar{X}_2 - (m_1 - m_2)}{s\sqrt{\frac{1}{N_1} + \frac{1}{N_2}}}$$

with $N_1 + N_2 - 2$ degrees of freedom, $\bar{X}_1$ = mean of the first sample, $\bar{X}_2$ = mean of the second sample, N_1 = number of items in the first sample, N_2 = number of items in the second sample,

$$s^2 = \frac{N_1\sigma_1^2 + N_2\sigma_2^2}{N_1 + N_2 - 2}, \quad \sigma_1^2 = \frac{\sum_{i=1}^{N_1}(x_i - \bar{X}_1)^2}{N_1},$$

$$\sigma_2^2 = \frac{\sum_{i=1}^{N_2}(x_i - \bar{X}_2)^2}{N_2}.$$

We assume the variates are not paired. If the variates are paired, naturally we use $d_i = x_i - y_i$, and test the hypothesis $m_1 = m_2$ by

$$t = \frac{\bar{d}_i}{s}\sqrt{N}$$

with $N - 1$ degrees of freedom where

$$s^2 = \frac{\Sigma(d_i - \bar{d}_i)^2}{N - 1} \quad \text{and} \quad \bar{d}_i = \frac{\Sigma d_i}{N}.$$

To find confidence limits at the α level of significance in all cases above we assume m unknown, $m_1 - m_2$ unknown or finally m_d unknown in

$$t = \frac{\bar{d}_i - m_d}{s}\sqrt{N},$$

and since these other quantities are known we can solve for m, $m_1 - m_2$ or m_d. Thus we get three cases.

1. $$m = \bar{X} \pm \frac{st_\alpha}{\sqrt{N}},$$

where $\bar{X}$ and s is found from the sample and t_α is given by tables of Student's t distribution.

2. $$m_1 - m_2 = \bar{X}_1 - \bar{X}_2 \pm st_\alpha\sqrt{\frac{1}{N_1} + \frac{1}{N_2}}$$

3. $$m_d = \bar{d}_i \pm st_\alpha\sqrt{N}.$$

To test the hypothesis that the population value of a **coefficient of correlation** ρ is zero we set

$$t = \frac{\sqrt{N - 2r}}{\sqrt{1 - r^2}}$$

and use the tables of Student's distribution with degrees of freedom $N - 2$, where N is the number of pairs in the correlation, and r is the sample coefficient of correlation.

To test whether a **coefficient of partial correlation** $r_{12\cdot34\ldots k}$ from N sets of values is significant or not we use

$$t = \frac{\sqrt{N - kr_{12\cdot34\ldots k}}}{\sqrt{1 - r^2_{12\cdot34\ldots k}}}$$

with degrees of freedom $N - k$ and the tables of Student's distribution.

It may be asked what should be done if the variates are not distributed normally but form a distribution which is moderately skewed. In such a case, if the degrees of freedom are 8 or more it seems safe to use Student's t distribution. If the variates are distributed in a J-shaped distribution it would be wise to use the 1% level of significance before rejecting a hypothesis unless the degrees of freedom are 50 or more in which case the usual t tables may be used. In case $\sigma_1^2 \neq \sigma_2^2$, Student's t test does not apply. There is no general agreement in this case, but if N_1 and N_2 are both large (more than 100) we may use

$$t = \frac{\bar{X}_1 - \bar{X}_2 - (m_1 - m_2)}{\sqrt{\frac{s_1^2}{N_1} + \frac{s_2^2}{N_2}}}$$

where

$$s_1^2 = \frac{\sum_{i=1}^{N_1}(x_i - \bar{X}_1)^2}{N_1 - 1}, \quad \text{and} \quad s_2^2 = \frac{\sum_{i=1}^{N_2}(x_i - \bar{X}_2)^2}{N_2 - 1},$$

and refer t to the tables of the normal curve.

Student's t distribution approaches a normal curve as the degrees of freedom increase. (L.A.A.)

STUDENT'S t TEST. **Student's t Distribution.**

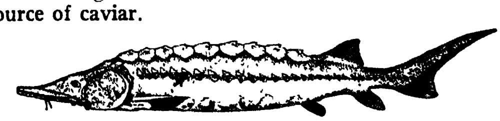
STUFFING BOX. A device for preventing leakage or transfer of fluid between moving parts, usually consisting of a relatively soft packing compressed or confined by an adjustable member called a gland. Stuffing box packings differ from gaskets in that they are used in confined spaces, and do not of themselves withstand stresses due to fluid pressure. In the usual form, the stuffing box consists of a hollow cylinder surrounding the moving (reciprocating or rotating rod or shaft) member; the space between the hole and the rod or shaft is filled with packing compressed by the gland. Packings may consist of relatively plastic material, bonding such substances as cotton fabric, rope, or asbestos, but packings of rubber, leather, pressed graphite, or molded plastics are also used.

In high-speed machinery, such as turbines and rotary compressors, where no adequate cooling is available, and in high-pressure equipment where small clearances are required, and for which packings are inadequate, devices known as labyrinths may be used. A labyrinth consists of a series of projections on the rotating element, running in close contact with grooves on the stationary element. To enable a labyrinth to function as a seal, there must be some fluid flow; the fluid first passes a restriction and then expands into a chamber, which consumes a certain amount of energy. After a series of such expansions, a considerable pressure drop will exist between the initial and terminal points of the labyrinth. In order to render the device operable, there must always be some leakage at the terminal point. The effective operation of a labyrinth is less marked for liquids than for vapors. (See **Fluid Seals.**) (H.C.H.)

STUPOR. Partial unconsciousness. In stupor the patient can be aroused as a rule by various stimulating measures. Stupor is seen in certain central nervous system diseases, psychoses, and severe infections, but is more often associated with overdoses of drugs or alcohol. (D.M.H.)

STURGEON. Pisces, Chondrostei. Fishes (**Pisces**) of moderate to very large size, found in the oceans and fresh waters of the entire northern hemisphere. Their chief external characteristic is the series of bony plates arranged in rows along the back and sides, separated by wide spaces containing only small hard elements.

The sturgeons are excellent food fishes and are the source of caviar.



Sturgeon.

Among the true sturgeons the small **sterlet,** ***Acipenser ruthenus***, and the giant hausen, *A. huso*, of Asiatic and European waters are noteworthy. The group also includes the shovel-beaked sturgeons, *Scaphirhynchus*, of the Mississippi River system and the rivers of central Asia, and the paddle fishes, *Polyodon*, of the same order are sometimes called toothed sturgeons. (A.W.L.)

STURM'S THEOREM. A method for locating the **real roots of a polynomial equation** is given by Sturm's theorem, which may be stated as follows:

Let $P(x) = 0$ be a polynomial equation with real coefficients and without multiple roots. Modify the usual process (Euclid's algorithm) for finding the **highest common factor** of $P(x)$ and its first **derivative** $P_1(x)$ by exhibiting each remainder as the negative of a polynomial P_k, thus:

$$P = q_1P_1 - P_2, \quad P_1 = q_2P_2 - P_3, \quad P_2 = q_3P_3 - P_4, \cdots,$$
$$P_{n-2} = q_{n-1}P_{n-1} - P_n,$$

where P_n is a constant $\neq 0$. If a and b are real numbers, with $a < b$, neither of which is a root of $P(x) = 0$, then the number of real roots of $P(x) = 0$ between a and b is equal to the excess of the number of variations of sign of

$$P(x), P_1(x), P_2(x), \cdots, P_{n-1}(x), P_n,$$

for $x = a$ over the number of variations of sign for $x = b$. Terms which vanish are to be dropped out before counting the variations of sign. (L.L.S.)

STYE. A staphylococcal infection of a **sebaceous gland** on the margin of the eyelids. Styes are frequently seen with errors of refraction of the eye. (D.M.H.)

STYLE. Flower.

STYLET. Small sharp structures used for piercing. The term applies to the calcareous **spines** of the **proboscis** of some **nemertine** worms and to the slender piercing organs of some insect mouths. The latter are modified **mandibles** and **maxillae.** (A.W.L.)

STYLOLITE. A columnar-like structure, at right angles, or highly inclined to the bedding planes of certain **limestones,** believed to be produced by differential vertical movements induced under great pressure. The term is derived from the Greek words meaning column and a stone. (E.S.C.S.)

STYLOMMATOPHORA. Gasteropoda.

STYLOPID. Strepsiptera.

SUB-LAND DRILL. Counterbore.

SUBAERIAL FAN. Alluvial Fan.

SUBCUTANEOUS. Situated under the skin, as a subcutaneous **tumor** or **abscess,** etc. (R.S.M.)

SUBCUTICULA. The **tissue** beneath the **cuticula** of **flukes** and tapeworms (**Cestoda**). In these parasitic forms of flatworms (**Platyhelminthes**) the body is covered with a resistant noncellular cuticula and the ectodermal cells have sunk into the **parenchyma,** so that the layer immediately within the cuticula is composed of a mixture of ectodermal and mesodermal cells and muscle fibers. (A.W.L.)

SUBERIN. This is a waxy substance which is found in the walls of cork cells in the outer tissues of stems, roots, and other parts of the plant. It is impervious to water and so prevents the loss of water from the living cells of the plant. Suberinization also prevents the entry of food, thus causing the early death of cork cells. The walls are comparatively thin. It is very similar to cutin, which forms on the walls of epidermal cells and makes them waterproof. (R.M.W., B.S.M.)

SUBLIMATION. This term applies to the transition, under suitable conditions, directly between the vapor and the solid state of a substance. If solid iodine is placed in a tube and slightly warmed, it vaporizes and the vapor reforms into crystals on the cooler parts of the tube. Many crystalline substances, both metallic and non-metallic, may be similarly sublimated in a vacuum; fairly large crystals of selenium have been thus prepared. The most familiar sublimates are **frost** and **snow.** As in the case of other changes of state, sublimation is accompanied by the absorption or evolution of heat, the quantity of which per unit mass is called the "heat of sublimation" of the substance. At pressures near the triple point (see **Three-Phase Equilibrium**) the heat of sublimation is approximately equal to the sum of the heats of fusion and vaporization. (See **Vapor Pressure; and Distillation, Evaporation, and Drying.**) (L.D.W.)

SUBMAXILLARY GLAND. Salivary Gland.

SUBMENTUM. Labium.

SUBNEURAL GLAND. A gland found below the brain in the **ascidians.** Its duct leads to the ciliated funnel, an organ supposed to be sensory. The function of the gland is unknown. (A.W.L.)

SUBNORMAL DISPERSION. If the **Lexis ratio,** D, is less than 1, the distribution is said to possess subnormal dispersion. (See **Coefficient of Dispersion.**) (L.A.A.)

SUBNORMAL OF A CURVE. Tangents and Normals to a Plane Curve.

SUBSEQUENT STREAMS. Consequent Streams.

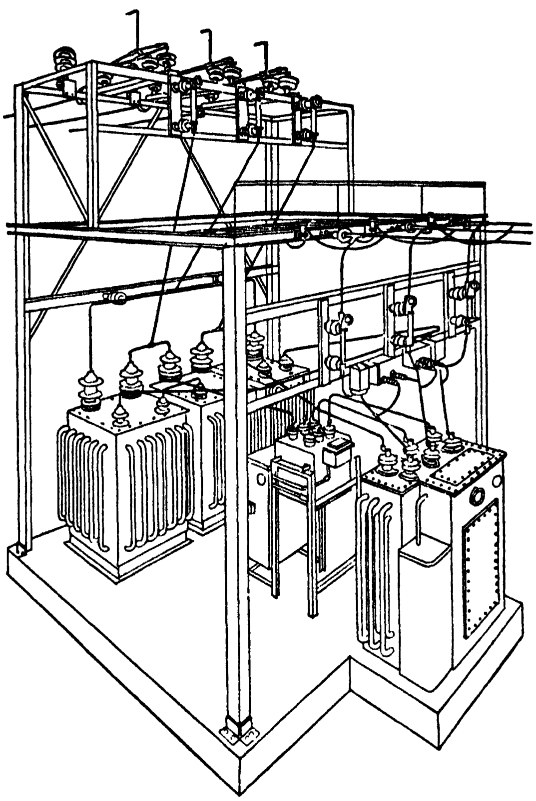
SUBSIDENCE. Subsiding air is sinking air and is associated with lateral divergence. Subsidence in the atmosphere is a stabilizing influence; it also decreases relative humidity within the sinking air as it warms the air. Atmospheric pressure usually rises under the influence of subsidence which is normally associated with anticyclones. Clear or partially clouded skies are the usual weather in a region of subsidence. (P.E.K.)

SUBSILICIC. A term proposed by Clarke, in 1911, to replace "basic." (R.M.F.)

SUBSOIL. Soil.

SUBSTATION. An electrical substation is a point in the transmission system, outside of the main generating station, where the power may be transformed and switched to render more flexible and reliable service. Depending upon their purpose in the transmission scheme, substations may be classified as transmission, distribution and industrial. The transmission substation consists merely of **transformers** and **circuit breakers** for connecting the secondaries to various outgoing lines. For more reliable service, by offering better switching facilities, the station is usually somewhat more complex than this, having various combinations of breakers and feeders by using auxiliary bus systems. The equipment and its arrangement in the distribution substation varies widely between different stations, being determined by the reliability of service deemed necessary, the type of distribution system served, etc. The primary function of such a substation is to receive the power from the high-voltage transmission line and transform it to the distribution voltage (usually of the order of a few thousand volts) and distribute this power to the various distribution feeders. The substation may contain voltage-regulating equipment and always contains certain fault-protecting devices, the complexity being governed by the type load being served from the station. A typical outdoor substation is shown. Industrial substations are designed to meet the needs of a particular plant and contain the same general components as the others. The various pieces of equipment composing the substation

may be located in a substation building or may be of weatherproof construction and located out-of-doors. The latter arrangement offers certain advantages, among them the avoiding of arranging high-voltage lines inside the building, avoiding of the high-voltage entrance connec-



Typical outdoor substation.

tions, the lesser cost since no building is required, etc. Outdoor substations have the breakers and transformers in weatherproof encloures with the **relays**, operating mechanisms, etc., usually in cabinet type structures along the side. The connecting buses are arranged in a neat system of parallel and perpendicular buses supported from steel framework. Distribution substations are frequently located in residential sections of cities so considerable care is taken to make them pleasing in appearance, the electrical apparatus being neatly arranged, the grounds landscaped, etc. (L.R.Q.)

SUBSTITUTE MEMBER. Graphical Statics.

SUBSTITUTION METHOD. Physical Measurements.

SUBSURFACE WATER. Ground Water.

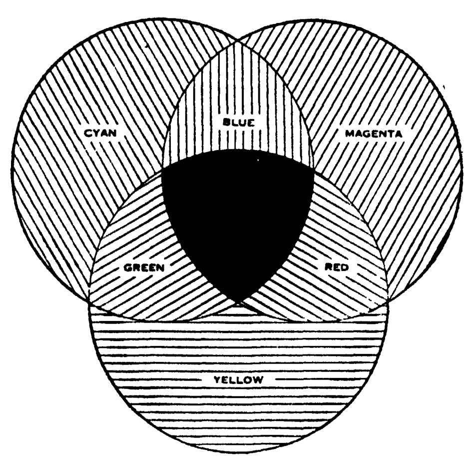
SUBTANGENT TO A CURVE. Tangents and Normals to a Plane Curve.

SUBTRACTION. Subtraction is the **inverse** operation to **addition.** The result of subtracting one number from another is called the difference of the two numbers. The difference $a - b$ between two numbers a and b is that number c such that $b + c = a$. It follows that $(a - b) + b = a$ and $(a + b) - b = a$. That is, the operations of addition and subtraction are mutually destructive: each undoes the effect of the other.

To subtract one number from another, change the sign of the number to be subtracted and proceed as in addition. (L.L.S.)

SUBTRACTIVE COLOR PROCESS. A method of photographic color synthesis using two or more superimposed colorants which selectively absorb their complementary colors from white light.

Most modern processes of color photography make use of a subtractive synthesis to yield prints or transparencies. In a 3-color process the colorants cyan, magenta,



(*Neblette's Photography.*)

and yellow are used to control the amounts of red, green and blue in a beam of white light. This beam of white light may be either that of a projector with its color transparency, or the light reflected from a white support, such as paper, on which the color reproduction is printed. In the first case, the light passes through the colorants once, while in the print viewed by reflection the light must traverse the colorants twice.

The colorants are positive or negative images which have been prepared by one of the methods discussed under **color image formation.** A cyan positive image (a cyan colorant controls red light), for example, may be prepared from the negative that recorded the red present in the subject. The magenta and yellow colorant images are likewise made from green and blue record negatives. These colorant images are superimposed in register to yield the final reproduction. The three colorants may be in separate removable layers or they may be physically inseparable as in the modern integral tripacks (see **Bipacks and Tripacks**). The contrast of the colorant images must be approximately double for a picture to be viewed by transmitted light as compared to one to be viewed by reflection. The accuracy of color reproduction by a subtractive synthesis as compared to an additive is chiefly dependent on how satisfactorily the three colorants cyan, magenta, and yellow fulfil their role, as red, green and blue absorbers respectively. Color correction is often adopted to improve the accuracy of reproduction when using the colorants generally available. (H.C.C.)

SUBTRACTIVE REDUCERS. Photographic Reduction.

SUBUMBRELLA. Medusa.

SUCCESSION, PLANT. This is the term used to designate the gradual replacement of one plant association by another. Succession is caused by slow changes in the environmental factors which influence the establishment, development and survival of plants. Many of these changes, such as shading, increase in the humus

content or porosity of the soil, decrease in soil temperature, etc., are brought about by plants themselves.

A good example of a plant succession occurs in the filling of a shallow pond. At first the deeper parts of such a pond are occupied only by submersed aquatic species of plants. As the pond becomes shallower, as a result of the accumulation of plant remains and the deposition of the silt caught in such remains, floating-leaf species such as water lilies invade the area and largely shade out the underwater species. With further decrease in the depth of the water the floating leaf aquatics are replaced by cattails, reeds, bulrushes and other typical marsh plants. At a still later stage in succession the former pond will be occupied by a wet meadow composed largely of sedges, rushes, and spike rushes. Still later swamp shrubs such as willows, alders, and buttonbush invade the area only to be replaced in turn by trees of species which can tolerate a poorly drained substratum. Still further successional stages may ultimately result in the development of a climax association (see **Plant Association**) on the area.

Another example of plant succession which can be observed in many parts of the country is the natural reforestation of abandoned farm land. The pioneer invaders of such an area are mostly herbaceous plants, the very first to appear being mostly annuals. Soon shrubs invade the area to be followed in turn by certain species of trees. The first tree species to occupy the area, however, seldom represent a stable plant association. In large parts of the eastern United States, for example, pines of one species or another are usually the first kind of tree to occupy abandoned fields, but they are in time replaced by other species, most commonly by oaks or hickories or both. In many regions still further successional stages will be passed through before a stable climax association is attained.

Other examples of kinds of areas on which plant succession is initiated are sand dunes, burned over forest lands, cliffs or raw talus slopes, and the bottoms of lakes which have been exposed by drainage. Important consideration should be given to the principles of plant succession in forest and range management and in other land utilization problems. (B.S.M.)

SUCCESSIVE DERIVATIVES. **Higher Derivatives.**

SUCCESSIVE INTEGRATIONS. **Double Integrals** and **Triple Integrals.**

SUCCULENTS. Succulent plants are those which are fleshy, that is, have their stems or leaves greatly enlarged to serve as water-storage organs. Succulents occur wild in regions in which there is a very limited supply of available water, as in the desert lands of western America, central Asia, and many parts of Africa. Among stem succulents the outstanding representatives are the members of the **Cactus** family, with the milkweed and **spurge** families also ranking high. Leaf succulents include many plants such as *Sedums, Crassulas, Bryophyllums*, and *Gasterias*. Many of the leaf succulents are plants of extremely curious habit. In some, the leaves are so swollen with stored water that they form a nearly spherical mass growing almost buried in the ground; in others the masses of leaves form compact rosettes at the tips of the branches; while in others the swollen leaves appear like small green beads along a slender stem.

Because of their odd and often ornamental habit, succulent plants are frequently grown in cultivation, especially as house plants. Many are especially desirable for this purpose, since they require little care and are remarkably tolerant to all conditions except too much water, which will cause quick rotting and death to many of them. Many of this group of plants produce large gaudy flowers which add to their popularity as house plants. (R.M.W.)

SUCKER. Pisces, Teleostei. A fish (**Pisces**) which lives near the bottom of streams, feeding on vegetation and small animals. The mouth is usually provided with fleshy lips and in some species opens at a downward angle. These fishes constitute the family Catostomidae, including the **mullets** and **buffaloes** as well as the species commonly called suckers. They are not highly valued as food fishes, but the common sucker, *Catostomus commersoni*, often abundant in small streams and lakes, is excellent although bony. (A.W.L.)

SUCKING FISH. **Remora.**

SUCROSE. **Carbohydrates.**

SUCTORIA. **Ciliophora.**

SUDBURITE. The term proposed by H. P. Coleman, in 1912, for a type of basaltic lava frequently characterized by **amygdaloidal** and **pillow** structures, and chemically the effusive form of **norite.** Type locality, Sudbury, Ontario, Canada. (R.M.F.)

SUFFICIENT STATISTIC. A sufficient statistic T used in estimating a parameter θ is a **statistic** which even in small **samples** extracts all the information contained in the sample. If a sufficient statistic exists it should always be used in preference to any other statistic. Unfortunately they do not always exist. If a sufficient statistic is normally distributed with its **expected value** equal to the **population parameter** and **variance** proportional to $\frac{1}{N}$, it is an **efficient statistic.** The necessary and sufficient condition for a sufficient statistic will be given.

If the population distribution is continuous let $P(x_1, x_2, \cdots, x_N; \theta_1, \theta_2, \cdots, \theta_h)$ be the probability function of $x_1, x_2, \cdots, x_N$; if the distribution is **discrete**, let $P(x_1, x_2, \cdots, x_N; \theta_1, \theta_2, \cdots, \theta_h)$ be the discrete probability of obtaining $x_1, x_2, \cdots, x_N$. In either case a necessary and sufficient condition that T be a sufficient statistic for estimating θ_1 is that P factor as follows: $P(x_1, x_2, \cdots, x_N; \theta_1, \theta_2, \cdots, \theta_h) = g_1(T; \theta_1, \theta_2, \cdots, \theta_h) \cdot g_2(x_1, x_2, \cdots, x_N; \theta_2, \theta_3, \cdots, \theta_h)$. (L.A.A.)

SUGAR. Sugar is the name given to a group of chemical compounds included in the **carbohydrates.** They are composed of carbon, hydrogen, and oxygen, usually in the proportions of $C_6H_{12}O_6$ or $C_{12}H_{22}O_{11}$. Sugars are colorless compounds, either solid or liquid, and many form aqueous solutions having a sweet taste. Commercial sugar is sucrose or saccharose, which has the chemical formula $C_{12}H_{22}O_{11}$, and occurs in many plants, mostly in amounts too small to be of importance commercially. A few plants, however, contain this sugar in their sap in considerable quantity. The most important sugar-containing plants are sugar cane and the **sugar beet.** Sweet **Sorghums,** several **Palms,** and Sugar Maples also yield sugar.

SUGAR CANE. *Saccharum officinarum.* Gramineae. This plant is a perennial grass, growing best in regions having a continuous hot climate and abundant moisture. The plant possesses a shallow fibrous root system and thick underground rhizomes from which rise the erect stems 1–2″ in diameter and 6–15′ in height. These stems are many-jointed, solid, and bear at the nodes broad leaves with clasping bases. Each leaf is 3 or more feet long. The inflorescence is a loose panicle, which is rarely produced on plants grown outside the tropics. The **spikelets** of the **panicle** are two-flowered, the lower one sterile, the upper fertile. At the base of the spikelet is a tuft of long silky hairs. The grain is

very small, rather silky, and rarely viable, especially in plants grown in less favorable regions.

Propagation of sugar cane is therefore done by means of stem cuttings rather than seed. In this propagation, young stems are cut up into sections, each containing three buds. These sections are planted in holes in the ground and covered with about 2" of soil. Sprouts appear above ground in about two weeks and grow rapidly. The crop is ready for the first harvest in 12–15 months; successive crops may be gathered yearly thereafter for a number of years, varying greatly with the nature of the soil.

In harvesting the stout stems are cut down, stripped of their leaves and top, and hauled to the factory as soon as possible. There the canes are passed between heavy variously toothed rollers, which crush and shred them. The crushed material is passed through a series of heavy rollers which squeeze out much of the juice. Hot water is sprayed over the stem mat as it passes through the rollers, ensuring extraction of greater amounts of the juice. The residue remaining after extraction is called **bagasse,** and is used as a fuel to run the mill. The extracted juice is strained to remove solid materials, then heated and allowed to stand in tanks so that any dirt present in the liquid may settle out. The clear liquid is then treated with lime, or other chemicals, which remove additional impurities, which unite with the lime and rise to the surface of the liquid as a scum, or settle to the bottom as a sediment. The clear liquid is then evaporated under partial vacuum to a sirup. Boiling is continued in vacuum pans until the sirup becomes very thick and concentrated, at which time small crystals begin to appear. These crystals increase in size as more liquid is added and boiled down. When the desired crystal size is reached, the concentrated sirup is removed to centrifugal machines consisting of perforated cylindrical baskets within heavy jackets. Rapid revolving of these baskets causes the liquid portion of the sirup to be thrown out through the holes to the sides of the container. The crystalline portion remains in the basket. This is washed to remove any sirup which remains as a film over the crystal surface, then removed and dried. The use of sugar is too well known to need mention. It is an important source of energy and also much used to impart a sweet flavor to substances which might be unpleasant otherwise. As a by-product of this process a thick viscous brown liquid is obtained. This is molasses, which is used for cooking, for stock feeding, and for the manufacture of rum and alcohol.

Sugar Maple. *Acer saccharum.* Another source of sugar, of limited importance commercially, is the sugar maple, *Acer saccharum,* a deciduous hardwood tree of eastern North America. The sugar is obtained from the sweet sap of the tree. To obtain this sap, small holes are bored into the sapwood near the base of the trunk, a channeled spout driven into each hole, and a bucket hung on the spout. Clear, snappy, cold nights and warm quiet days favor the flow of sap, which may run 3 or 4 gallons to a tree daily for a period of 3 or 4 weeks. The colorless sap is poured into slightly tilted flat pans so corrugated that the sap gradually flows downward. Wood fires under the pan cause the thin layer of sap to evaporate rapidly, producing a thin brownish sirup which is mostly sucrose, but characteristically flavored by substances contained in the sap. This sirup may be further concentrated until it crystallizes as a brown sugar, which is usually prepared in small cakes. From a good tree 2 lbs. of sugar or a quart of thick sirup may be obtained each year. Maple products are much used to flavor tobacco, and in candy manufacturing. Maple sirup is frequently mixed with other sirups before marketing. The principal producing regions are Vermont and New York, with other New England states and the states along the Great Lakes producing the rest.

Honey. Another source of sugar is the nectar found in many flowers. The amount found in each flower is too minute to be directly obtained by man. Certain insects gather this nectar in quantities. One insect in particular, the honey-bee, is an especially industrious collector of nectar. This they store in waxen cells, first having partially digested the nectar. Bees can be made to store much more honey than will be needed for carrying them through the winter. This surplus honey is then available to man. Certain flowers, notably clover, buckwheat, and lindens, give to honey obtained from them a particularly attractive fragrance. Honey is used most commonly as a table luxury. (R.M.W.)

SUGGESTION. Producing a condition in which activity, conduct, or thought is determined by impressions or ideas imparted by others. (See **Hypnosis.**) (D.M.H.)

SUINA. A division of the hoofed animals including the **pigs** and **peccaries.** They differ from the other members of the order **Artiodactyla,** to which they belong, in the absence of horns, in the thick skin and bristly hair, and in the fact that they are not ruminants. (A.W.L.)

SULFA DRUGS. Thioalcohols and Related Compounds.

SULFADIAZINE. Sulfonamide Drugs.

SULFAGUANADINE. Sulfonamide Drugs.

SULFAMERAZINE. Sulfonamide Drugs.

SULFANILAMIDE. Sulfonamide Drugs.

SULFAPYRIDINE. Sulfonamide Drugs.

SULFATE. Sulfuric Acid.

SULFATHIAZOLE. Sulfonamide Drugs.

SULFIDE. Hydrosulfuric Acid.

SULFINIC ACIDS. Thioalcohols and Related Compounds.

SULFINYL COMPOUNDS. Thioalcohols and Related Compounds.

SULFITE. Sulfurous Acid and Sulfites.

SULFONAMIDE. Thioalcohols and Related Compounds.

SULFONAMIDE DRUGS. A group of chemotherapeutic agents capable of curing serious generalized or systemic bacterial infections in man. In 1935, Domagk, a German investigator, was the first to observe the clinical value of *prontosil,* a red compound derived from azo dyes. Para-amino-benzene-sulfonamide was shown to be the effective portion of the prontosil molecule, and this substance was given the name sulfanilamide.

Sulfanilamide was the first of the group to receive wide clinical trial. It was found to be effective in the treatment of hemolytic streptococcal and staphylococcal infections. Within the space of a few years the following related drugs were the most important ones to be synthesized and given clinical trial: *sulfapyridine, sulfathiazole, sulfaguanadine, sulfadiazine* and *sulfamerazine.* They act by inhibiting the growth of bacteria rather than by killing organisms. All of them are now in use for

the treatment of various infections. Sulfadiazine at present is the most widely used because it is highly effective and less toxic than most of the others. It is used in the treatment of hemolytic streptococcal and staphylococcal infections, in **puerperal sepsis, pneumonia, gonorrhea,** meningococcus, **meningitis,** the **dysenteries, cystitis, pyelitis** and many other acute infections.

Until the advent of **penicillin,** the sulfonamides were supreme in chemotherapy. Penicillin and the sulfonamides are, in general, effective against the same organisms, but penicillin has the advantage of being nontoxic. The current widespread use of sulfonamides without the direction of a physician is decried because of the serious and sometimes fatal toxic reactions which may ensue. Hemolytic **anemia, agranulocytosis,** hyperleukocytosis, **purpura, hemorrhagica,** various skin eruptions, **hepatitis, psychoses,** kidney stones, **hematuria,** complete suppression of kidney function and anuria may occur during the course of therapy. (D.M.H.)

SULFONIC ACIDS. Thioalcohols and Related Componds.

SULFONYL COMPOUNDS. Thioalcohols and Related Compounds.

SULFUR. Symbol: S. Atomic number: 16. Atomic weight: 32.06. Isotopes: 32(96%), 33(1%), 34(3%). The chemical element sulfur is known in two different forms, namely, (1) alpha-**rhombic** sulfur, yellow, density 2.07, melting point 112.8° C. to form gamma-sulfur; (2) beta-**monoclinic** sulfur, yellow, density 1.96, melting point 119° C. to form gamma-sulfur. Below 96° C. beta-monoclinic changes to alpha-rhombic. The boiling point of sulfur is 444.6° C., as a brownish-red vapor turning deep red at 500° C. and straw yellow at 650° C. The discovery of sulfur is prehistoric. Sulfur is largely consumed (1) in insecticides, either as "flowers of sulfur" or as calcium sulfide, "lime-sulfur," (2) in making sulfur dioxide gas and sulfites, such as calcium hydrogen sulfite plus sulfurous acid solution used as the cooking liquor for making sulfite paper pulp from wood (see **Paper**), (3) in making sulfur trioxide, **sulfuric acid,** and sulfates.

Free sulfur occurs in the alpha-rhombic form; brittle; fracture conchoidal; hardness 1.5–2.5; specific gravity 2; luster, resinous; color, usually yellow, but may be brownish, reddish, or greenish, transparent to translucent.

Alpha-rhombic and beta-monoclinic sulfur are soluble in **carbon** disulfide, and when the solution is allowed to evaporate spontaneously in air, the residual sulfur crystallizes as alpha-rhombic. Sulfur burns with a beautiful violet transparent flame of characteristic odor when ignited in air at 250° C. to form sulfur dioxide, and combines with many metals when heated, e.g., **iron** powder to form ferrous sulfide. Color and **viscosity** of sulfur change with change of temperature approximately as follows: maximum of viscosity (50,000 times that of water at 17° C.) is at about 200° C.; at this temperature liquid sulfur is dark red, having arrived at this by passing through stages from pale yellow. Viscosity at 300° C. is about 2000. At about 200° C. the liquid darkens almost to black. If, at a temperature near the boiling point, liquid sulfur is poured into cold water, it forms a soft, elastic, ductile mass like rubber, which in a few days at ordinary temperatures changes to alpha-rhombic sulfur. When liquid sulfur is kept at a temperate only slightly below the melting point for a sufficient time for part of the liquid to crystallize, and the remaining liquid poured off, beta-monoclinic crystals are obtained, which within a few days at ordinary temperatures change to alpha-rhombic sulfur.

Sulfur occurs as free sulfur in many volcanic districts, and may have been formed in part by **sublimation,** by decomposition of hydrogen sulfide, or metallic sulfides, or by organic agencies. It is often associated with **limestones** and **gypsum.** Sulfur is found in Spain, Iceland, Japan, Mexico, and Italy (especially Sicily, which was the producer for the world until about the beginning of the twentieth century, when Herman Frasch, by inventing the superheated water method of mining sulfur, made available the great Louisiana and Texas deposits. This method of mining is at the same time a method of purifying sulfur, as in the process of heating, accompanying materials remain unmelted at the temperature at which sulfur melts and is drawn off). In the Louisiana and Texas deposits the sulfur is associated with gypsum, occurring in the cap-rock overlying the salt plugs that have pierced the strata underlying the Gulf coastal plain. In the United States sulfur is also found in California, Colorado, Nevada, and Wyoming. Sulfur also occurs as (1) sulfides, e.g., iron disulfide, **pyrite** (FeS_2), lead sulfide, **galenite** (PbS), copper iron sulfide, copper pyrite ($CuFeS_2$), zinc sulfide, **zinc blende** (ZnS), mercury sulfide, **cinnabar** (HgS); and (2) as sulfates, e.g., calcium sulfate, **gypsum** ($CaSO_4 \cdot 2H_2O$), barium sulfate, **barite** ($BaSO_4$).

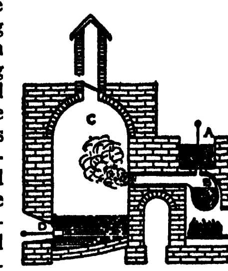


Diagram of furnace for the sublimation of sulfur. *A*, sulfur as charged to furnace; *B*, sulfur melted by heating and vaporized; *C*, chamber maintained below the melting point of sulfur for the direct condensation of sulfur as finely divided solid (sublimed sulfur).

Acids: Sulfur is a constituent of several acids. In increasing order of oxidation the following are those which contain sulfur and oxygen but not carbon: hydrosulfuric acid (H_2S); thiosulfuric acid ($H_2S_2O_3$); tetrathionic acid ($H_2S_4O_6$); hyposulfurous acid ($H_2S_2O_4$); sulfurous acid (H_2SO_3); dithionic acid ($H_2S_2O_6$); persulfuric acid ($H_2S_2O_8$); chlorosulfonic acid ($Cl \cdot SO_2OH$), liquid, boiling point 155° C., reactive with explosive violence with water forming sulfuric acid plus **hydrochloric acid,** and formed by distillation of concentrated sulfuric acid and **phosphorus** pentachloride or oxychloride; fluosulfonic acid ($F \cdot SO_2OH$); those which contain carbon (thioic acids): thiocarbonic acid (H_2CS_3); ethane thiolic acid (CH_3COSH); ethane thionic acid ($CH_3 \cdot CSOH$); ethane thionthiolic acid, methane carbodithioic acid ($CH_3 \cdot CSSH$); methyl sulfonic acid ($CH_3 \cdot SO_2OH$); methyl sulfinic acid ($CH_3 \cdot SOOH$); benzene sulfonic acid ($C_6H_5 \cdot SO_2OH$).

Bases: Sulfur is a constituent of some bases, e.g., trimethyl sulfonium hydroxide ($(CH_3)_3SOH$).

Bromide: Sulfur bromide (S_2Br_2), dark red liquid, boiling point 56° C. at 0.2 mm. pressure.

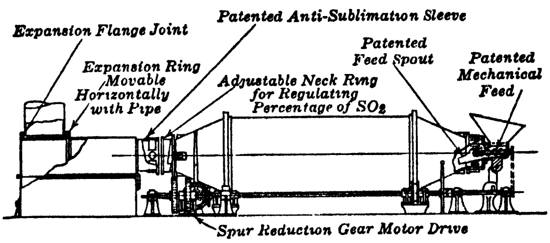
Chlorides: Sulfur chloride, sulfur monochloride (S_2Cl_2), yellowish-brown liquid, of irritating odor, boiling point 139° C., formed by reaction (1) of **chlorine** and sulfur heated, (2) of chlorine and **carbon** disulfide, and separated from **carbon** tetrachloride by fractional distillation. It dissolves sulfur readily, and is used in the process of vulcanization of rubber; sulfur dichloride (SCl_2), dark red fuming liquid, boiling point 59° C., formed by reaction of sulfur monochloride and chlorine in the presence of a trace of iodine; sulfur tetrachloride (SCl_4), unstable above −20° C., formed by saturating sulfur monochloride with chlorine at −22° C.; thionyl chloride ($SOCl_2$), colorless liquid, boiling point 78° C., fumes in moist air to yield **hydrochloric acid** and sulfurous acid, formed by reaction of sulfur trioxide and sulfur monochloride at about 80° C.; sulfuryl chloride (SO_2Cl_2), colorless, fuming liquid, boiling point 69° C., with water yields hydrochloric acid plus sulfuric acid, formed by reaction of chlorosulfuric acid heated with a catalyzer, e.g., **mercuric** sulfate; thiocarbonyl **chloride** ("thiophosgene," $CSCl_2$), red fuming liquid, boiling point

73° C., formed by reaction of carbon disulfide and chlorine followed by treatment with **stannous** chloride.

Fluorides: Sulfur hexafluoride (SF_6), colorless, odorless, tasteless gas, melting point −55° C., remarkably stable, unaffected by fused alkalis, formed by reaction of sulfur and **fluorine**; thionyl fluoride (SOF_2) and sulfuryl fluoride (SO_2F_2) are gases which react with water to give hydrofluoric acid in both cases plus sulfurous and sulfuric acids, respectively.

Hydride: Hydrogen sulfide (H_2S), colorless gas, odor of rotten eggs, poisonous, density 1.539 grams per liter, 0° C., 760 mm., or 1.190 when air equals 1.000, melting point −83° C., boiling point −60° C., not decomposed at 350° C., burns in air to form sulfur dioxide and water, preferred reagent in solution for the preparation of many metallic sulfides, e.g., copper sulfide. Made by action of dilute **hydrochloric** or sulfuric acid on a sulfide, such as **ferrous** sulfide or **calcium** sulfide, and used either as gas or solution. As a solution in water, see Hydrosulfuric acid, below.

Oxides: Sulfur dioxide (SO_2), colorless gas, sharp characteristic odor, density 2.9269 grams per liter, 0° C., 760 mm., or 2.264 when air equals 1.000, melting point −73° C., boiling point −10.0° C., critical temperature 157° C., critical pressure 78 atmospheres, very soluble in water forming sulfurous acid, formed by the burning in air of (1) sulfur, (2) sulfur-containing organic material, e.g., coal, protein, (3) sulfides, and (4) by the reaction of sulfites and an acid. Used (1) as a refrigerant,



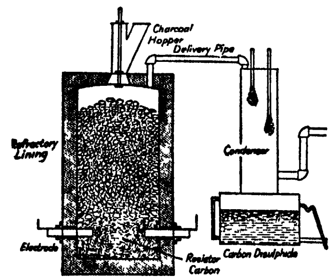
Sulfur burner.

(2) in the preparation of sulfur trioxide, sulfuric acid, sulfites, (3) as a disinfectant, (4) in bleaching; sulfur sesquioxide (S_2O_3), by dissolving sulfur in sulfur dioxide, or by reaction of sulfur trioxide and hydrazine; sulfur trioxide (SO_3), (1) alpha-sulfur trioxide, colorless liquid, boiling point 45° C., crystallizes to needle crystals of melting point 17° C., fumes in air, reacts with water vigorously, (2) beta-sulfur trioxide (probably S_2O_6), white solid, looks like asbestos, fumes in air, reacts with water somewhat less vigorously than the alpha form yielding sulfuric acid. Sulfur dioxide and oxygen of air react when heated in the presence of a catalyzer, e.g., platinized asbestos or vanadium pentoxide, to yield sulfur trioxide; sulfur heptoxide (S_2O_7), sublimes at 10° C., formed by the reaction of ozone and sulfur dioxide or trioxide, unstable; sulfur tetroxide (SO_4), solid, formed by the action of the silent electric discharge on sulfur dioxide plus oxygen, unstable.

Sulfides: Sulfides of many elements are known. Metallic sulfides are (1) soluble, e.g., **sodium, potassium, ammonium** sulfides (Na_2S, K_2S, $(NH_4)_2S$), (2) reactive with water, e.g., **calcium** sulfide (CaS) to form calcium hydrogen sulfide and calcium hydroxide, **aluminum** sulfide to form hydrogen sulfide and aluminum hydroxide, (3) insoluble, e.g., **silver** sulfide (Ag_2S) brown, **lead** sulfide (PbS) brown, **copper** sulfide (CuS) black, **ferrous** sulfide (FeS) black, **zinc** sulfide (ZnS) white, **arsenious** sulfide (As_2S_3) yellow, and (4) organic sulfides are noteworthy, e.g., methyl sulfide (dimethyl sulfide $(CH_3)_2S$), phenyl sulfide (diphenyl sulfide $(C_6H_5)_2S$), carbon disulfide (CS_2), carbonyl sulfide (COS).

Hydrosulfuric acid and soluble sulfides are important chemical reagents for the precipitation of insoluble sulfides, which are produced and separated from each other by means of their characteristic solubilities in various acids, and in excess sodium or ammonium sulfide.

Carbon disulfide is a colorless, odorous liquid, boiling point 46° C., inflammable, explosive when mixed with



Electric furnace for the manufacture of carbon disulfide.

air and ignited, and poisonous. Carbon disulfide dissolves sulfur, yellow phosphorus, iodine, bromine, chlorine, hydrocarbons, oils, fats. Made by reaction of carbon (coke) and sulfur in an electric furnace, and recovered by condensation of the vapor. Used (1) as a solvent, (2) as an insecticide, (3) in the manufacture of carbon tetrachloride.

Other compounds of sulfur are discussed as follows:

Benzothiophene. (See **Thiophene and Related Compounds.**)

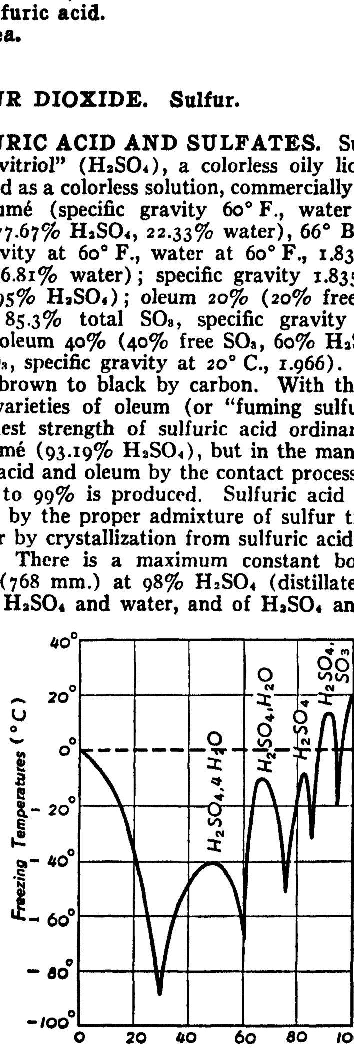
SULFUR DIOXIDE. **Sulfur.**

SULFURIC ACID AND SULFATES. Sulfuric acid, "oil of vitriol" (H_2SO_4), a colorless oily liquid, is encountered as a colorless solution, commercially of strength 60° Baumé (specific gravity 60° F., water at 60° F., 1.7059, 77.67% H_2SO_4, 22.33% water), 66° Baumé (specific gravity at 60° F., water at 60° F., 1.8354, 93.19% H_2SO_4, 6.81% water); specific gravity 1.835 (approximately 95% H_2SO_4); oleum 20% (20% free SO_3, 80% H_2SO_4, 85.3% total SO_3, specific gravity at 20° C., 1.927); oleum 40% (40% free SO_3, 60% H_2SO_4, 89.0% total SO_3, specific gravity at 20° C., 1.966). Sometimes colored brown to black by carbon. With the exception of the varieties of oleum (or "fuming sulfuric acid"), the highest strength of sulfuric acid ordinarily used is 66° Baumé (93.19% H_2SO_4), but in the manufacture of sulfuric acid and oleum by the contact process a strength of 98% to 99% is produced. Sulfuric acid 100% may be made by the proper admixture of sulfur trioxide and water, or by crystallization from sulfuric acid 98% upon cooling. There is a maximum constant boiling point 317° C. (768 mm.) at 98% H_2SO_4 (distillate) for mixtures of H_2SO_4 and water, and of H_2SO_4 and SO_3.



Freezing-point curve of system: sulfuric acid—water—sulfur trioxide. (*Mellor, Modern Inorganic Chemistry, Longmans, Green & Co.*)

The freezing point relations of water-sulfur trioxide mixtures is shown in the diagram. Sulfuric acid when mixed with water generates much heat. A commonly used strength for dilute sulfuric acid is 24.5 grams H_2SO_4 per 100 milliliters of solution (5 normal).

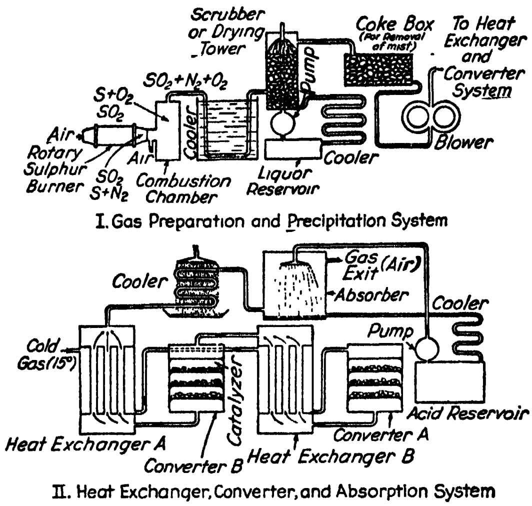
Dilute sulfuric acid reacts (1) with many hydroxides, e.g., **sodium** hydroxide, to yield two series of sulfates (the acid is dibasic), e.g., sodium sulfate or sodium hydrogen sulfate, depending upon the ratio of acid to base reacting, (2) with many ordinary oxides, e.g., **magnesium** oxide, to yield the corresponding sulfate, e.g., magnesium sulfate solution, (3) with some carbonates, e.g., **zinc** carbonate, to yield the corresponding sulfate, e.g., zinc sulfate solution plus **carbon dioxide** gas (calcium carbonate is soon coated by a layer of calcium sulfate, which prevents further reaction), (4) with some sulfides, e.g., **ferrous** sulfide, to yield the corresponding sulfate, e.g., ferrous sulfate plus hydrogen sulfide gas, (5) with many metals, e.g., zinc, if not too pure (but not copper), to yield the corresponding sulfate, e.g., zinc sulfate solution plus **hydrogen** gas, (6) with solutions of some salts to yield the corresponding sulfate, e.g., **barium** chloride, changed to barium sulfate precipitate, **calcium** citrate, malate, tartrate to calcium sulfate precipitate and the free organic acid in solution.

Higher strengths of sulfuric acid react similarly in kind to the cases of (1), (2), (3), (6) above, but not, in general, in the remaining cases. (4) Sulfides react to yield the corresponding sulfates, but accompanied by **sulfur**; (5) reactions of metals depend upon the metal and the strength of sulfuric acid. **Copper** and concentrated sulfuric acid yield copper sulfate and **sulfur** dioxide gas. Iron reacts similarly, yielding ferric sulfate in the place of copper sulfate. Concentrated sulfuric acid is (7) thus an oxidizing agent, and a further example is the oxidation of **sulfur** to sulfur dioxide (the reacting sulfuric acid is reduced to sulfur dioxide), (8) a sulfonating agent, e.g., **naphthalene** sulfonated to naphthalene sulfonic acids (mono- alpha or beta, di- several), (9) an esterification agent, e.g., methyl **alcohol esterified** to dimethyl sulfate ($(CH_3O)_2SO_2$), melting point −32° C., boiling point 189° C., or methyl hydrogen sulfate ($CH_3O \cdot SO_2OH$), ethyl alcohol esterified o diethyl sulfate ($(C_2H_5O)_2SO_2$), melting point −26° C., boiling point 208° C., or ethyl hydrogen sulfate ($C_2H_5O \cdot SO_2OH$), (10) a dehydration agent, e.g., **formic acid** into **carbon monoxide**, sugar blackened with separation of carbon, (11) an addition agent, e.g., ethylene into ethyl hydrogen sulfate, (12) a non-volatile acid upon heating, e.g., with **sodium** chloride or nitrate, **hydrogen chloride** or **nitric acid**, respectively, is volatilized and sodium sulfate or sodium hydrogen sulfate remains as a residue.

In order to obtain sulfuric acid, two sources of sulfur are available for conversion into sulfur dioxide, which is the first stage. These are (1) sulfur, (2) metallic sulfides, namely, **pyrite** (iron disulfide (FeS_2)), and **copper, lead, zinc** sulfides of smelter operations. In all these cases sulfur element is converted into sulfur dioxide gas by roasting in a current of air. In the second stage of the process sulfur dioxide is converted into sulfur trioxide by either of two methods, (1) "contact process," (2) "chamber process," both of which are catalytic. In the contact process sulfur dioxide, carefully purified, is mixed with air, and passed over a specially prepared **catalyzer.** The catalyzer commonly used is finely divided platinum (derived from platinum salts) on the surface of **asbestos, magnesium** sulfate, or **silica** gel, which act as porous, large surface supports. Vanadium pentoxide distributed on such a support as silica gel is also used. The third stage of the process involves the absorption of sulfur trioxide in water to form sulfuric acid. Experiment has demonstrated that the most satisfactory absorbent is 98% to 99% sulfuric acid. Acid of this strength is maintained in the absorber. When "oleum" is desired, water is not added.

In the chamber process, the above second and third stages are combined by introducing into large lead-lined chambers the required ratios of **sulfur** dioxide, water

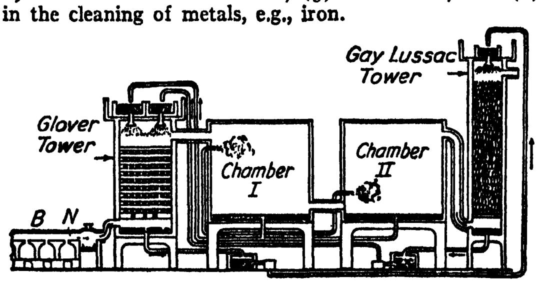
mist, and **nitrogen** oxides. Carefully designed towers are arranged (a) Glover tower, *before* the chambers, to introduce the nitrogen oxides previously dissolved in sul-



Sketch—Contact process for sulfuric acid (platinum catalyst).

furic acid ("Gay-Lussac acid"), and to cool the sulfur dioxide-air mixture from the burners, (b) Gay-Lussac tower, *after* the chambers, to recover the reduced and unused nitrogen oxides by dissolving them in sulfuric acid ("Glover acid"). An incidental stage in the chamber process is the concentration of "chamber acid" (62–70% H_2SO_4) by evaporation in acid-resistant pans, such as fused quartz, or by spray evaporation to the desired concentration.

The uses of sulfuric acid have been suggested by the chemical reactions previously cited, and the largest quantities are used (1) in the production of **explosives,** where it is used with nitric acid as "mixed acid," (2) in refining **petroleum** distillates, usually "oleum" used, (3) in the production of superphosphate **fertilizer** and phosphoric acid, ordinary "chamber acid" used, (4) of hydrochloric and nitric acids, (5) of sulfates, and (6) in the cleaning of metals, e.g., iron.



Chamber process for sulfuric acid.

All metallic sulfates, except **barium** sulfate, **strontium** sulfate, **lead** sulfate, **mercurous** sulfate, are soluble in water, but **calcium** sulfate and mercuric sulfate are only slightly soluble.

Metallic sulfates, upon heating, behave in an individually characteristic manner, e.g., sodium sulfate stable, sodium hydrogen sulfate into sodium pyrosulfate, barium sulfate stable, ferric sulfate into ferric oxide plus sulfur trioxide (an early method for obtaining sulfur trioxide).

Solutions of sulfates give a white precipitate, insoluble in hydrochloric acid, with barium chloride solutions. (R.K.S.)

SULFUROUS ACID AND SULFITES. Sulfurous acid (H_2SO_3) is a colorless solution formed when **sulfur** dioxide gas is dissolved in water, and the presence of sulfur dioxide imparts its own odor. Sulfur dioxide may be completely expelled from sulfurous acid solution by boiling.

As a bleaching agent, sulfurous acid is used for whitening wool, silk, feathers, sponge, straw, wood; as a bleaching and preservative agent for dried fruits, and decolorizes a solution of rosaniline (fuchsine, magenta).

Sulfurous acid is a strong reducing agent, being oxidized to **sulfuric acid** (1) on standing in contact with air, (2) by **chlorine, bromine, iodine** yielding **hydrochloric, hydrobromic, hydrioidic acids,** respectively, (3) by **nitric** or **nitrous acid** yielding nitric oxide, (4) by **permanganate.** Sulfurous acid is itself reduced by **zinc** and dilute sulfuric acid, to **hydrogen sulfide.** Sulfurous acid is formed (1) by dissolving sulfur dioxide gas in water, (2) in effect, by reaction of sulfite or bisulfite solution and an acid.

Sodium sulfite (Na_2SO_3) and sodium hydrogen sulfite ($NaHSO_3$) are formed by reaction of sulfurous acid and sodium hydroxide or carbonate in the proper proportions and concentrations. Sodium sulfite dry, upon heating, yields sodium sulfate and sodium sulfide. Sodium pyrosulfite, "sodium metabisulfite" ($Na_2S_2O_5$), is a common sulfite. Crystalline sulfites are obtained by warming the corresponding bisulfite solutions. **Calcium** hydrogen sulfite ($Ca(HSO_3)_2$) is an important substance used in conjunction with excess sulfurous acid in converting wood to paper pulp. Sodium sulfite and **silver** nitrate solutions react to yield silver sulfite, white precipitate, which upon boiling decomposes forming silver sulfide, brown precipitate. **Barium** sulfite is soluble (a white precipitate formed by the addition of barium chloride to sulfite solution containing hydrochloric acid is barium sulfate in consequence of the previous oxidation of sulfite).

As an esterification agent, sulfurous acid forms dimethyl sulfite ($(CH_3O)_2SO$), boiling point 126° C., and diethyl sulfite ($(C_2H_5O)_2SO$), boiling point 161° C. Sulfites give a white precipitate with barium chloride, soluble in hydrochloric acid with evolution of sulfur dioxide. Sulfites decolorize iodine in acid solution. (R.K.S.)

SUMMER EGG. A form of egg produced by some species of **crustaceans,** usually during the summer. These eggs have thin shells and are parthenogenetic (i.e., they develop without being fertilized), in contrast with the eggs of biparental generations. The significance of such specialization in the reproductive processes is considered under **parthenogenesis.** (A.W.L.)

SUMNER LINE. The Sumner line is a **line of position** obtained from the observation of altitude of some celestial object. This method for obtaining a line of position was discovered by Captain Thomas H. Sumner in 1837, and circumstances leading to the discovery are described in the American Practical Navigator, Bowditch, H.O. publication number 9.

The method employed by Sumner for obtaining a celestial line of position was standard procedure for American ship masters until the early part of the 20th century. For this reason it is worthy of consideration here, in spite of the fact that it has been almost completely superseded by the methods described in the article on **celestial navigation.** Captain Sumner used the old-fashioned method for determining **latitude** and **longitude** at sea from an observation of the altitude of a celestial object. These methods require the solution of the astronomical triangle. To solve this triangle at least three parts must be known. At sea, the altitude of the object, as obtained from **sextant** observations, will give one part, and the declination of the object will give another. To obtain the third part, either the latitude or the longitude of the observer must be known. Since latitude and longitude are the coordinates for which the navigator is seeking, it would seem at first

glance that a solution of the problem is impossible. However, if the object observed is approximately due east or west, a change in latitude of several miles will produce but slight effect on the computed longitude. On the other hand, if the object is nearly due north or south, a change in longitude will produce but slight effect in the computed latitude. An approximate value of latitude and longitude can be obtained by methods of **dead reckoning** (DR). If the observed object is within 45° of east or west, the DR latitude is used and the longitude is computed. When the object is within 45° of the meridian, the DR longitude is used in the computation of the latitude. If the DR position is known to within 20 miles, the computed latitude or longitude will be accurate to within ¼ of a mile, unless the observed object is close to the **zenith.**

In Captain Sumner's case, his ship had experienced gales and fog for a number of days, and the DR position was very uncertain. When the clouds broke away, he obtained an altitude of the sun in the forenoon. Since his DR position was uncertain, he assumed several values for latitude separated by about 20 miles, and computed the corresponding longitudes. On plotting these positions he found that they lay along a straight line on a **mercator chart.** He made the assumption, which has since been established as sound, that his ship must be on the line.

After the publication of this discovery, the use of Sumner lines became the standard procedure for most navigators. If two objects, differing in bearing by at least 45°, are available for observation, two Sumner lines can be obtained and a **fix** determined. If, as is frequently the case during daylight hours, only one object is available, this one object is observed twice with an interval of time between the two observations sufficient to produce a change in **bearing** of at least 45°. The fix of these two lines is obtained by moving one line to the time of the other by the method of running fix.

A Sumner line is, in reality, a small circle on the earth, with a point on the earth directly under the observed object as center. Unless the object is within 10° of the zenith, the curvature is so slight as to be negligible in drawing the line on a mercator chart. (W.K.G.)

SUN. The sun is without question the most important of all of the celestial objects, not only to the earth, but also to all other members of the **solar system.** Whatever life exists on the earth, or elsewhere in the solar system, is absolutely dependent upon the **radiation** from the sun for its existence. All forms of energy which we employ on the earth come from the sun, either by its present radiations, as in the case of water power or wind power, or from its radiations in the past, as in the case of coal or oil. Even the **tidal energy,** which comes principally from the moon, is influenced to a considerable extent by the position of the sun relative to the moon. From the purely scientific point of view, the sun is of tremendous importance to the astronomer, since it is a typical **dwarf** star of the G_0 **spectral class,** and is close enough to the earth to permit of careful analysis.

Somewhat detailed descriptions of the different portions of the sun and its surrounding atmosphere will be found in articles on the **photosphere,** the **reversing layer, chromosphere, corona, prominences,** and **sun spots.** The mean distance of the sun, as determined from many measurements of **solar parallax,** is 149,680,000 kilometers, or 93,005,000 miles. The mean diameter is 1,393,700 kilometers, or 866,000 miles; about 109.1 times the diameter of the earth. Since volume is proportional to the cube of the diameter, we find that the volume of the sun is 1,300,000 times that of the earth. In order to get some concept of these sizes and distances consider the sun as a globe 2′ in diameter; the earth on this same scale would be a sphere only 0.22″ in diameter, and would be distant from the sun 215′. On this same scale the nearest **star** would be 11,000 miles away! The mass of the sun may be determined from the gravitational attraction which it exerts upon the earth and is found to be 331,950 times that of the earth, or 1.982×10^{33} grams (or 2×10^{27} tons). From the mass and the volume the mean density of the sun is found to be about ¼ that of the earth, or 1.4 times that of water. The gravitational force on the surface of the photosphere is 27.6 times that on the earth, which is equivalent to saying that a person weighing 100 lbs. on the earth would weigh nearly 1½ tons on the sun.

From a large number of observations of sun spots and also by spectroscopic observations the rotation period of the sun has been found to be different at different distances from the sun's equator. At the equator the sidereal period of rotation is about 24.65 days; in latitude 30°, 25.85 days; in latitude 60°, 30.93 days; and at the poles about 34 days. Such a varying rotation period indicates certainly that the sun is not a solid, but there is no adequate explanation for the differing rotation periods, even for a gaseous object. The sun's equator is inclined to the plane of the ecliptic by 7° 10′.5.

Observations of the **continuous spectrum** from the sun and the application of the **laws of radiation** indicate that the effective temperature of the surface of the sun is about 5750° K. From the value of the **solar constant** we calculate the rate of radiation from the surface of the sun as 89,500 **calories** per sq. cm. per min.; equivalent to about 84,000 hp. per sq. meter. Residents of northern climates will appreciate this amount of energy better when they realize that it would melt a sheet of ice 40′ thick in about 1 minute! The problem as to the source of this tremendous amount of energy is a vexing one, as is the whole problem of radiation from the stars. (W.K.G.)

SUN BITTERN. Aves, Gruiformes. A South American bird (**Aves**), *Europyga helias,* cf moderate size, related to the cranes. (A.W.L.)

SUN COMPASS. The sun compass is a device utilizing the direction of the sun for direction or orientation purposes. The instrument operates on much the same principle as that of the **sun dial.** In the sun dial the gnomon for casting the shadow is set accurately parallel to the earth's axis of rotation and the direction of the shadow indicates local apparent **time.** In the sun compass the dial is set for local apparent time and the direction of the shadow is used in connection with a **compass card.** The instrument is quite complicated, for it must be set for terrestrial **latitude, longitude,** and local apparent time. It has been of great service in connection with flights in the polar regions of the earth, where the weakness and uncertainty of the horizontal component of the earth's magnetic fie'd render the use of the magnetic **compass** very dangerous. (W.K.G.)

SUN DIAL. It is logical to suppose that from the earliest times mankind has used the apparently moving sun as a means for reckoning time. As the sun apparently moves across the heavens during the day the position and length of the shadow cast by an opaque rod will continually change. The positions or lengths of this shadow may be used for the purpose of subdividing the period between sunrise and sunset. Any device which utilizes the shadow cast by the sun for the purpose of subdividing the day into equal parts is known as a sun dial.

It is difficult to say just when the first sun dial was constructed. The earliest written record that we have is found in Isaiah XXXVIII:8, which was written

approximately 700 years before the Christian era. The earliest instrument which has come down to us is a device which was built in Egypt but for which the exact date of construction is unknown. The first dial was constructed for Rome in about 146 B.C. Sun dials came into general use during the 13th century, and the development of the different types advanced rapidly following this period. By the time that mechanical clocks and watches made their appearance in the 15th century a multitude of different types of sun dials had been constructed and many volumes written regarding the theory of the various devices.

There are two fundamental types of sun dials. The most common type of fixed dial is that which marks the divisions of the day by the direction which the shadow of the sun has at any particular instant. The dial itself may be set at any desired angle, but the most common is the type in which the plate is horizontal and the style, which casts the shadow, is so placed as to be parallel to the axis of rotation of the earth. The second fundamental type of dial makes use of the fact that the length of the shadow of the sun varies throughout the day, being the shortest at noon and the longest at sunrise and sunset. Practically all portable sun dials are of this type. The great difficulty with this type of dial is that, because of the change in **declination** of the sun with **season**, it is necessary to have different scales of time for different periods of the year.

It is impossible in a work of this character to discuss the multitude of ingenious and beautiful types of sun dials that have been used in the past for the purpose of keeping time and are in use at present as ornaments or items of curiosity. In adjusting the horizontal type of sun dial, such as may be purchased from a number of dealers in garden supplies or curios, it is important to remember that the style should be parallel to the axis of the earth. That is, it should lie exactly in the true north-south plane, and the north end should be so elevated that the angle which the style makes with the horizontal plate is equal to the latitude of the observer. When properly adjusted the sun dial will read local apparent time. This time will differ from that ordinarily kept by watches both by the **longitude** difference between the position of the dial and the **standard time meridian** and also by the **equation of time**. (W.K.G.)

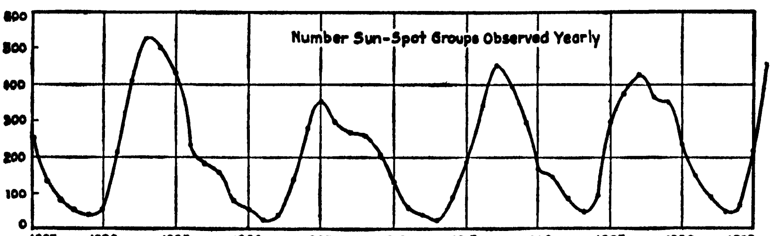
SUN SPIDER. Solpugida.

SUN SPOTS. As the term implies, sun spots are spots on the surface of the sun which make their appearance on the **photosphere**. There is no record of when these phenomena were first observed. Frequently, they are so large as to be seen with the unaided eye when the brilliancy of the sun is cut down either by thin clouds or by darkened glass. There are Chinese records of sun spots long prior to the early part of the seventeenth century, when Galileo first observed them through his telescope.

In the first place, it must be clearly understood that sun spots are not really dark. They are merely darker than the surrounding regions of the photosphere, and, if the brilliant photosphere were not present, the sun spots themselves would appear intensely brilliant. A typical sun spot has a dark irregularly shaped central portion known as the umbra, surrounded by a lighter region known as the penumbra. Because of the distance of the sun, the smallest sun spots which can be studied must be at least 150 miles in diameter. Spots with diameters of 40,000 to 50,000 miles are quite common, and instances have been recorded where a number of spots were so close together that the penumbra blended into one area nearly 150,000 miles across.

Sun spots are usually relatively short-lived. About a quarter of them last but a single day, and as many again from 2–4 days. In a few cases large spots have persisted for over a month, the longest case on record being a large group of spots which lasted for nearly 18 months.

Sun spots confine themselves almost exclusively to the solar latitude zones between 5° and 40° north and south of the solar equator. The total number of spots on the surface of the sun varies, with a somewhat regular periodicity of approximately 11 years. The accompanying figure shows the total number of spots observed during each single year from 1885 to 1936. It will be noted that the shape of the curve and the interval between maxima and minima is not the same for each cycle. Along with the variation in number of sun spots there goes a shift in the average location of the spots. At the beginning of a cycle the spots are located at the outer regions of the latitude zones, i.e., between 30° and 40° solar latitude. As the number increases the maximum number of spots is located in about 16° latitude, and by the end of the cycle the spots are about 5° from the solar equator. The beginning of the new cycle is heralded by the appearance of a few spots at considerable distance out from the equator.



The sun-spot number cycle. The point for each year represents the number of sun-spot groups observed during that year. The curve shows the roughly periodic variation in the numbers. (*From data by S. B. Nicholson.*)

Many attempts have been made during the last two centuries to correlate terrestrial phenomena with the number of spots on the surface of the sun. The correlation between sun-spot number and electromagnetic phenomena on the earth is positive, and we find that at times of sun-spot maximum magnetic storms, with the accompanying shifts in compass variation, and interference with radio and telegraphic communication, are most prevalent. Maximum and minimum auroral displays follow slightly after times of maximum and minimum sun spots. The correlation between solar disturbances and weather conditions on the earth is both weak and puzzling. It has been shown that the solar constant varies with sun-spot number, being a maximum when the number of spots is greatest. However, there is definite evidence that the temperature of the air at the earth's surface is lower at the times of sun-spot maximum. Studies of the width of tree rings, made by Douglass in Arizona, indicate direct correlation between the periods of wide rings and the sun-spot periodicity.

Sun spots are observed to have a distinctly whirling character, not unlike cyclonic storms in the atmosphere of the earth. They are distinctly **magnetic** in character, spots in which the whirling motion is in one direc-

tion, all having one magnetic polarity, while spots whirling in the opposite direction will have the opposite magnetic polarity. When two spots are observed relatively close together, as is frequently the case, the two are whirling in opposite directions, and hence have opposite magnetic polarity.

It is believed that sun spots are caused by a whirling mass of gas just below the surface of the photosphere. Hot gases are brought up until they break through the photosphere, where the sudden reduction in pressure causes them to cool and spread out over the surface, causing a relative darkening. The influence of spots is felt clear out through the atmosphere of the sun, for at the time of sun-spot maximum there is also a maximum number of **prominences**. The shape of the solar **corona** is also influenced by the number of spots on the surface of the sun. In spite of the tremendous amount of attention that sun spots have received, there is no adequate explanation as to their origin. (W.K.G.)

SUN STROKE. HEAT STROKE. This condition is due to exposure to high temperatures which overwhelm the heat-regulating mechanism of the brain. The onset may be sudden, with immediate loss of consciousness, or this event may be preceded by headache, nausea, dizziness, and visual disturbances. The face is flushed, the skin hot and dry. The temperature in severe cases can rise to 109° F. Rapid feeble pulse and shallow respirations precede death. The latter may occur within a few minutes after onset of symptoms, but if the patient survives 48 hours, recovery is probable. The milder degrees of reaction to intense heat are classified as heat cramps, due to loss of **sodium** chloride in perspiration, and heat exhaustion. In heat exhaustion there are pallor, weakness, dizziness, profuse perspiration, slight elevation of temperature, but rarely loss of consciousness.

Heat cramps are prevented by the ingestion of extra sodium chloride during hot weather. The treatment of heat exhaustion requires only rest in a cool place and perhaps mild stimulants. Heat stroke is an emergency which demands prompt treatment. Cold baths, cold enemas, ice packs, and stimulants are used. (D.M.H.)

SUNDEWS. *Drosera* species. **Insectivorous Plants.**

SUNFISH. Pisces, Teleostei. A name of varied uses, applied to fresh-water and marine fishes (**Pisces**) of three distinct forms and many species, all superficially similar in the short, high, and compressed body. One species, *Lampris luna,* is found in the Mediterranean and the northern Atlantic. It attains a length of 4′ and is bluish with silver spots and red fins. Another group of several species related to the globe fishes is characterized by the very short truncated tail and by the enormous size that they attain. One species is known to reach a weight of 500 lbs. These giant sunfishes are widely distributed in temperate and tropical seas.

In marked contrast the familiar fresh-water sunfishes of North America are among the small pan fish related to the basses. They reach a maximum length of 5–10″. The common sunfish or **pumpkin-seed** reaches about 8″. The various species are found in streams and ponds, especially the latter, and rank as superior food fish and fair game fish. They take dry or wet flies and on light tackle are a valuable supplement to the larger bass in the waters of heavily settled areas. (A.W.L.)

SUNFLOWER. *Helianthus annuus.* **Composite Family.**

SUNSTONE. Feldspar.

SUNU. Mammalia, Artiodactyla. *Nesotragus.* A large African **antelope** related to the sing-sing. The species is black with white rings around the eyes and white under parts and ears. The horns are long and thin. (A.W.L.)

SUPERCHARGER. The performance of an internal combustion engine is indicated, among other things, by the brake hp. output. A review of the factors affecting power indicates that atmospheric conditions have a significant effect. (See **Engine Performance.**) A naturally aspirated (unsupercharged) engine is able to draw into the cylinders on suction strokes only from 70–85% of the fuel charge which it is theoretically capable of inducing (see **Volumetric Efficiency**). Consequently, the mean effective pressures are not as large as they might be, and power output per cu. in. of piston displacement does not reach its maximum possible value. Compression of the incoming air, or air-fuel mixture, somewhat above ambient pressure is a natural way of increasing output at sea level or of regaining it at altitudes. A compressor used for this purpose is designated a *supercharger.*

The reader should be cognizant of the fact that raising the sea-level power of an existing engine by adding a supercharger is not ordinarily feasible, as the original design may be insufficient to withstand the increased structural stresses created by higher cylinder pressures. However, supercharging for the purpose of regaining sea-level rating at higher altitudes may be readily added provided the supercharger is not used at sea level and is employed only to offset the effect of altitude. Thus it is seen that supercharging falls into two categories: (1) supercharging that contemplates increasing capacity per cu. in. of piston displacement under approximately constant atmospheric conditions; and (2) supercharging that will keep power of an engine up near its rated output at high altitudes. The first category is sometimes termed "ground boosting," and the second "altitude supercharging." The latter predominates in the aeronautical field. The former will be found occasionally in stationary, marine, and surface-vehicle usage of engines and in the two-cycle aircraft engine.

Either centrifugal compressors (see **Air Compressor**) or positive displacement blowers can be used to supercharge. For ground boosting the latter are excellent, since boost varies linearly with speed, and so cylinder pressures and shaft torque hold up well under slow-speed operation, whereas the pressure boost given by a centrifugal compressor varies as the square of the speed and drops off rapidly as speed is cut. On the other hand, the displacement type suffers from excess bulk and weight compared to the centrifugal—a fact not likely to recommend it to the aeronautical field.

Sea-level gasoline engines are not often supercharged because they are most frequently found in small capacities where, by relatively high rotative speeds, engine size may be kept small. Furthermore, unless special high-octane fuels are used, supercharging may create detonation troubles. Diesels, however, are frequently supercharged, thus allowing the burning of larger amounts of fuel without creating excessive combustion-chamber temperatures. The higher mean effective pressures, coupled with the use of two-cycle principle of operation, has done much to remove from the Diesel the stigma of excessive weight and bulk. Displacement blowers used in this field have been of the lobe and eccentric-vane types. These are often driven from the crankshaft by means of V-belts. The Buchi supercharge system uses a centrifugal compressor driven by an exhaust gas turbine.

High-altitude flights in airplanes would have been impossible without supercharging of the engine. Beginning at the time of World War I, research and experiment in airplane-engine supercharging has made great strides and accomplished remarkable results The tactical advantage attained by the use of military aircraft with superior flight ceilings, and airplane critical alti-

tudes, has provided the greatest stimulus for development in this field, since comparatively simple supercharging (or none at all) will fulfill most civil aviation needs.

Airplane-engine superchargers are, universally, high-speed centrifugal types because of the emphasis on minimum size and weight. The principal types are (1) the internal gear-driven type, receiving its drive from the crankshaft, and (2) the external exhaust gas turbine-driven type. Since supercharging may be obtained by staging the over-all compression as well as by single stage, and as different gear ratios to drive the same impeller are sometimes employed, many different combinations of equipment are possible. The variations mainly represent individual ideas of how to obtain maximum power at altitudes without sacrificing too much power driving surplus compressor capacity at sea level. Three

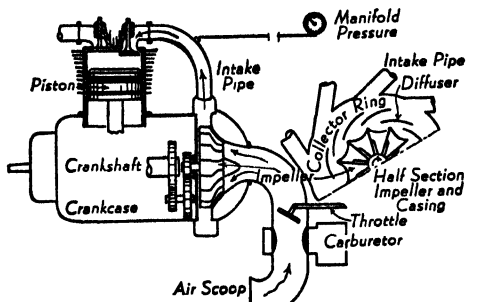


Fig. 1. Single stage supercharger. Diagram emphasizes induction system.

of the many systems developed are shown in Fig. 2, while Fig. 1 shows the standard simple single-stage, single-speed, internal gear-driven supercharger.

The standard gear-driven supercharger is an integral part of large-capacity engines. As Fig. 1 shows, the carburetor is located on the suction side of the impeller, so a combustible mixture is being compressed. The duralumin impeller is geared up to make from 10 to 15 thousand rpm, and is capable of boosting atmospheric pressure approximately 1 atmosphere. It would not be permitted to accomplish this at sea level as the cylinder explosion pressures would be too high; also, **detonation** would probably occur. By throttling the intake at the **carburetor**, the cylinder pressures can be kept within safe limits. This is gauged, by the pilot, by the ***manifold pressure;*** that is, the mixture pressure just before it enters the cylinder. As an airplane climbs (engine rpm constant), it is necessary to open the throttle gradually in order to keep manifold pressure constant. When the throttle is full open a *critical altitude* is reached, and further gain in altitude will be attended by decrease of output since there is no more supercharger reserve left. All this is diagrammed for engine A in the graph, Fig. 2.

In the effort to reduce the required low-altitude supercharger drive power and at the same time increase the power available at high altitudes, additions are made to the standard system, three of which appear in Fig. 2. They are: (B) single-stage, two-speed, (C) two-stage, two-speed, and (D) two-stage with exhaust gas turbine driving the auxiliary stage.

In system B, a gear-shifting mechanism is incorporated which makes possible a low and high gear ratio. Although it adds but little extra weight or complexity to the installation, it produces an increase in power at medium altitudes (not much gained at extreme altitudes). Also, the low blower ratio is not as wasteful of power near sea level. Its application is limited because of low compression efficiency and high manifold temperatures (detonation), which are produced where extra high gear ratio is attempted. The attached graph shows that take-off is with low blower ratio engaged. After reaching critical altitude, some more altitude is gained before changing to high blower.

The two-stage, two-speed supercharger has a main stage like that of engine A, although usually with smaller ratio, thus giving lower main stage critical altitude. An auxiliary stage, also engine-driven, has an impeller whose speed is made selective by a gear-shifting mechanism, incorporating clutches. The auxiliary stage, therefore, adds a low-blower and high-blower ratio to the main

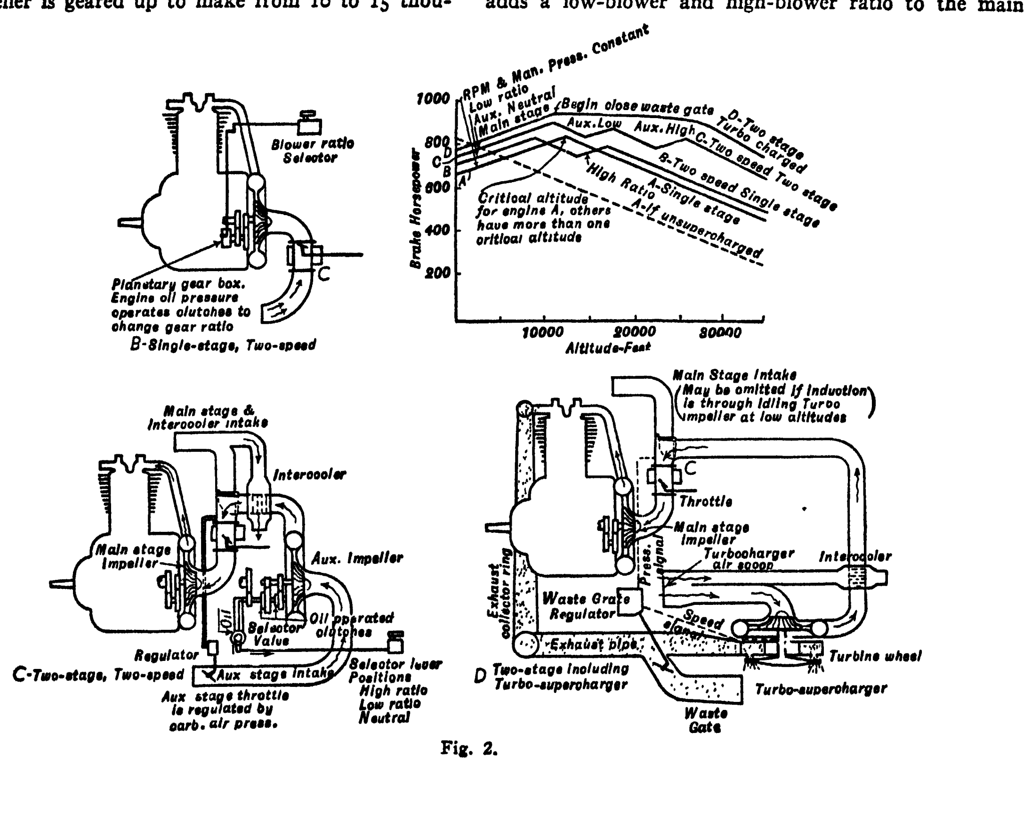

Fig. 2.

stage supercharge. This system is superior to a single-stage high-ratio supercharger for high altitudes, for the auxiliary stage may remain idle (neutral position) until the supercharge of the main stage is completely developed. Furthermore, an intercooler is included between the two stages which not only improves compression performance, but opposes detonation, since otherwise the adiabatic temperature rise of both stages in series would be very great at high altitudes.

Advantages of this extra complication are shown in the C curve of power output. Disadvantages are cost, weight, and complication of the extra stage, the ducts, and the intercooler, as well as the added drag of the larger air scoop area.

The exhaust gas turbo-supercharger consists of a single-stage turbine wheel directly connected to the compressor impeller. The engine exhaust is collected and led to a nozzle box where it arrives at a pressure of several lbs. per sq. in. gauge. Pressure ratio across the nozzles of the supercharger varies with altitude, but is typically 1.5 to 2.5. However, this can be controlled by releasing part of the exhaust to the atmosphere through a waste gate. The turbine speed and air-pressure boost can be controlled in this manner. Advantages of this method of supercharging are: (1) partial use of the energy in the incompletely expanded exhaust gases; (2) more latitude in arrangement of the auxiliary stage in an airframe (gear-driven stages must be *on* or *in* the engine); (3) turbine tends to run faster and give compensating supercharge as altitude is increased because atmospheric pressure decreases more rapidly than exhaust manifold pressure; (4) the power output is maintained up to much higher altitudes than for other types. Disadvantages are: (1) weight and complication of extra ducts, intercooler, controls, etc.; (2) some loss of power at low altitude when waste gate is open, probably caused by induction pressure drop through turbo-charger impeller and intercooler (avoidable by use of extra air scoop for main stage); (3) structural conditions imposed on turbine wheel are severe, viz., high centrifugal stresses contemporary with high temperature; (4) higher back pressure is created on cylinder exhaust than would otherwise exist.

Fig. 2-D diagrams a turbo-supercharger installation. Here it becomes the auxiliary stage; in some engines, especially in-line types, it may be the main stage. Exhaust gas from the collector ring flows to the nozzle box, some of it being diverted through the partly open waste gate. Gas expanding through the nozzles to atmospheric pressure flows across the blades, turning the turbine wheel at high speed. The direct-connected impeller draws in air from the intake duct, where it may have some ram, and adiabatically boosts it in pressure and temperature. Passing through the intercooler the temperature is lowered, after which fuel is added at the carburetor and the mixture given its second stage of compression by the gear-driven impeller. Waste-gate position is controlled by two signals, one derived from carburetor air pressure, one from turbine shaft speed. The latter includes both speed anti-surge and maximum safe-speed components. The power output curve shows that as the main stage reaches critical altitude, the turbo-supercharger is brought into play (by waste-gate closure) and maintains the power nearly constant until altitudes are reached where a combination of factors, chiefly attainment of maximum allowable turbine speed and loss of compression efficiency, create a normal type of altitude power loss.

The power necessary to drive a supercharger is considerable but, of course, it is more than repaid by increased engine output. The power required to operate the supercharger of a single-stage type is a function of the pressure ratio, the air temperature, the thermal efficiency, and the compressor efficiency.

Let

P = Net engine brake hp.
W = Air-fuel ratio.
f = Specific fuel consumption, lbs. per brake hp. hour.
e = Adiabatic compression efficiency. 65–75% for the centrifugal supercharger.
T = Air temperature at supercharger inlet.
R = Pressure ratio ($R > 1$).

$$\text{Supercharger horsepower} = \frac{PfWT}{10{,}000e}\,[R^{.186} - 1].$$

Consider the power required to drive the supercharger of an engine having a critical altitude of 8000′. R is theoretically 1.35, T is 490° R. For $f = .6$, $W = 16$, $e = .65$, the equation above shows that the supercharger would consume about 6% of the output. ((F.T.M.)

SUPERCONDUCTIVITY. An abnormally high electrical **conductivity** appearing quite abruptly in certain metals when cooled through a very low, characteristic transition temperature. In 1911 Onnes, at Leyden, found that a column of frozen mercury with which he was experimenting, and which had a resistance of 0.084 ohm at 4.3° K., acquired a vanishingly small resistance (less than 0.000003 ohm) when cooled to 3° K. The resistance was measured by the potential drop while carrying a known current. The more familiar metals exhibiting this property are magnesium, zinc, cadmium, mercury, aluminum, tin (tetragonal only), and lead. Alloys of these metals also show the effect, as do some alloys of metals not mentioned; e.g., the alloy composed of two parts of gold and one of bismuth; also some compounds, as lead sulfide and tungsten carbide (though neither tungsten nor carbon is superconductive). The transition points are always within a very few degrees of absolute zero. For columbium it is 9.2° K., for columbium carbide, 10.1° K.; for magnesium it is only 0.7° K. The transition is sharper for metallic monocrystals than for microcrystalline masses.

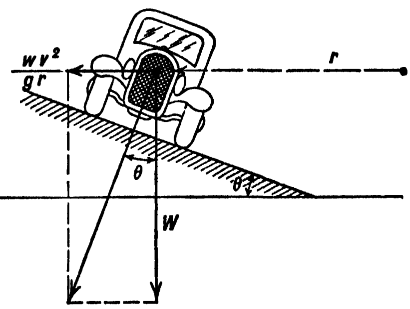
One of the most remarkable aspects of the phenomenon, discovered by Onnes and Tuyn, is the apparent "perpetual motion" of a current in a superconducting circuit, such as a lead ring immersed in liquid helium. The current may be started inductively by cooling the metal in a magnetic field and then withdrawing the field, whereupon the current continues to flow indefinitely. If two points on such a ring are connected to a galvanometer and the ring parted between these points while it is thus conducting, the current stops, but not until it causes a throw in the galvanometer. The superconductive state may be removed, not only by heating but by applying a magnetic field of above a certain threshold intensity, or by using too strong a current. Another curious phase may be described as the almost perfect diamagnetism of metals when superconductive, the magnetic **permeability** being reduced practically to zero. These phenomena are not explained on any simple theory. There is no evidence of any structural change, and the relations observed between superconductivity and thermal conductivity, specific heat, etc., at low temperatures do not throw much light on the question. (L.D.W.)

SUPERCONTROL TUBE. **Variable Mu Tube.**

SUPERCOOLED LIQUID. **Supersaturated Vapor.**

SUPERCOOLED LIQUID IN THE ATMOSPHERE. Drops of rain and cloud droplets often are cooled to temperatures well below 32° F. and remain in liquid form. They are then said to be supercooled. If such drops and droplets are disturbed, they freeze almost instantly, partially or entirely, depending on their temperature and size. Passage of aircraft through supercooled drops and droplets in the atmosphere results in rapid and severe icing. (P.E.K.)

SUPERELEVATION. When the plane of a roadway is tilted on a curve (commonly known as banked), it is said to be superelevated. The purpose of superelevation is to permit a vehicle to round a curve on a roadway at high speed without danger of overturning or skidding. The superelevation can be made so that the resultant of dead weight and centrifugal force passes through the vertical plane of symmetry of the vehicle. In this condition, no side sway would be felt by the occupants. However, the superelevation necessary to accomplish this is different for each vehicle speed, so that it is apparent that the superelevation of a highway presupposes an average vehicle speed. The same is true of railways, although the variation of speeds with which the trains round curves is less than in the case of highway traffic.



To illustrate how the superelevation depends upon vehicle speed, let it be assumed that an automobile approaches a curve on a highway at a speed of V (ft. per sec.). If the radius of the turn is r, the centrifugal acceleration is $\frac{V^2}{r}$. Furthermore, assume that the weight is W pounds. While negotiating the curve, the car is subject to two forces, one, the weight vertically downward, the other, centrifugal force acting horizontally away from the center of curvature, and having a magnitude $\frac{WV^2}{gr}$. The surface of the road must be perpendicular to the resultant for no "side sway." If superelevation is given as the angle of bank (see figure), the angle of superelevation θ has a tangent equal to centrifugal force divided by weight. This tangent is $\frac{V^2}{gr}$, demonstrating that the superelevation must be made with respect to the radius of curvature and the velocity of the vehicle. It is independent of the dimensions and weight of the vehicle. (F.T.M.)

SUPERFICIAL VELOCITY. Gas Absorption.

SUPERFINISHING. An abrasive process for removing smear metal, scratches and ridges produced by machining and grinding operations, and other surface irregularities, from parts that are to have a highly finished surface. The process resembles lapping in that a lubricated abrasive stone is applied to the surface at comparatively low speeds and light pressures. A superfinishing head whose base is attached to the cross-slide of an engine lathe may be used. The base supports two vertical cylindrical guides on which the head proper may be manually adjusted to the work by the hand lever shown. The abrasive stone is carried in a vertical slide which is subjected to the action of a spring for applying pressure to the stone. The stone pressure may be regulated to suit the requirements of the work by turning the screw at the top of the slideway.

In operation, the work rotates between centers at a surface speed of about 30 ft. per min. for roughing to from 70 to 100 ft. per min. for finishing operations. The stone is moved axially along the surface of the work by using the coarsest feed of the lathe carriage. As the carriage feeds, the stone is subjected to short, frequent, axial oscillations by the motor at the rear of the superfinishing head. For average work, a spring pressure of from 12 to 20 lbs. per sq. in. is employed, using kerosene as a lubricant. The cutting action cycle is as follows: when the stone is first applied to the work, it comes in contact with the peaks of the minute serrations with a high unit pressure because of the small area of contact, causing the abrasive to tear out comparatively large metal particles and effecting a comparatively large loss of abrasive particles. These particles are immediately washed away by the lubricant. This tearing tendency is rapidly reduced as the serrations wear flat, and the metal particles finally become so small that they immediately oxidize and begin to fill the pores of the stone. This metallic oxide is in itself a polishing agent and contributes to the finishing action. When the combination of improvement in surface condition of the work and the dulling and glazing of the stone face have reached a certain point, the decrease in unit pressure allows the lubricant to prevent further contact between the stone and the work. The surfaces in contact have such a comparatively large area, and consequently such a low unit pressure, that the lubricant is drawn between the surfaces and forms an oil film as in perfectly lubricated bearings. For repetitive work the process therefore ceases at the same point in each cycle, and surfaces of like degrees of finish are obtained on duplicate parts. After a superfinished part is removed and an unfinished part is substituted, the stone is automatically dressed sharp by its application to the peaks of the serrations on the new part and the cycle is repeated. (H.C.H.)

SUPERHEAT. Superheat is the addition of heat to produce **vapor** at a higher temperature than saturation. Superheat is possible when the vapor is led away from the liquid from which it was boiled. For this reason, superheaters are installed in **boilers** so that the final product may be elevated in temperature from 50 to 200 or 300° F. above the saturation temperature. The temperature added is called the degree of superheat, and the equipment to superheat is known as a superheater.

The effectiveness with which water vapor may be employed as a working medium in a power cycle is enhanced by superheating it. The less erosive character of dry steam and the lower heat losses from pipes carrying dry steam, have made superheating very desirable, so that many boilers are equipped with **superheaters** at present. (F.T.M.)

SUPERHEATER, STEAM. The superheater is heat-transfer surface, tubular in character, arranged to receive saturated steam at the inlet of the tubes and deliver superheated steam steadily at the outlet. Heat is received from combustion of fuels by direct radiation to the surface of the superheater tubes, by convection of hot furnace gases made to flow over the tube surfaces, or both. Superheater tubes are made small in diameter to promote maximum contact of the steam with the hot tube wall. Usually the superheater is placed within the boiler setting and thus uses heat from the boiler furnace, but separately set and fired superheaters have occasionally been employed.

Superheaters may be classified as *convection* or *radiant* types; also as *interdeck,* which is primarily convective, but receives considerable radiant energy as it is screened from the furnace by only a few rows of tubes. Both types are usually constructed of small smooth tubes in single or multiple hairpin loop, with sufficient loops in parallel between headers to pass the required quantity of steam.

On account of the alloy steels employed in their construction, and because of the low coefficient of heat transfer to dry vapor, superheating surface tends to become expensive. By using higher temperature differences, surface can be saved, but at the risk of encountering

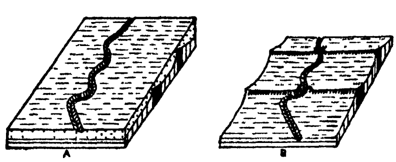
slagging difficulties, whereas conservatively low temperature differences not only yield expensively larger superheaters, but also incur the difficulty of disposing of them and supporting them. The convection-type superheater has a rising superheat characteristic while the radiant type has just the reverse. At higher ratings the furnace gas is at higher temperatures, but that does not affect the energy level of the combustion quanta, which are the source of heat for the radiant superheater. Therefore an increased flow through the radiant superheater will have less superheat per pound. But the heat supply to the convection superheater is actually increased, and increased more rapidly than the steam flow, hence there is more superheat per pound.

Since the maximum steam temperatures now employed are close to the working limit of metals employed, close control over the superheat is essential in the steam generator of advanced design. This is true not only of the superheater itself, but also for the turbine. Superheat may be controlled in a number of ways, of which the following are the more important:

1. Follow the superheater with a water-spray desuperheater operated by a temperature regulator.
2. Gas by-passing. This method is employed for regulating convection superheaters. It is necessary to employ an oversize superheater, one which will give the required superheat at the lowest specified load. At higher loads the by-pass is opened, allowing some of the gas to flow around rather than over the superheater. Although the gas passing the superheater is hotter, its volume is less, hence the compensation.
3. Combine convection and radiant types in series or place an interdeck type so as to receive the proper proportions of radiant and convection energy. Neither of these methods is adequate to maintain uniform temperature over a load range, but the variation will be substantially less than for either type alone. May be combined with gas by-passing.
4. Other methods employing a combination of radiant and convection superheaters with twin furnaces which may be differentially fired are said to have given excellent results over a wide range of superheat control.
5. By-pass a varying portion of the steam, at an intermediate point in the superheater, through a tubular desuperheater cooled by boiler water or steam. (F.T.M.)

SUPERHETERODYNE. Receiver.

SUPERIMPOSED RIVER VALLEY. A river valley which is independent of present structural control may be described as either superimposed or antecedent.



Diagrams illustrating the development of a superimposed river valley.

In the former case it is implied that the river has been able to maintain its course across resistant structures such as ridges, because it started as a consequent stream and has been "let down" on the underlying or non-conformable structure. (R.M.F.)

SUPERLINGUA. Paragnatha.

SUPERNORMAL DISPERSION. If the Lexis ratio, D, is greater than 1, the distribution is said to possess supernormal dispersion. Ordinarily when D is significantly greater than 1, we presume the **variable** consists of sets which have constant probabilities within the set but probabilities which differ from set to set. (See **Coefficient of Dispersion.**) (L.A.A.)

SUPERPOSITION, LAW OF. The fundamental law in **stratigraphy** and historical geology stating that underlying strata are older than overlying strata unless the formations have been inverted by folding or by low-angle thrusts. (R.M.F.)

SUPERPROPORTIONAL REDUCERS. Superproportional reducers are useful in the reduction of negatives of extremely high contrast due to the contrast of the subject as well as overdevelopment. Negatives of subjects of normal contrast which have been overdeveloped should be reduced in a proportional reducer.

The alkaline persulfates are the only oxidizing substances which form practical superproportional reducers. (See also **Photographic Reduction, Photographic Subtractive Reducers, Proportional Reducers.**) (C.B.N.)

SUPER-REGENERATIVE RECEIVER. In the ordinary regenerative **receiver** the sensitivity goes up as the **feedback** is increased but if the feedback is increased to produce the maximum amplification (just before oscillations start) the circuit is unstable and breaks into oscillation. The super-regenerative circuit utilizes this high gain point without the instability by introducing a voltage of low radio frequency in the plate supply lead. Since this voltage subtracts from the plate supply voltage every half-cycle it will lower the net plate voltage to the point where any started oscillations die out. The circuit is adjusted so oscillations actually start to build up, giving very high gain, but are killed off at the low radio frequency (quench frequency) rate and so do not reach an objectionable amplitude. The quenching frequency may be generated by a separate oscillator **tube** or may be generated by the regular detector tube in a so-called self-quenching circuit. The gain of these detectors is enormous but they are subject to several limitations such as: poor quality, radiation and subsequent interference with other receivers, strong interchannel hiss, poor selectivity, etc. They are, nevertheless, quite widely used for reception in the **very high frequency** region. (L.R.Q.)

SUPERSATURATED AIR. Air devoid of salt, dust, and ions can be supersaturated with respect to a free water surface. Inasmuch as the atmosphere contains numerous salt particles, dust, and ions, as well as microscopic plants and animals, supersaturation is seldom if ever a reality because these materials, particularly salt particles and ions, serve as nuclei for condensation. Actually many clouds form at less than saturation with respect to open water surfaces. (P.E.K.)

SUPERSATURATED SOLUTION. Solutions.

SUPERSATURATED VAPOR. A supersaturated vapor is one which remains dry, although its heat content is less than that of dry and saturated steam at the pressure. Supersaturation is an unstable condition, and is found in the **steam** emerging from the nozzles of a **steam turbine.** The abnormality of the phenomenon is similar to that of supercooling. An experiment often performed in physics laboratories is the careful, slow cooling of water in a vessel absolutely free from vibration or motion. In a perfectly quiescent state, the water may be slowly cooled to below the normal freezing temperature without appearance of ice. In the supercooled state a slight jar on the containing vessel will immediately create a return to normal condition, with a rise of temperature to the freezing point, and the appearance of crystals of ice in the water. Supersaturation probably results from the very rapid expansion of steam in the nozzle, permitting the traverse of a short distance before the condensation of moisture is completed. At a certain definite point, however, known as the Williams limit, the supersaturation vanishes, and the steam regains the wet state which would be normal in view of the pressure and

the heat content. Supersaturation of vapor is impossible in the presence of numerous changed ions or dust particles. (F.T.M.)

SUPERSONICS. **Ultrasonics.**

SUPPRESSED CARRIER. **Modulation.**

SUPPRESSOR GRID. This is a third grid introduced in the thermionic vacuum **tube** between the screen grid and the **plate** to suppress **secondary emission** from the plate. By doing this the undesirable dip in the plate characteristic of the **tetrode** is eliminated. (L.R.Q.)

SUPPURATION. The formation of **pus**. Any infection in which pus develops is suppurative. The common pyogenic or pus-forming organisms are staphylococci and streptococci. (D.M.H.)

SUPRARENAL GLAND. Also called adrenal. **Endocrine Gland.** (A.W.L.)

SURCHARGE. **Retaining Wall.**

SURFACE GAUGE. **Measurement.**

SURFACE INTEGRAL OF VECTOR FUNCTION. Let $\mathbf{F}(\mathbf{r})$ be a **vector function** of the position vector $\mathbf{r}$, let S be a region on a curved **surface**, and let $\hat{\mathbf{n}}$ be a unit normal vector, normal to S at any point of the region, and let θ be the angle between $\mathbf{F}$ and $\hat{\mathbf{n}}$. Then the **surface integral** $\iint_S F \cos\theta \, dS$ is called the surface integral of the vector function $\mathbf{F}$, and is denoted by

$$\iint_S \mathbf{F} \cdot \hat{\mathbf{n}} \, dS.$$

(L.L.S.)

SURFACE INTEGRALS. Let $f(x, y, z)$ be a **function** which is **continuous** within and on the boundary of a region S on a given curved **surface**. Let this region be divided up into n sub-regions ΔS_k, and let (x_k, y_k, z_k) denote any point in ΔS_k. Form the sum

$$\sum_{k=1}^{n} f(x_k, y_k, z_k)\Delta S_k = f(x_1, y_1, z_1)\Delta S_1 + \cdots + f(x_n, y_n, z_n)\Delta S_n.$$

The limit of this sum as each $\Delta S_k \to 0$ (and $n \to \infty$) is called the surface integral of $f(x, y, z)$ over the region S, and is denoted by

$$\iint_S f(x, y, z) dS.$$

Let $R(x, y, z)$ be a continuous function in a region S on a curved surface; divide S into sub-regions ΔS_k as before, and let $\Delta\sigma_k$ be the projection of ΔS_k on the XY-plane. Then the limit of the sum

$$\lim_{\Delta\sigma_k \to 0} \sum_{k=1}^{n} R(x_k, y_k, z_k)\Delta\sigma_k$$

is defined as a surface integral of $R(x, y, z)$ and may be denoted by $\iint_\sigma R(x, y, z)d\sigma$. In rectangular coordinates, the element $d\sigma$ becomes $dxdy$, and the integral is written $\iint_S R(x, y, z)dxdy$. Similarly we may define surface integrals $\iint_S Q(x, y, z)dzdx$ and $\iint_S P(x, y, z)dydz$.

These surface integrals usually occur in combination as a sum, usually written in the form

$$\iint_S (Pdydz + Qdzdx + Rdxdy).$$

(L.L.S.)

SURFACE OF REVOLUTION. The surface generated by revolving a plane curve about a line lying in its plane is called a surface of revolution.

Examples are: the **sphere**, right circular **cylinder** and **cone**, **ellipsoid** of revolution, **hyperboloid** of one and of two sheets of revolution, and **paraboloid** of revolution.

To find the equation of a surface generated by revolving a curve in one of the coordinate planes about one of the axes in that plane: Substitute in the equation of the curve the square root of the sum of the squares of the two variables not measured along the axis of revolution for that one of these two variables which occurs in the equation of the curve. (L.L.S.)

SURFACE TENSION. Fluid surfaces exhibit certain features resembling the properties of a stretched elastic membrane; hence the term surface tension. Thus, one may lay a needle or a safety-razor blade upon the surface of water, and it will lie at rest in a shallow depression caused by its weight, much as if it were on a rubber air-cushion. A soap bubble, likewise, tends to contract, and actually creates a pressure inside, somewhat after the manner of a rubber balloon. The analogy is imperfect, however, since the tension in the rubber increases with the radius of the balloon, and the pressure inside, which would otherwise decrease, remains approximately constant; while the liquid "film tension" remains constant and the pressure in the bubble falls off as the bubble is blown.

Whenever two dissimilar substances make contact at an interface, the inequalities of molecular attraction (cohesion), together with other forces in operation, tend to change the shape of the interface until, in accordance with the **least energy principle**, the potential energy of the whole molecular system attains a minimum value. If both substances are fluid, the surface does actually adjust itself to this condition. For example, a drop of oil suspended at rest in another liquid of the same density assumes a spherical form because the minimum-energy curvature is the same for all points of the surface. But if the drop is rotating, centrifugal forces alter the equilibrium and the drop becomes spheroidal; or in the case of a drop hanging from the end of a pipette, gravity enters as a component and the drop becomes pear-shaped. (See also **Capillarity.**)

In any case, the value of the surface tension at any interface is determined by the nature and the physical condition of the two substances in contact. The surface tension of a liquid (against air) decreases with rising temperature. An empirical formula known as the Eötvös-Ramsey-Shields law expresses it as proportional to $t_c - t - 6°$, in which t is the temperature of the liquid and t_c is its critical temperature, both in degrees centigrade. According to Macleod, the surface tension of a liquid against its saturated vapor is expressed by $K(\rho_L - \rho_V)^4$, in which ρ_L and ρ_V are the densities of liquid and vapor and K is an approximate constant for a given substance. At the critical point, when the densities become equal, the surface tension should be zero and thus no longer impede diffusion; though this conclusion is in slight disagreement with the Eötvös-Ramsey-Shields law above. (L.D.W.)

SURFACE-ACTIVE COMPOUNDS. Those substances that lower the surface tension of a liquid when exposed to a gas, e.g., water in air, or reduce the interfacial tension between two immiscible liquids, e.g., kerosene and water. Effective substances in this respect are the sodium soaps of the fatty acids, namely, lauric with C_{12}-chain, myristic C_{14}-, palmitic C_{16}-, stearic C_{18}-, oleic C_{18}- and 1 olefin bond, and linoleic C_{18}- and 2 olefin bonds. These reduce the surface tension of pure water in air at 20° C. from 73 dynes per cm. to the order of 25 upon dissolving 1/10% soap in the water. The laurate and myristate are more soluble than the higher -C soaps, and

are thus better for use with sea water. They are made from such oils as coconut, babassu, and palm-kernel. Olefin bonds in the C-chain bring about greater lowering of the surface tension, and hydroxyl groups, as in recinoleate (hydroxyoleate from castor oil) cause less lowering than the plain chain. Soaps of higher than C_{18}- are practically insoluble in water, and consequently ineffective in lowering the surface tension of water.

Some simple interfacial tension values are the following:

System	Interfacial Tension dynes per cm. at 20° C.
n-Hexane—water	51
Carbon disulfide—water	48
Carbon tetrachloride—water	45
Chlorobenzene—water	37
Benzene—water	35
Nitrobenzene—water	26
Diethyl ether—water	11
Aniline—water	6

Although detergency is a complicated phenomenon, certainly among the important factors are surface and interfacial tensions, since the lowering of these assists in the penetration and wetting of the material to be cleansed, and in the emulsification and suspension of the "dirt" by the action of the cleansing solution. Another factor is the orientation of the molecules of the detergent. These are made up of two oppositely charged groups, one of which is hydrophilic (water-loving) and the other hydrophobic (water-fearing). In ordinary soap the —COONa group is the former and the hydrocarbon residue (—$C_{17}H_{35}$ of stearate) is the latter, and the result is that the —COONa group faces into the water *at its surface* and the hydrocarbon residue faces away from the water. Oily dirt is displaced from fabric by the wetting action of the soap solution to form droplets that can be easily detached from the fabric by stirring, and are thereupon emulsified in the soap solution. Rinsing completes the separation.

The chief disadvantage of soap as a detergent is that it forms insoluble soaps with the calcium, magnesium, and iron salts of hard water, and not until after this reaction has taken place does the residual soap function as a cleansing agent. This causes a loss of soap equivalent to the hardness of the water—a loss which may be ½ of the soap used—and it also causes clots of the insoluble soap which must be removed as so much more dirt. This handicap in the use of soap in hard water can be overcome (1) by the addition of sodium hexametaphosphate or of tetrasodium pyrophosphate, which form water-soluble complex ions with the hardness-producing metals, or (2) by the use of sulfates of the C_{12}- and C_{14}-chain alcohols instead of soap. These compounds, in the form of their sodium salts, possess a double advantage (which may, however, be offset economically by their higher cost) in that (a) the calcium, magnesium, and iron of the hard water do not produce insoluble compounds, and (b) they may be used in acid solution in contrast to soap which cannot be so used since the free fatty insoluble acid is thereby formed. These sulfates, such as Dreft, Drene, Gardinol, are made by hydrolyzing the oil, reducing the free fatty acid so formed to the corresponding alcohol, reacting this alcohol with sulfuric acid to produce the organic hydrogen sulfate, and then neutralizing with sodium carbonate to form the sodium salt desired, thus:

$$\underset{\text{Free fatty acid}}{R\text{—}COOH} \rightarrow \underset{\text{Alcohol}}{R\text{—}CH_2OH} \rightarrow \underset{\text{Organic hydrogen sulfate}}{R\text{—}CH_2OSO_2OH} \rightarrow \underset{\text{Sodium salt of organic hydrogen sulfate}}{R\text{—}CH_2OSO_2ONa.}$$

Other detergents useful with hard water and for wetting purposes are the sodium salt of a monogylceride monosulfate, as in the case of sodium glyceryl monolaurate sulfate (Syntex M), and a sodium secondary alcohol sulfonate, as in the case of sodium dioctylsulfosuccinate (Aerosol OT). Sodium dibutylsulfosuccinate is stated to be soluble even in 75% solution of zinc chloride, and a 0.1% solution of this agent in 20% sodium sulfate has a surface tension of only 37.5 dynes per cm.

Surface-active compounds are numerous and widely used as wetting agents and detergents in kier-boiling, bleaching, dyeing and scouring baths in the textile industry. A tabulated list of 350 such materials may be found in *Silk and Rayon* in various issues in the years 1937-39. These compounds are also important in the leather industry for wetting dry hides and skins; in the insecticide spray industry; in glass- and metal-cleaning compounds; in the wet processing of clay and cement; in flame-proofing textile fibers and wood; and in materials for removing wall-paper. (R.K.S.)

SURFACES. Metal products, particularly sheet, plate, and bars, are supplied in various surface finishes. Hot-rolled or forged surfaces generally have a layer of oxidized metal, or scale, which may be loosely to very tightly adherent. This layer may be removed by chemical action resulting in a pickled finish.

Hot-rolled and pickled products are often finished to size by cold-rolling flat products or cold-drawing bars and certain shapes. This gives a smooth, dense surface. For some purposes it is desirable to have a roughened surface on cold-rolled products. This can be accomplished by grit-blasting the finishing rolls. Where high-dimensional accuracy and smooth surface are required, bar stock may be finished by grinding or machining; however, cold-drawn bars are the most widely used.

In addition to these surface finishes, stainless steel, bronze, and certain other non-ferrous alloys may be ground and polished in various degrees up to a high luster or mirror finish. Many alloys may also be brightened by **electropolishing.**

Bearing surfaces of machine parts are sometimes prepared by **superfinishing,** a mechanical lapping operation which gives a mirror finish and permits very small dimensional tolerances.

Instruments for measuring the roughness of commercial finishes are usually of the tracer type in which a finely pointed diamond stylus is drawn across the surface. The motion of the stylus is highly magnified and recorded by electrical means. Indications of surface roughness are measured in microns or in micro-inches. Several types of optical instruments are also used to evaluate surface roughness.

In addition to finishes in which the base-metal surface is retained, protective films and coatings are widely used on metal products. These range from oils and other liquid rust-preventatives to relatively heavy metallic coatings applied by electrodeposition or other means. (See **Anodizing, Bonderizing, Calorizing, Chromizing, Galvanizing, Parkerizing, Sherardizing, Siliconizing, Terne Plate, Tinplate, Vitreous Enamel.**)

Very hard surfaces on steel are produced by processes known as **carburizing, nitriding,** and **hard surfacing.**

A surface may be represented analytically by (1) an **explicit** equation form $z = f(x, y)$, or (2) by an **implicit** equation form $F(x, y, z) = 0$, where x, y, z denote **rectangular coordinates,** or **spherical coordinates,** or **cylindrical coordinates,** or (3) by a set of **parametric equations** $x = f(u, v)$, $y = g(u, v)$, $z = h(u, v)$.

To study the surface defined by a given equation, find the traces of the surface on the coordinate planes, obtained by putting each coordinate x, y, z equal to 0 in turn, and then find sections of the surface by planes parallel to the coordinate planes, obtained by putting each coordinate equal to constant values in turn. By

putting together these plane sections, one obtains an idea of the nature of the surface. (R.H.H., L.L.S.)

SURGE IMPEDANCE. **Characteristic Impedance.**

SURGE TANK. The surge tank is a water tank employed to absorb irregularities in flow. It may be used where the total amount of water flowing around the closed cycle is constant, but where the volume passing one point in the cycle varies from that at another. For example, in a condensing power plant, the rate at which feedwater is pumped back to the boiler may be different from that at which steam is supplied to the turbine, although the integrated flows over a definite time interval would be the same. A surge tank interposed between the point of discharge of condensate from the condenser, and the intake to the boiler feed pump, would have a water level which would rise and fall to take care of these irregularities, and in this surge of water in the tank there would be compensation for the different rates of flow.

A hydroelectric plant is frequently provided with a surge tank which is attached to the **penstock** near the plant, by means of a vertical stand pipe. The use of the surge tank is to cushion the penstock **water hammer** which would otherwise arise when turbine gates are suddenly closed. The surge tank is doubly valuable to a penstock because it will not only absorb energy during the deceleration, but will also provide a ready reservoir from which the turbines can draw temporarily, as when they are started during normal operations, or when the sudden heavy demand causes rapid opening of the gates. (F.T.M.)

SURICATE. Mammalia, Carnivora. An animal of southern Africa, *Suricata tetradactyla,* related to the monogooses and with them belonging to the civet group. It is of moderate size, gray with transverse dark bands on the back and a whitish crown, and has rather short legs. It makes an interesting pet. This species shares the name meerkat with one of the mongooses. (A.W.L.)

SURVEYING. This term covers the art of determining the shape, contour, position, or dimensions of any part of the earth's surface, and further, of representing this information on paper. Maps and profiles are the usual method of representing the results of a survey. The data from which these drawings are constructed is obtained by field work, which consists in measuring distances and angles both horizontal and vertical. When the area surveyed is less than 100 sq. mi. in extent, it is considered a plane surface, and the surveying of it is called plane surveying. Surveys of larger tracts of the earth's surface must recognize the fact that the earth's surface is curved. This class of surveying is known as geodetic surveying, and of necessity is more difficult and exacting. However, in no case is a survey to be considered as an exact representation of the area which was surveyed. All surveying is, of course, accurate precise work, necessitating the use of specially designed instruments. However, the degree of precision obtainable varies with the class of survey and the need for precise results. The precision attained in a survey is represented by percent of difference allowable in two measurements of the same distance, or allowed error of closure of a closed survey.

Land surveying consists of the measurement of distances and angles for the purpose of establishing new boundary lines or reestablishing old boundaries when the original **corners** have been obliterated.

Route surveying is a general term used to cover all surveys made subsequent to and in connection with the final location of a highway, railroad or similar cross-country project. The first step in route surveying is a general study and investigation of all territory along the proposed route. This is known as a reconnaissance. The second step is the preliminary survey of one or more tentative locations which are selected as a result of the reconnaissance. The preliminary survey is made in order to secure information from which a **topographic map** and **profile** of each of these locations may be made. The establishing of a trial center line of the project on the route finally selected after studying the topographic maps and profiles is called the paper location. The location survey which is the final step is the field work involved in establishing the final center line on the ground and in running a set of profile levels (see **Profile Leveling**) for this center line.

Any survey made with a **transit** is a transit survey.

A construction survey is any survey made in connection with the preparations for the actual construction of a highway, railroad, bridge, building, sewer or any other engineering structure. In general it consists of locating stakes for lines and grades.

Surface surveys of mining claims and underground surveys of mines are classed under the heading of mine surveying.

City surveying applies to surveys made within the boundaries of a city for mapping and municipal construction purposes. It is usually based on a higher degree of accuracy than ordinary land surveying.

Hydrographic surveying refers to surveys of large bodies of water made for the purpose of determining the configuration of the bottom and other pertinent information. The depth at various points, which are located by **triangulation** from the shore, is found by soundings.

Photogrammetric surveying is a term applied to the use of photographs of the earth's surface in connection with the preparation of maps. (See **Photogrammetry.**)

The many divisions of this subject are treated separately in this volume. (See **Maps, Azimuth, Bearings, Metes and Bounds, Land Subdivision, Level, Transit, Declination, Plane Table, Level Rod, Stadia, Differential, Curve, Tangent Offset, Topography, Contour, Compass, Triangulation, Traverse.**) (F.T.M., C.W.C.)

SURVIVAL OF THE FITTEST. **Evolution.**

SUSLIK. **Gopher.**

SUSCEPTANCE. **Admittance.**

SUSPENSION BRIDGE. **Bridge.**

SUSSEXITE. The term proposed by J. Kemp in 1892 for an igneous rock composed chiefly of **nepheline** and **aegirine**, and essentially free from **feldspar**. Type locality, Sussex County, New Jersey. (R.M.F.)

SUSU. **Dolphin.**

SUTURE. 1. The line of union of the adjacent flat bones making up the skull. 2. The surgical sewing-up of a wound or incision. Suture material is generally classified either as absorbable or non-absorbable. The absorbable type is made of either plain or **chromic** catgut. Non-absorbable material is silk, linen, fine wire, or strands of synthetic composition.

A fascial suture is one fashioned of a strip of **fascia** which is usually removed from the thigh where it covers the external muscles. Such sutures are often described as living sutures as they act similarly to a graft. They are used principally in the repair of large **herniae** where the tissues are weak. (R.S.M., D.M.H.)

SWAGE. **Forging.**

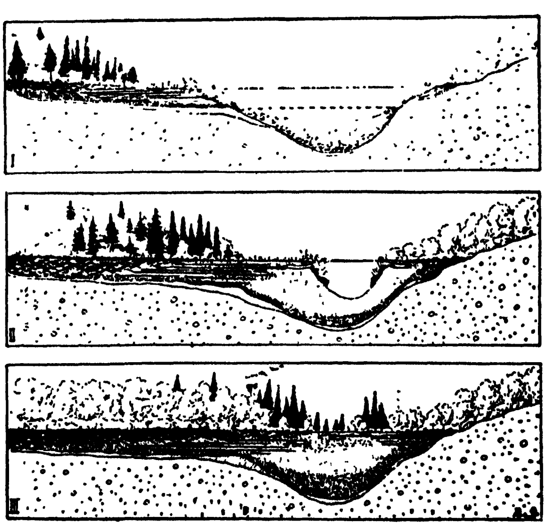
SWALLOW. Aves, Passeriformes. An insect-eating bird (**Aves**) with a short wide beak, long and relatively narrow wings, weak feet and legs, and usually a forked

tail. The distribution of the swallows is worldwide. They constitute the well-marked family Hirundinidae.

The swallows' nests are built in burrows, holes in trees, and about human dwellings, hence some of the species are familiar friends. In North America the purple martin, *Progne subis,* is widely known from the large colonies that nest in bird houses year after year. Among the true swallows of this continent the barn swallow, *Hirundo erythrogaster,* is among the most beautiful and is undoubtedly the most widely known. The bank, *Riparia riparia,* cliff, *Petrochelidon albifrons,* and rough-winged, *Stelgidopteryx ruficollis,* swallows are also widely distributed and locally common, though less beautiful than the tree swallow and the western violet-green swallow, *Tachycineta thalassina.* The glossy blue and green shades of the upper parts of the last two species are very striking, but both species are found in wild areas, hence they are less familiar than those mentioned above. (A.W.L.)

SWALLOWTAIL. Insecta, Lepidoptera. A large **butterfly,** usually with slender tails extending from the hinder angles of the hind wings. The many species of swallowtails belong to the family Papilionidae. They are widely distributed in the tropical and temperate zones, especially in the former where some are very beautiful and brilliantly colored. Twenty-one species occur in North America. Most of them are yellow with black markings or vice versa but the common pawpaw swallowtail of the eastern and southern states is greenish-white with black bands and some red marks. Some of our species have metallic blue or green scales on the hind wings. Although some species lack the tails, they are also called swallowtails by association with the typical forms. (A.W.L.)

SWAMP. Where the flatness of the land, the presence of impervious soils or bed rock, or abnormal amounts of plant material obstruct or entirely prevent the normal drainage of an area, an excess of moisture will accumulate to the point of saturation and a swamp will come



Origin and evolution of a peat bog. (*After Dachnowski.*) I, II and III, illustrating the successive stages in the filling of a pond by the growth of the peat bog. (*Field, Outline of Geology, Barnes & Noble.*)

into existence. While most swamps are level this is not a necessary condition, for hillside swamps are by no means uncommon, due to a constant supply of percolating ground water which maintains the swampy condition.

Lake basins are occasionally filled with vegetation and sediment, thus becoming swamps; these are frequently referred to as muskegs, a word of American Indian origin. Swamps may be formed on the flood plains of rivers as well as upon their deltas; they are characteristic of the flat ill-drained areas of the Atlantic Coastal Plain, examples of which are the Great Dismal Swamp which covers about 2000 sq. miles in the states of Virginia and North Carolina, and the Everglades of Florida, covering about 4000 sq. miles.

Coastal salt-water swamps may develop in the zone between high and low tides or extend up river estuaries; examples of these are common along the Atlantic and Gulf coasts of the United States. In certain northern latitudes swamps develop into peat bogs. Peat bogs are an important source of fuel in Northern Europe, and also serve as an interesting illustration of the origin of **coal,** as exemplified in the **peat, lignite,** bituminous coal series. The accompanying figure illustrates the formation of a peat bog. (R.M.F.)

SWAN. Aves, Anseriformes. A large bird (**Aves**) related to the geese and of similar form and habits. They differ in the length of the neck, which is at least as long as the body in the swans. Although the more familiar species are white, some swans are marked with black and in Australia a species with almost entirely black plumage occurs. The two North American species, the whistling, *Cygnus columbianus,* and trumpeter, *C. buccinator,* swans, breed far to the north and are not often seen. The whistling swan also bears the name whooper in Europe. (A.W.L.)

SWAY BRACING. **Bridge.**

SWEAT GLAND. A coiled tubular **gland** derived from the outer layer of the skin of **mammals** but extending into the inner layer. These glands are distributed over almost the entire surface of the body in man and many other species but are lacking from the skin of some marine and fur-bearing species.

The secretion of the sweat glands varies greatly. Human sweat is composed chiefly of water, with various salts and organic compounds in solution. It contains minute amounts of fatty materials, **urea,** and other wastes. In certain parts of the body the sweat glands are modified and produce wholly different secretions, including the wax of the outer ear. The sweat of other animals is normally different in composition from that of man.

The sweat glands perform an important function in the maintenance of body temperature by drawing heat from the surface of the body when the temperature of the air is too high to permit adequate radiation. Animals without sweat glands, such as the dog, accomplish the same result by panting, and so evaporating water from the moist lining of the oral cavity and **pharynx.** (A.W.L.)

SWEEP OSCILLATOR. This is the timing axis **oscillator** for a cathode ray oscilloscope. (See **Cathode-Ray Tube.**) (L.R.Q.)

SWEET FLAG. **Aroids.**

SWEET POTATO. *Ipomoea batatas.* Convolvulaceae. The plant is a trailing perennial, the stems of which twine in counter-clockwise direction around supporting objects. These stems arise from much-thickened roots which are rich in **starch.** In cultivation many varieties have been developed, with many different leaf shapes. Dark green, heart-shaped leaves with shining surface occur in several varieties, while in others the leaves are variously lobed and dissected. The flowers, seldom produced in plants grown in northern latitudes, are about 2″ across, purple, and borne either singly or in small axillary **cymes.** The fruit is a **capsule.**

Various methods of propagation are employed. Small roots may be planted whole, **adventitious buds** soon

forming and giving rise to shoots which appear above the ground in about four weeks. Root cuttings from growing plants may also be used, especially in regions where the growing season is long. On occasion stem cuttings may be used, but necessarily demand a long growing season and reach maturity very late in the season. Seed may be grown, but germination is slow and uneven, and the product not uniform.

The sweet potato is an American plant, a native of the West Indies and Central America. In cultivation it has gradually spread out of tropical lands, new varieties being developed to suit new localities. At present the crop is grown as far north as Cape Cod.

The principal use of the sweet potato is for human consumption, although some are fed to swine. The vines are frequently used as stock food. From the roots starch, flour, **glucose** and **alcohol** are extracted, to a limited extent.

Sweet potatoes are frequently called yams. This application of the name yam to the sweet potato is confusing, since the true yam is an entirely different plant, *Dioscorea Batatas* (Dioscoreaceae), widely grown in tropical lands for its edible tubers, which are rich in sugar, watery, and soft when cooked. The flowers are white. Propagation is mainly by cuttings of tubers, each containing one or more eyes, or small buds, such as are found in the white potato tuber. Yams are widely used as food.

Another species of Ipomoea, *I. purpurea,* is the Morning Glory, frequently cultivated for its showy flowers. (R.M.W.)

SWEETBREAD. Originally the **thymus** gland of the calf as an article of food, and secondarily applied to the **pancreas.** The term now indicates the pancreas more often in popular usage. Both of these glands are to be regarded as delicacies which are not common enough to be of great dietary interest. The pancreas contains a fairly large amount of **vitamin B.** Otherwise neither gland is a valuable food save for its energy content. (A.W.L.)

SWIFT. 1. Reptilia, Sauria. A **lizard.** The name is applied without scientific accuracy to some of the **iguanas,** including small species of two different genera. Most of these lizards occur in the southwestern United States and Mexico but one species, the pine or fence lizard, *Sceloporus undulatus,* is found as far north as Michigan, New Jersey, and Oregon. 2. Aves, Micropodiformes. Small birds (**Aves**) with short wide beaks and long slender wings. They are superficially like the swallows but are more closely related to the hummingbirds. The numerous species of swifts are widely distributed in both hemispheres, five occurring in North America. The common chimney swift, *Chaetura pelagica,* which has abandoned its original habit of nesting in hollow trees to occupy our chimneys, is both widely distributed and abundant, while the remaining species are found only in the far West and southward. The swifts make their nests of various materials cemented together and fastened to their support with saliva, and one species of the Oriental region uses the secretion alone, without foreign materials. The nests of this species are attached to the walls of caves and are the famous edible bird nests of Chinese epicures. (A.W.L.)

Chimney swift, *Chaetura pelagica.* Sooty brown. Tail feathers sharply pointed. Long narrow wings.

SWIMMERET. The **biramous appendages** of the abdomen of a **crustacean.** Also called pleopods. (A.W.L.)

SWINE. Pig.

SWING BRIDGE. Bridge.

SWINGING CHOKE. This is a variable inductance **choke** often used as the input choke for a smoothing **filter** of a **power supply.** The requirements for the input choke vary with the load on the filter so one value of inductance is needed for no load (other than the bleeder across the filter output) and a much lower value is needed when load is applied. By proper adjustment of the air gap in the **core** of an iron-cored choke this variation in inductance can be made automatic as the current through it varies with the load demand. (L.R.Q.)

SWITCH, ELECTRIC. The switch is a circuit making and breaking device used in electrical circuits for manual operation under normal circuit conditions. It is distinguished from the **circuit breaker** in function since the breaker performs these operations under abnormal conditions such as overloads. The breaker is usually more complex in mechanical and electrical construction since it must be capable of handling the abnormal circuit conditions usually present when it functions. The same apparatus, however, often is used to serve both as an ordinary switching means, i.e., opening and closing the circuits under normal conditions at the will of the operator, and as a circuit breaker, i.e., operating automatically when the circuit ceases to function normally. This is true both of the many small breakers which are replacing fuses in many applications and of the large power oil breakers used for protecting and controlling high-voltage transmission lines.

There are many different types of switches. Not considering the numerous kinds of small snap switches, push button switches, instrument and control switches, the switches in common use are either knife switches, disconnecting switches (a type of knife switch), or oil switches. The knife switch may be single-, double-, or triple-pole, single- or double-throw, fused or plain, front-connected or back-connected. There are several special types such as field-discharge switches, motor-starting switches, quick-break switches, etc. The ordinary knife switch is arranged to be mounted on the front of the switchboard and thrown directly by hand. Rear-mounted switches are operated by linkage connected to a handle projecting through the switchboard. These are used for higher voltages and for improved switchboard appearance. Knife switches are available in capacities up to 20,000 amperes and 750 volts. Like any other piece of electrical equipment, they must be selected and applied with due consideration to current-carrying capacity and voltage rating.

The disconnecting switch (often called a "disconnect") is a form of knife switch used primarily to isolate apparatus for inspection or repair, or as a transfer switch so that connections may be changed. It is a switch for opening the circuit only after the current has been interrupted by other means.

Live parts of the oil switch are surrounded by oil retained in a tank. Oil switches are manually operated and not intended to be opened under other than normal load. (F.T.M., L.R.Q.)

SWITCH RAILS. Railway Track.

SWITCHBOARD. Originally the power switchboard consisted of a panel of some insulating material with various knife **switches** mounted on it, and it was from this that the modern switchboard derived its name.

However, the present-day board has little in common with the earlier ones other than being the center of the control system for the switching of electrical energy. The primary function of the board is to permit the proper distribution and control of the energy to various loads. In performing this function it should meet certain fundamental requirements, among which are:

1. Safety to operating personnel.
2. Economic operation of apparatus.
3. Flexibility consistent with economics involved.
4. Rugged mechanical construction and arrangement of components. The exact construction of the power switchboard will be governed by its particular application but such boards may be grouped into the following classes:

a. Direct-control panel type.
b. Remote mechanical-control type.
c. Direct-control truck type.
d. Electrically operated.

Direct-control boards are generally used for low- and medium-capacity installations where cost is to be kept to a minimum. Such boards have the **circuit breakers**, disconnect **switches**, **instruments**, etc., mounted directly on the board. Sometimes low-voltage boards are of the live-front type, i.e., the switches, etc., are mounted on the front of the board, but the trend is to the dead-front type where breakers and switches are mounted on the rear. Remote mechanical-control boards have the breakers mounted separately from the board and operated through mechanical linkages by controls on the board, thus giving greater safety for personnel. The truck type boards are used in many industrial applications for 15,000 volts and less. These boards have the equipment mounted in steel compartments, completely assembled by the manufacturer, and capable of being withdrawn for inspection and servicing. All high-voltage parts are enclosed and interlocks are provided for safety when the trucks are withdrawn. The electrically operated board has the breakers and other high-voltage equipment located separately from the board and controlled by **solenoids** or **motor** operating devices. Such boards may be of the panel type or truck type.

Several materials are more or less standard for use as the panel, among them marble, slate, ebony asbestos and steel. The first three are insulating materials but are being rapidly replaced in modern boards by steel because of its greater strength and improved appearance.

The switchboard equipment varies with the application and type of board, but will include one or more of the following components: breakers, disconnect switches, voltmeters, ammeters, watt-hour meters and other operating **instruments**, **relays**, and the necessary bus construction for connecting the various circuits. The present trend is for the board to be assembled in the manufacturer's plant and be shipped as a unit or as several completely wired units requiring a minimum of connecting in the field. Such construction usually results in a neater and more practical board than would be obtained if built up entirely in the field.

The telephone switchboard bears even less resemblance to its namesake than does the power board. The modern telephone board is a jack and plug system for connecting any line with any other line in the office or for connecting to other offices or exchanges (see **Telephony**). If switches were used (as was the case in very early practice) the complications would be beyond all reason. The board has jacks for all lines being served, various signalling lights, patch cords for connecting from one line to another, and certain associated switches and circuits for the operator's use in handling the connections. The exact components and arrangement are determined by the type service being rendered by the board, i.e., common battery, local battery, A boards, B boards, long distance, etc. (L.R.Q.)

SWITCHING. Switching refers to the practice or policy used in connection with the subdivision and distribution of power from a central point to a number of radiating power lines. Switching is practiced in most power stations, and in certain **substations** or switching centers. There are three possible situations to be met, viz.:

1. Power may be distributed at the same voltage at which it is generated.
2. Power may be distributed at a higher voltage than that generated.
3. Power may be distributed at several voltages, one of which is the same as the generator.

Naturally, switching employed to get the first-named condition is simpler because it does not involve the use of transformers for changing voltage. However, this switching arrangement is confined to small stations because ordinary transmission line voltages are very much higher than the usual generator voltage.

The simplest switching arrangement possible is known as the single-bus system. A single bus is provided, to which are connected the generators and the feeder lines. Both **generators** and feeders are connected to the bus through automatic circuit breakers and disconnecting switches. For normal switching conditions, this simple arrangement will meet every requirement. However, there is no flexibility, and the failure of any generator circuit requires the withdrawal of the corresponding machine and breaker from service. A double-bus single-breaker system provides more flexibility at very little additional cost. This switching arrangement is shown in Fig. 1. Such an arrangement will eliminate the possibility of a long shut-down resulting from a bus failure. It also permits maintaining service while working on either bus, such as cleaning the insulators, etc. It does not, however, eliminate the necessity of withdrawing apparatus from service in case of trouble on the circuit breaker, and in some cases this system is extended to include a circuit breaker in the line to each bus.

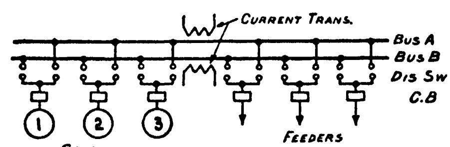


Fig. 1. Double bus, single circuit breaker system.

In larger stations, or in more important switching centers, different types of switching systems have been developed, some of which are extremely complicated, but are justified by virtue of the service rendered. A double-bus double-breaker system, in which will be found both low and high tension buses, is shown in Fig. 2. Here

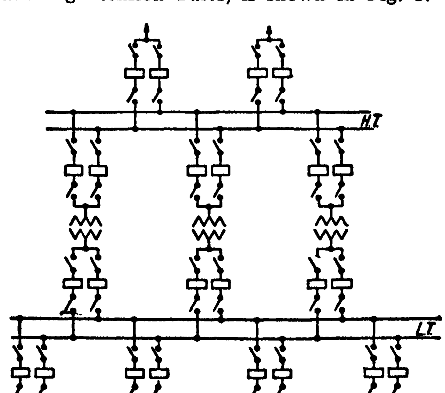

Fig. 2. Bus system using double buses and double breakers

the outgoing lines (two in number) operate at a voltage higher than that of the generators (four). The increase of voltage is accomplished by transformers located between the high- and low-tension buses. There are three transformers in parallel. In this system the failure of any one bus, or any one circuit breaker, or any one disconnecting switch, will cause only momentary interruption of activity on that line, as in each case there is a spare unit. The installation of duplicate equipment, or duplicate circuits, is very expensive, but the indirect cost to a power and light company of loss of customer goodwill through temporary interruptions of service, is considered great enough to justify such a switching system in the more important centers. (F.T.M.)

SWORD-BEARER. Insecta, Orthoptera. A long-horned **grasshopper** of the group known as cone-headed grasshoppers from the conical prolongation of the head. The sword-bearer is named from the long **ovipositor** of the female. This organ is a slender slightly curved blade longer than the entire body. The species is found in the northern states east of the Rockies. (A.W.L.)

SWORDFISH. Pisces, Teleostei. A large marine fish (**Pisces**), *Xiphias gladius,* whose upper jaw is prolonged into a flat pointed process, the sword, about ⅓ the length of the body. The dorsal fin is very large and scales are lacking. These fishes reach a maximum length of about 16′ and a weight of several hundred lbs. They are related to the sailfish.

The sword is said to be used to spear larger prey and cases are on record of its being driven deep into the planking of wooden ships. (A.W.L.)

SWORDTAIL. Pisces, Teleostei. *Xiphophorus.* A small fresh-water fish (**Pisces**) from Central America, popular among keepers of tropical aquaria. The tail of the male is prolonged into a slender tapering lobe, straight or nearly so and sometimes longer than the body. They belong to the **killifish** family. (A.W.L.)

SYCON. **Porifera.**

SYENITE. Syenite is a coarse-grained, granular, therefore intrusive, **igneous rock** of the general composition of **granite** except that **quartz** is either absent or present in relatively small amount. The **feldspars** are **alkaline** in character and the dark mineral is usually **hornblende.** Soda-lime feldspars may be present in small quantities. The term syenite was originally applied to hornblende granite like that of Syene in Egypt from whence the name is derived. Syenite is not a common rock, some of the more important occurrences being in New England, Arkansas, Montana, New York State (syenite gneisses), Switzerland, Germany and Norway. (E.S.C.S.)

SYLVANITE. The mineral sylvanite is **telluride** of **gold** and **silver** approximating the formula $(Au, Ag)Te_2$. It is **monoclinic,** occurring in bladed, columnar and granular forms as well as arborescent and branching. It is a brittle mineral; hardness, 1.5–2; specific gravity, 7.9–8.3; luster, metallic; color and streak, steel gray to yellowish-gray. This mineral is found associated with gold and tellurides of gold and silver or with sulfides such as **pyrite.** It is found in Rumania, Australia, Colorado and California. It was named for Rumanian Transylvania where it was first found.

Krennerite is another telluride of gold and silver with a similar composition to sylvanite, but crystallizing in the orthorhombic system. Calaverite is a gold telluride with only a small silver content. (E.S.C.S.)

SYLVITE. The mineral sylvite is **potassium chloride,** KCl, occurring in cubes, or as cubes modified by **octahedra.** It is therefore **isometric.** It has a perfect cubic cleavage; uneven fracture; is brittle; hardness, 2; specific gravity, 1.9; luster, vitreous; colorless when pure but may be white, bluish, yellowish or reddish due to impurities. It is soluble. It is much rarer than **halite** and has been found as sublimates at Mt. Vesuvius and as bedded deposits at Stassfurt, Germany. It is used as a source of potash salts. Potassium chloride was called by the early chemists *Sal digestivus Sylvii,* whence the name of the mineral. (E.S.C.S.)

SYMBIOSIS. This name is applied to an association of two organisms in which each derives some benefit from the association. The two organisms may both be plants. Or one may be a plant; the other, an animal. It is often difficult to determine exactly what each component gains when living together in this way. When careful study shows that one organism gains much more than the other, the association is really one of parasitism. A frequently cited example of true symbiosis is the **lichen,** a composite plant formed of a **fungus** and an **alga** growing together to produce an organism entirely unlike either component. Here the fungus gains nutrient from the alga; presumably the alga gains protection and an increased supply of water. However, it seems as though the fungus gained the greater benefit from its association with the alga. Another example of symbiosis in which the two organisms are both plants is found in **mycorhizae.** Here fungus **hyphae** grow closely around or within the root tissues of some higher plant, which seemingly receives an increased supply of water and inorganic food materials from the presence of the fungus. The latter obtains food. Nodule-forming **bacteria** in roots may be considered an example of symbiosis.

The dependence of plants on insects to effect **pollination** is not usually to be regarded as a case of symbiosis. Symbiosis does, however, seem to exist in such plants as the **Yucca** and the **Fig,** which are entirely dependent on insects for pollination, while the **larva** of the insects live in the **ovary** and feed on the **ovules** of the plants pollinated. Here obviously the two organisms are mutually benefited and dependent each on the other. (See **Animal Association.**) (R.M.W.)

SYMBOLS, CHEMICAL. **Chemical Composition.**

SYMMETRICAL or **UNSYMMETRICAL FOLDS.** **Anticline.**

SYMMETRY. The significance of this term in mathematics is treated in the article on **Locus of an Equation.** In zoology, symmetry is the arrangements of the parts of animal bodies in relation to centralized axes. The bodies of some 1-celled animals are asymmetrical and of others, notably the Heliozoa, spherically symmetrical with the hard parts of the skeleton radiating in various directions from a common center. By far the most common forms of symmetry, however, are those known as radial and bilateral.

Radial symmetry is especially common among the **sessile** animals such as **sea anemones** and the related **jellyfishes** whose movements are weak. These animals have a principal axis passing through the mouth from which similar structures extend on several radii. The same form of symmetry appears in the echinoderms although these animals begin life as bilaterally symmetrical larvae. The radial symmetry of the adult accompanies sluggish movement and in some forms food-securing habits like those of sessile animals.

Bilaterally symmetrical animals have similar halves flanking a median plane in the principal axis of the body. Sense organs are concentrated near the end that goes first in locomotion, forming a head in which the mouth opens as a rule. This end of the body is the cephalic end, in contrast with the opposite caudal end where the tail is attached in the vertebrates. The originally upper and lower or dorsal and ventral surfaces are also dif-

ferentiated, since the animal rests on the latter while the former is exposed to surrounding influences, and the sides of the body are known as right and left. This type of symmetry prevails in all actively moving animals.

The value of each type of symmetry is clearly correlated with the mode of life in which it is found. Sessile animals receive food and are subjected to dangers only when the responsible factors approach under their own powers of locomotion or on currents in the water. It is an advantage to the animal to be able to perceive such factors as easily in one direction as another. Bilaterally symmetrical animals move about in search of food, hence the end of the body that normally goes first has the chief need of powers of perception, while the upper and lower surfaces are exposed to different environmental conditions and the sides are similar in their contacts. (A.W.L.)

SYMPATHETIC NERVOUS SYSTEM. **Autonomic Nervous System.**

SYMPHYLA. Small and rare animals living in moist debris at the surface of the ground. They are related to primitive **insects** and **centipedes** and are usually regarded as a class of the phylum **Arthropoda.** They have a pair of antennae but no eyes. The segments of the body are well marked, bearing eleven or twelve pairs of legs. The animals breathe by **tracheae.** (A.W.L.)

SYNAPSE. The association between nerve cells of animals above the **coelenterates.** In coelenterates the nerve net is made up of cells whose processes are structurally connected but in the higher **nervous systems** the fine terminal branches of nerve processes merely come into close contact with those of adjacent cells. While some structural continuity persists in these animals, the synaptic association is regarded as an important foundation for the highly specialized type of nervous coordination that reaches its most complex state in man. The synapse has the important property of allowing impulses to pass in only one direction. (A.W.L.)

SYNAPSIS. **Meiosis.**

SYNCARIDA. **Crustacea.**

SYNCHRO. **Selsyn.**

SYNCHRONIZING, POWER CIRCUITS. **Parallel Operation.**

SYNCHRONIZING, RADIO CIRCUITS. There are various types of synchronizing requirements in the field of radio and television engineering. In certain applications two or more **oscillators** need to be synchronized, i e., tied together so their frequencies remain the same. This may be accomplished by injecting into each circuit a synchronizing signal from some common source (which may be one of the oscillators being synchronized). It is characteristic of many oscillator circuits that they will lock in frequency with an injected signal if its frequency is near the natural frequency of the oscillator or is a **harmonic** of the natural frequency. In **television** it is essential that the reproducing circuits of the receiver be synchronized with the transmitter camera device so the reconstructed scene will have its components in the proper places. This is accomplished by transmitting synchronizing pulses from the **transmitter.** In many of the recently developed electronic devices the synchronization of various components of the system plays an extremely important part but the basic method is that used for two oscillators. (L.R.Q.)

SYNCHRONOUS CONDENSER. This is a synchronous **motor** operated over-excited and without load. When built only for this application the shaft does not have any means provided for taking off motor power and is consequently much lighter than the corresponding motor. A synchronous motor will draw a leading current when over-excited, the magnitude of the current and its angle of lead being determined by the load and the amount of over-excitation on the field. When there is no load (as is the case of the synchronous condenser) the current is almost 90° out of phase with the voltage and thus gives the same effect as a condenser. Such operation not only tends to counteract the usual lagging current taken by most industrial loads but also serves to stabilize the voltage at the end of a long transmission **line.** The advantages are so pronounced that many large power systems have synchronous condensers across them. The trend at present is towards totally enclosed machines having hydrogen as the cooling medium as it provides better cooling and gives less windage loss. (L.R.Q.)

SYNCHRONOUS CONVERTER. **Converter.**

SYNCHRONOUS IMPEDANCE. This is a fictitious **impedance** used to replace the combined actual impedance of the **armature** of an **alternator** and the effect of armature reaction. By its use the voltage **regulation** of the alternator may be calculated from no-load tests. (L.R.Q.)

SYNCHRONOUS MOTOR. **Motor, Electric.**

SYNCLINE. The syncline is a structure in which the strata are bent downward in an inverted arch, the sides of which are designated the limbs. The syncline may be a broad open fold or tightly compressed with steep dips, and **pitch** either upward or downward. (R.M.F.)

SYNCLINORIUM. **Anticlinorium.**

SYNCOPE. A fainting spell, in which the unconsciousness is due to a temporary cerebral anemia; i.e., insufficient circulation of blood in the **brain.** (R.S.M.)

SYNCYTIUM. A mass of **protoplasm** containing many **nuclei**, not separated by cell boundaries. In some cases the syncytium is a network in which partially distinct cell bodies are connected by protoplasmic strands while in others the mass is broadly continuous. The nerve net of the jellyfishes is an example of the former type and the plasmodium of Mycetozoa (**Sarcodina**) is a conspicuous illustration of the latter. The plasmodium is formed by the joining of separate cells. The formation of syncytia by repeated nuclear subdivision without accompanying division of the **cytoplasm** has also been observed. (A.W.L.)

SYNDROME. A group of symptoms characterizing or occurring in any abnormal state or disease. (R.S.M.)

SYNECOLOGY. **Autecology.**

SYNGAMY. A synonym of **conjugation.**

SYNGENETIC. **Epigenetic.**

SYNODIC PERIOD. The synodic period of any member of the **solar system** is the time required for the object to go from some particular position relative to the sun as seen from the earth back to the same position again. In the case of the **moon** the synodic period is the time required for the moon to go from **conjunction,** or new moon, back to conjunction again. This period of approximately 29.5 days is the original **month** as used by ancient astronomers in the construction of the **calendar.**

Since a planet is best observed at **opposition**, the synodic period of the planet gives the interval of time between successive positions of favorable observation. The synodic period is related to the sidereal period, i.e., the actual period of revolution of an object about the sun, by a simple relationship:

Let P be the sidereal period of the object.
S the synodic period of the same object.
E the sidereal period of the earth (approximately 365.25 days).

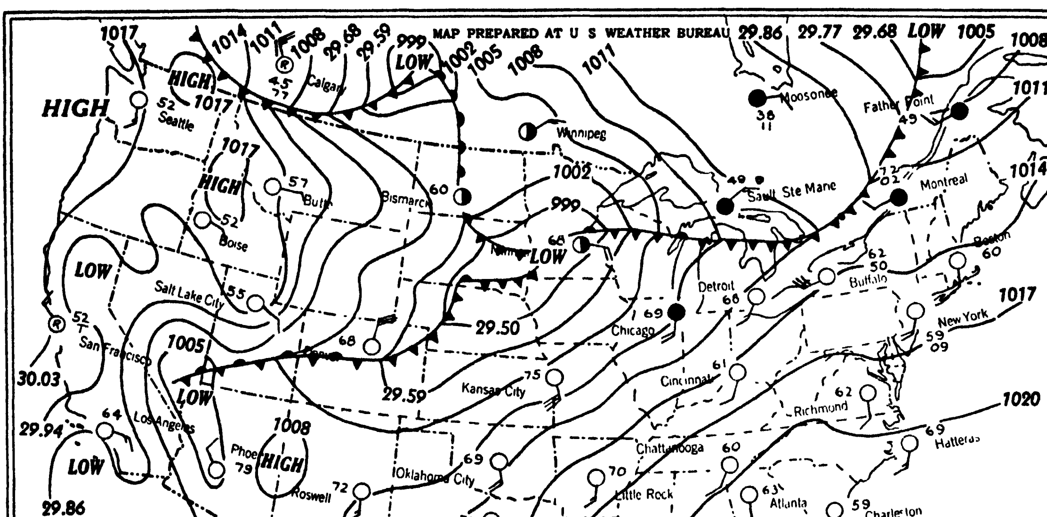
Then

$1/S = 1/P - 1/E$ for planets with orbits inside that of the earth.

$1/S = 1/E - 1/P$ for planets with orbits outside that of the earth.

(W.K.G.)

SYNOPTIC REPORTS AND CHARTS. In meteorology, observed weather conditions are placed in brief coded form as a synopsis of the conditions. Such briefs of conditions are known as synoptic reports. Likewise, a map upon which numerous weather reports are placed and upon which an analysis of the data appears is known as a synoptic chart. Synoptic charts may show conditions at sea level, any other level, or in cross-section.



Weather maps of the United States and adjacent areas are issued daily by the United States Weather Bureau. A sample map is illustrated. Narrow black lines are isobars. Sea level pressure is the same everywhere along an isobar. In addition, the isobars show the direction and velocity of the wind. Winds blow nearly parallel to the isobars. On the average, they blow at an angle of 20° across the isobars, directed away from high pressure and toward low pressure. The distance in miles between isobars divided into 2500 will yield the approximate surface wind velocity ($V = 2500/D$). The numbers at the ends of the isobars are pressure values of the isobars shown in millibars on one end and inches of mercury on the other. Winds blow clockwise about regions of high pressure and counterclockwise about regions of low pressure. The high cell over the southeastern part of the U. S. is therefore feeding warm moist air over the eastern part of the country. A double low center is located just east of the Rockies in the Saskatchewan-Dakota region. The fronts are the heavy lines on which are attached teeth and lobes, according to the symbols listed in the lower left corner of the map. All of the storminess of the day is associated with the low centers or the frontal zones. During the summertime, fronts and cyclonic systems are comparatively weak. In winter, they are well defined and vigorous. The daily weather map is useful to the layman in interpreting forecasts and in amateur forecasting. (P.E.K.)

SYNOVIA. The transparent sticky fluid contained in a joint cavity or tendon sheath. It is secreted by the synovial membrane, the shiny smooth lining membrane of a joint or tendon sheath. The fluid serves as a lubricant to the joint or tendon so that no friction occurs between opposing surfaces. (R.S.M.)

SYNOVITIS. Inflammation of a **synovial** membrane characterized by an increase in synovial fluid, swelling, pain about the involved joint. If the fluid in a joint becomes infected, suppuration may occur; surgical treatment to drain the pus from the joint may be necessary. (D.M.H.)

SYNTEXIS. The term proposed by Loewinson-Lessing, in 1899, for the generation of **magmas** either by remelting or assimilation of portions of the **lithosphere** regardless of the type or variation of its lithology. (Contrast with **Anatexis.**) (R.M.F.)

SYNTHETIC DIVISION. Synthetic division is an abbreviated process using detached coefficients for find-

ing the quotient of a polynomial in one variable x by a divisor of the form $x - r$, where r is a constant. It may be indicated thus:

To divide the polynomial $a_0x^4 + a_1x^3 + a_2x^2 + a_3x + a_4$ by $x - r$, the following scheme is computed:

$$\begin{array}{lllll|l} a_0 & a_1 & a_2 & a_3 & a_4 & r \\ & a_0r & A_1r & A_2r & A_3r & \\ \hline a_0, & A_1=a_0r+a_1, & A_2=A_1r+a_2, & A_3=A_2r+a_3, & R=A_3r+a_4 & \end{array}$$

Then the quotient is $a_0x^3 + A_1x^2 + A_2x + A_3$ and the remainder is R. A similar process applies to a polynomial of any other degree.

The synthetic division process may be described in words by the following rule:

To divide a polynomial in one variable x by a binomial divisor of the form $x - r$, arrange the polynomial in descending powers of x, as $a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n$.

Arrange the detached coefficients $a_0, a_1, \cdots, a_n$ in order in the first line, supplying any missing power of x with a zero coefficient, and write r at the right.

Bring down a_0 in the first place in the third line. Multiply a_0 by r, write the product in the second line under a_1, and write their sum in the third line directly underneath; multiply this sum by r, add the product to a_2, and write the sum underneath in the third line, etc., continuing in the same way until finally a product is added to the last coefficient a_n.

Then the last sum in the third line is the remainder, and the preceding sums are the coefficients of the powers of x in the quotient, beginning with x^{n-1} and arranged in descending order.

If the remainder in this synthetic process is zero, the divisor is shown to be a factor of the given polynomial. (L.L.S.)

SYNTHETIC SUBSTITUTION. If the **synthetic division** process is carried out with a **polynomial** $P(x)$ and a divisor $x - r$, by the **remainder theorem** the last result R is the value $P(r)$ of the polynomial $P(x)$ when we substitute r for x; in this case, if we are concerned only with the remainder R (and not with the quotient), we may call the process synthetic substitution. (L.L.S.)

SYNTHETIC RESINS. Plastics.

SYPHILIS. An infectious disease, congenital or acquired, caused by the spirochete, *Treponema pallidum.* Syphilis is characterized by primary and secondary stages during which it is highly contagious, and a noncontagious, late or tertiary stage, marked by involvement of many organs and tissues. In the congenital form there is no primary lesion and late manifestations predominate.

The early history of syphilis is not entirely clear. It is thought by some historians that the disease was first introduced into Europe by Columbus' returning sailors, and subsequently spread through Italy where it became a great scourge, by the soldiers of Charles VIII. Another view is that the disease has existed in civilized man since antiquity. Early Egyptian and Assyrian inscriptions as well as bony changes found in mummies are interpreted as supporting this theory. In the Middle Ages, syphilis occurred in severe, widespread epidemics with enormous mortality rates. Later it became a milder disease, and its venereal nature was recognized. It was not until 1905, when Schaudinn discovered the *Treponema pallidum* to be the causative organism, that syphilis and **gonorrhea** were recognized as two distinct diseases. The next landmarks were the development of the diagnostic **Wassermann Reaction** in 1906 and the discovery in 1908 by Ehrlich of salvarsan (**Arsphenamine,** "606") which is a highly effective remedy against the disease.

It is estimated that 10% of the population of the United States is infected with syphilis. The incidence varies widely in different groups, from less than 1% to 25% or higher. It is especially high in Negroes.

1. *Acquired Syphilis.* Syphilis is usually transmitted during sexual intercourse. Occasionally an extragenital sore occurs—on the lip or finger—from kissing or from contact with contaminated material, drinking glasses, etc. The causative agent is a motile "corkscrew" spiral organism which abounds in primary and secondary lesions. The spirochetes gain entry through an abraded surface, usually on the genital organs. In the male, the primary sore is commonly on the penis, where it is easily seen. In the female, it is found either on the mucous surface of the **vulva** or within the **vagina** where it may remain unnoticed.

The primary stage is marked by the appearance of the **chancre,** which develops at the site of invasion, usually 2–4 weeks after exposure. Before the chancre develops, the organisms often have invaded the body tissues by way of the lymph channels and blood stream. A fully developed chancre appears as a clean, slightly raised, hard, circumscribed **ulcer,** which exudes a thin, highly infectious secretion. By dark-field microscopic examination, this secretion can be seen to teem with spirochetes. The lesion is painless, but tender lymph nodes may develop in the groin. The blood Wassermann test is usually negative throughout the primary stage and the diagnosis can be made only by finding the spirochetes in the chancre.

The secondary stage begins 6 weeks to 6 months after the primary. By the time of onset of this period, the organisms have invaded the tissues, and the body's defense reactions are active. **Antibodies** are being produced, and the Wassermann reaction is positive. The second stage may be so mild as to pass unnoticed, but it is usually ushered in with a rash over the skin and **mucous membranes.** The eruption is extremely variable and may imitate any skin disease. The commonest type is the macular, in which the lesions consist of flat, or slightly raised, rose-colored spots, most prominent over the abdomen and chest. Characteristic features of the secondary eruption are its symmetrical distribution, painless, non-itching nature, and its tendency to appear on the palms and soles. Its duration is variable from weeks to months, and it may fade and leave a faint pigmentation for a time. With treatment the rash disappears promptly. Spirochetes are present in skin and mucous-membrane lesions, and are particularly easy to demonstrate in the soft moist sores on the genetalia, the condylomata.

Constitutional symptoms in the secondary stage are usually mild. They consist of sore throat, slight fever, headache, and some enlargement of the superficial lymph nodes.

The latent period is the interval between the secondary and tertiary phases of the disease. During this time, the patient may enjoy excellent health, and be unaware that he has syphilis. The duration is variable—from a few weeks to many years—even 25 or 30. During this time, the various organs and tissues are harboring spirochetes, but these are inactive, hibernating as it were.

The tertiary stage is the late picture, which is usually seen only in untreated syphilis. It is marked by the development of **gumma,** tumor-like masses in the skin and visceral organs, and inflammatory changes in the cardiovascular and central nervous systems. Since any organ or tissue may be attacked in tertiary syphilis, the signs and symptoms are extremely varied.

The most common types of tertiary syphilis are those involving the cardiovascular and central nervous systems. Cardiovascular involvement usually appears earlier—10 to 15 years after infection. It occurs as **aortitis,** aortic **aneurysm** and sometimes **coronary occlusion.** In syphilitic heart disease, aortitis is commonly followed by insufficiency of the aortic valve. This mechanical defect puts a tremendous strain on the heart, which compensates by **hypertrophy** of the mus-

cle. Eventually the strain is too great for the reserve, and **heart failure** and finally death are the result.

Central nervous system syphilis may not develop for 30 years after the primary infection. It occurs as a **meningitis**, as an arteritis or **inflammation** of the small cerebral vessels with secondary changes in the brain tissue, and as involvement of the cells of the brain and cord in **tabes dorsalis** and **paresis**. The latter two are discussed elsewhere under their respective headings.

2. *Congenital Syphilis.* The congenital type of the disease is transmitted only through the mother who may have acquired her disease before or after conception. The spirochetes reach the fetus through the **placenta**, and disseminate widely through the fetal organs. In the most severe forms of infection, the child may show at birth an extensive skin eruption, fissures about the angles of the mouth and nose, the characteristic nasal discharge, "snuffles," bone lesions, and enlargement of the liver and spleen. Underdevelopment and poor nutrition are conspicuous; such a child rarely lives longer than a few days. In other instances, the infant may appear normal at birth, yet after a few months develop the typical signs and symptoms of the disease.

Children who survive the active congenital disease, or those in whom the infection remains latent, often show certain permanent stigmata which make the diagnosis apparent at a glance. "Saddle nose" and deformed teeth (Hutchinson's teeth)—peg-shaped notched incisors, which are widely spaced—are highly characteristic. Bony lesions, inflammation of the cornea of the eye (interstitial keratitis), deafness, and central nervous system syphilis such as occurs in the acquired form, are also seen in children with congenital syphilis.

3. *Prognosis and Treatment.* Syphilis can be cured, and congenital syphilis can be prevented. The success of treatment depends largely on the duration of the disease. If begun during the first few weeks or months after infection, proper treatment results in permanent cure in almost all instances. In the late, or tertiary stage when irreparable tissue damage has occurred, cure is not possible in the sense of a return to normal structure and function, although arrest of the disease and control of the symptoms can often be accomplished.

For many years, the arsenical drugs, **arsphenamine**, neoarsphenamine, Mapharsen, etc., used alternately with **bismuth**, have been the drugs of choice. Neoarsphenamine intravenously at weekly intervals for 6 weeks, alternating with 6 weekly injections of bismuth intramuscularly continued over a period of a year and a half, is the usual routine. Continuation of treatment for at least a year after the Wassermann test becomes negative is also included in most schemes of treatment. Congenital syphilis is treated similarly but more cautiously. Pregnant women found to be syphilitic are given more intensive arsenical therapy, especially just prior to delivery.

The accepted scheme for treatment is now undergoing considerable change because of the introduction of massive arsenotherapy and the advent of **penicillin**. Only for primary and secondary stage cases of syphilis is massive therapy used. The entire treatment consists of a total of 1.2 grams of Mapharsen given slowly by continuous intravenous drip 7–10 hours per day for several days. So far, good results and few toxic effects have been found. Penicillin is also being used in the treatment of acute primary and secondary syphilis. The drug is given in large doses over a period of several days, and the early results have been excellent. Further evaluation of the rapid treatments must await the passage of time.

In tertiary syphilis, the problems of treatment are somewhat different. Less intensive therapy is recommended. In central nervous system diseases, tabes and paresis, **tryparsamide** and fever therapy, either with malaria or a "hot box" are used. Iodides, neoarsphenamine, and bismuth are used cautiously, especially in cardiovascular syphilis. (D.M.H.)

SYRINX. **Sound Production.**

SYSTEM. For the use of this term in geology, see **Period.**

SYSTEMIC HEART. The principal **heart** of the **cephalopod** mollusks, in contrast with the supplementary **branchial hearts**. The systemic heart includes two or four auricles which receive blood from the gills. The blood passes from the thin-walled auricles into a single muscular ventricle whose contractions propel the liquid through the arteries to the body. (A.W.L.)

SYSTEMS OF ALGEBRAIC EQUATIONS. In the consideration of **equations** with more than one unknown, we may deal with single equations in several unknowns or with systems of such equations.

An **algebraic equation** with more than one unknown will, in general, be satisfied by an unlimited number of sets of values of the unknowns; such an equation is called an indeterminate equation.

A set of algebraic equations with more than one unknown is said to form a system when the equations are considered together with the object of determining whether they are satisfied by one or more sets of values of the unknowns. The term "simultaneous equations" is often used to mean a system of equations.

A solution of a system of equations with more than one unknown is any set of corresponding values of the unknowns which satisfy the equations of the system. (L.L.S.)

SYSTEMS OF CIRCLES. **Circle.**

SYSTEMS OF EQUATIONS INVOLVING QUADRATICS. **Quadratic Equations, Systems of.**

SYSTEMS OF LINEAR ALGEBRAIC EQUATIONS. **Linear Equations, Systems of.**

SYSTEMS OF LINEAR DIFFERENTIAL EQUATIONS. **Linear Differential Equations.**

SYSTEMS OF LINES. **Straight Line in a Plane.**

SYSTEMS OF LOGARITHMS. **Logarithms.**

SYSTOLE. That period during which the **heart** muscle is contracting and the blood is expelled from the ventricles of the heart into the aorta and arterial system (Compare Diastole). (R.S.M.)

T

T SECTION. This is a network connection which has two elements in series in one line and a third element in shunt from the junction of the two series elements to the opposite line, thereby giving a circuit diagram which looks like a T. (L.R.Q.)

TAB, AIRCRAFT CONTROL. An auxiliary airfoil attached to a control surface for the purpose of reducing the control force or trimming the aircraft. (F.T.M.)

TABES DORSALIS (Locomotor ataxia). A chronic syphilitic infection of the **spinal cord,** occurring as a manifestation of **tertiary** syphilis. It is the end-picture in about 5% of untreated cases. Pathologically, there is a degeneration of the cells of the posterior columns of the cord, and interference, therefore, with the sensations of touch and pain. The nerves of the organs of special sense, particularly the optic **nerve,** are often involved.

The signs and symptoms of tabes are numerous, and do not make their appearance in any set order. Sometimes well-marked neurological signs may be present in the absence of symptoms, or symptoms may be striking long before neurological signs can be detected. So-called lightning pains—severe shooting, lightning-quick pains in the legs are often an early symptom. Others are difficulty in urination, incontinence of urine, loss of sexual power, and diminished vision. Early signs are loss of the tendon reflexes, particularly the knee and ankle jerks, weakness of the eye muscles, changes in the pupils —small, unequal, irregular pupils which react sluggishly to light if at all. Abnormalities of gait are common; they are due to muscular incoordination and loss of the position sense. As the disease progresses, the walk is often characteristic: the foot is raised high, thrown forward forcibly, and slapped to the ground.

Visceral crises are characteristic of tabes. Of these, gastric crises are the most common. In their most severe form they consist of recurrent attacks of excruciatingly severe abdominal pain, accompanied by violent and continuous vomiting. Even **morphine** gives no relief. The crises may last several hours or several days. They may be the only manifestation of central nervous system syphilis.

The trophic disturbances, chronic ulcers, Charcot joints, which result from loss of sensation and therefore absence of reactions which normally protect the part, usually occur late in the disease. Charcot joints (named for the neurologist who described them) are tremendously deformed joints with marked destruction and abnormal mobility. The knees, hips and ankles are the most commonly affected.

The diagnosis of tabes is established on the basis of the history, physical findings, and a positive spinal-fluid Wassermann test. Tabes often occurs in combination with **paresis;** the picture is then spoken of as taboparesis.

Treatment is less effective in tabes than in other forms of neurosyphilis. Early cases sometimes do well on neoarsphenamine, but more fully developed ones require tryparsamide and fever therapy. The latter is given artificially in a specially constructed cabinet or "hot box," or by the inoculation of malaria parasites and the production of tertian or vivax **malaria.** The prognosis for cure is never very hopeful in advanced tabes, but even then improvement and remission may occur. (D.M.H.)

TABLING. Classification.

TACHYLYTE or **TACHYLITE.** Pure tachylite is a natural, **basic** black glass which may form along the chilled contacts of **dikes** or **sills.** It also occurs as a rind on basic **pillow lavas** which have been suddenly chilled by plunging into water. Occasionally it forms entire flows from certain Hawaiian volcanoes. (R.M.F.)

TACONIC REVOLUTION. Ordovician.

TACONITE. Term for the ferruginous **cherts** associated with the iron ores of Lake Superior district. (R.M.F.)

TACTILE ORGANS. Organs of touch. Sensory organs located at the surface of the body which are stimulated by pressure. The chief tactile organs of the human body are known as tactile corpuscles. They consist of an elliptical bulb about $\frac{1}{300}''$ or less in length, enclosed in a connective tissue sheath and divided incompletely by plates of the same tissue. From one to several coarse nerve fibers enter the corpuscle and follow a winding course inside, ending between or on the connective tissue cells. These corpuscles are especially abundant in the skin of the finger tips and in other parts where the sense of touch is highly developed, hence there can be no reasonable doubt that they serve this sense. They are related to other corpuscles of more limited occurrence which may also be tactile, and are supplemented in the skin by free nerve endings, some of them expanded into disklike nets, which are regarded as tactile.

In many invertebrates hairlike projections at the surface of the body serve for ready reception of tactile stimuli and in the vertebrates true hairs, often bristle-like, transmit such stimuli to the nerve endings at their bases. From the sensitiveness of the human scalp to light contacts transmitted through erect hairs it is easy to judge the value of these tactile hairs. They are well illustrated by the whiskers or vibrissae of the cat and other mammals. (A.W.L.)

TAFFRAIL LOG. Patent Log.

TAGMA. Body regions of **Arthropoda.** The bodies of these animals consist typically of the head, **thorax,** and abdomen but many forms show a confluence of parts or further subdivision. The **centipedes** and millipedes (**Diplopoda**), with a few related forms, have only a head and a long segmented body also called the trunk. **Arachnida** and **Crustacea** have a **cephalothorax** or prosoma in which the segments belonging to the head and thorax are not sharply separated, and a segmented abdomen or opisthosoma. Subdivisions of the abdomen such as appear in the centipedes are the anterior **mesosoma** and the posterior **metasoma,** sometimes called the postabdomen. The plural of tagma is tagmata. (A.W.L.)

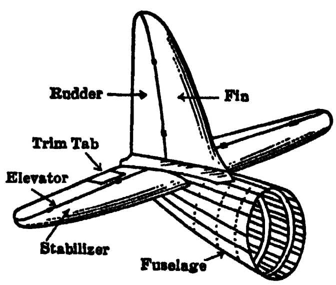
TAHR. Mammalia, Artiodactyla. A wild **goat,** ***Hemitragus jemlaicus,*** of the Himalayas. This species, together with two other Asiatic species, differs from the typical goats in the lack of a beard. It is found in forested regions at high altitudes but does not enter the open country of Tibet. (A.W.L.)

TAIL. A solid prolongation of the axis of the vertebrate body at the end opposite to the head. The tail contains a portion of the spinal column together with blood vessels, nerves and muscles, but it is entirely pos-

terior to the body cavity which is confined to the trunk. By association with the tail, this end of the body is known as the caudal end, a term applied to all bilaterally symmetrical animals. Many caudal appendages are called tails by a similar association, although they are not true tails. Thus the tail of the fish in the ordinary use of the term is properly the tail fin.

The tails of many **vertebrates** are without apparent value but in some of the **primates** they are prehensile appendages, used in climbing, and the hoofed animals use them in driving away insects. The tail of the **alligator** is an effective weapon. (A.W.L.)

TAIL, AIRPLANE. The rear part of an airplane, usually consisting of a group of stabilizing planes, or fins,



Typical cantilevered empennage.

to which are attached certain controlling surfaces such as elevators and rudders; also called "empennage." (F.T.M.)

TAILSTOCK. Lathe.

TAKE-OFF. Airplane.

TAKIN. Mammalia, Artiodactyla. A hoofed animal, *Budorcas taxicolor,* found in eastern Tibet and adjacent regions. It is a moderately large animal of heavy build, with strong curved horns. Related to the goats. (A.W.L.)

TALC. The mineral talc is a **magnesium silicate** corresponding to the formula $H_2Mg_3(SiO_3)_4$ which occurs as **foliated** to fibrous masses, its **monoclinic** crystals being so rare as to be almost unknown. It has a perfect basal cleavage the folia non-elastic although slightly flexible; it is sectile and very soft; hardness, 1; specific gravity, 2.5–2.8; luster, waxlike or pearly; color, white to gray or green; translucent to opaque. It has a distinctly greasy feel. Talc is a **metamorphic** mineral resulting from the alteration of silicates of magnesium like **pyroxenes, amphiboles, olivine** and similar minerals. It is found chiefly in the metamorphic rocks, often those of a more basic type due to the alteration of the minerals above mentioned. Of the many foreign localities may be mentioned the Austrian Tyrol, the St. Gotthard district of Switzerland, Bavaria and Cornwall, England. In Canada talc is found in Brome County, Quebec and Hastings County, Ontario. In the United States well-known localities are to be found in Vermont, New Hampshire, Massachusetts, Rhode Island, New York, Pennsylvania, Maryland and North Carolina.

A coarse grayish-green talc rock has been called soapstone or steatite and was formerly much used for stoves, sinks, electrical switchboards, etc. Talc finds much use as a cosmetic, for lubricants and as a filler in paper manufacturing. Most tailor's "chalk" consists of talc. The origin of the word talc is not definitely known. (E.S.C.S.)

TALLOW. Esters.

TALUS. The mass of coarse rock fragments which accumulate at the foot of a cliff as a result of the processes of weathering and gravity. In Great Britain the term scree is used for such material. (R.M.F.)

TAMANDUA. Mammalia, Edentata. The lesser **anteater** of Central and South America, a species related to the great anteater and of similar form. It differs in the short-haired prehensile tail, which is used in climbing. The name is that of the genus, derived from the Portuguese. (A.W.L.)

TAMARAO. Mammalia, Artiodactyla. A small **buffalo** native to the island Mindora in the Philippines. It is related to the Indian buffalo and to the anoa. (A.W.L.)

TANAGER. Aves, Passeriformes. An American bird (**Aves**) of brilliant coloration, related to the finches. The tanagers are chiefly birds of the Central and South American tropics, where about 400 species are found. Of the few species that enter the United States only the scarlet tanager, *Piranga erythromelas,* is widely known. The brilliant red of its body, contrasting with the black wings and tail, makes it one of our most striking species. The dull olive plumage of the female exemplifies a common contrast between the sexes in the entire group. (A.W.L.)

TANAIDACEA. Crustacea.

TANG. Drilling.

TANGENT OFFSET. A method occasionally used by surveyors to reduce field notes or area or route surveys to map form is known as plotting by "tangent offsets." A small-scale sketch of the traverse made with a protractor and scale, will greatly facilitate the plotting since it serves as a guide for locating the initial line so that the traverse will fall within the limits of the paper.

The use of tangent offsets is illustrated in Fig. 1. The initial line *ab* is located by means of the sketch men-

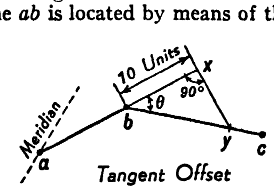


Fig. 1.

tioned above and prolonged a distance of 10 units to a point *x* where a perpendicular is erected. The line *xy*, equal to the natural tangent of angle θ multiplied by 10 units, is then plotted on the perpendicular. The angle θ may be obtained by direct measurement of the **deflection** angles in the field or by taking the difference of the **bearings** or **azimuths** of the two lines. A line connecting *b* and *y* will give the direction of *bc* and serves as a base upon which to lay off the distance from *b* to *c* as measured in the field. Each successive course may be plotted in relation to the preceding course by the method just described. To avoid errors in plotting it is well to occasionally check the bearing of a particular line in relation to a fixed meridian by means of scaled distances.

A method known as "offsets from the tangent" is frequently used for laying out **circular curves** in the field. The geometry of the method is illustrated in Fig. 2.

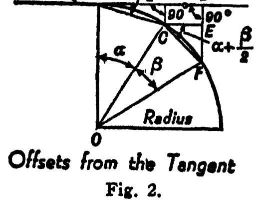

Fig. 2.

In order to lay out the curve it is necessary to locate points such as C and F in respect to the tangent through A which is the point where the curve begins. A transit is set up at A, sighted in the direction of the tangent AD, and points B and D located by taped distances. The transit is then set up over B, sighted back on A and a 90° angle turned. The tangent offset BC is taped which locates point C. Point F may be located in a similar manner. The coordinates used in the field operations are calculated from assumed **chord** lengths such as AC and CF which fix the value of the angles α and β respectively when the radius of the curve is given. (C.W.C.)

TANGENT PLANE TO A SURFACE. A straight line is said to be tangent to a surface at a given point P if it is the limiting position of a secant line through P and a neighboring point P' on the surface when P' is made to approach P along the surface.

All tangent lines to a surface at a given point lie in a plane, which is called the tangent plane to the surface at the given point.

If the equation of a surface in rectangular coordinates is $F(x, y, z) = 0$, the tangent plane at the point (x_1, y_1, z_1) has the equation

$$F_x(x_1, y_1, z_1)(x - x_1) + F_y(x_1, y_1, z_1)(y - y_1) + F_z(x_1, y_1, z_1)(z - z_1) = 0,$$

where $F_x(x_1, y_1, z_1)$ is the value of the **partial derivative** $\frac{\partial F}{\partial x}$ at the point (x_1, y_1, z_1), and similarly for the other coefficients. The equation of the tangent plane is often written

$$\frac{\partial F}{\partial x}(x - x_1) + \frac{\partial F}{\partial y}(y - y_1) + \frac{\partial F}{\partial z}(z - z_1) = 0,$$

but it must be understood that the values of $\frac{\partial F}{\partial x}$, etc., must be taken at the point of tangency.

If the equation of the surface in rectangular coordinates is of the form $z = f(x, y)$, the equation of the tangent plane at (x_1, y_1, z_1) is

$$f_x(x_1, y_1)(x - x_1) + f_y(x_1, y_1)(y - y_1) = z - z_1.$$

A normal line to a surface at a point P_1 is the line through P_1 which is perpendicular to the tangent plane to the surface at P_1.

If the equation of the surface in rectangular coordinates is of the form $F(x, y, z) = 0$ or of the form $z = f(x, y)$, the equation of the normal (line) at a point (x_1, y_1, z_1) is, respectively,

$$\frac{x - x_1}{F_x(x_1, y_1, z_1)} = \frac{y - y_1}{F_y(x_1, y_1, z_1)} = \frac{z - z_1}{F_z(x_1, y_1, z_1)},$$

or

$$\frac{x - x_1}{f_x(x_1, y_1)} = \frac{y - y_1}{f_y(x_1, y_1)} = \frac{z - z_1}{-1}.$$

(L.L.S.)

TANGENTS AND NORMALS TO PLANE CURVES. Consider a plane curve (Fig. 1); take a point P_1 on the curve, also take a second point P_2 on the curve and draw the secant line P_1P_2. If as P_2 approaches P_1 along the curve, the secant P_1P_2 approaches a limiting position P_1T, this line P_1T is called the tangent to the curve at P_1.

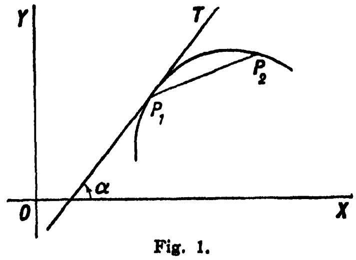

Fig. 1.

Another form of definition of tangent to a curve, which can be shown to be equivalent to the preceding, is the following (Fig. 2): Let a line l be drawn cutting the curve in two points P and Q, and let this line move parallel to itself so that P and Q move closer together: then if when P and Q approach coincidence, the secant line PQ approaches a limiting position P_1T, this line P_1T is called the tangent to the curve at P_1.

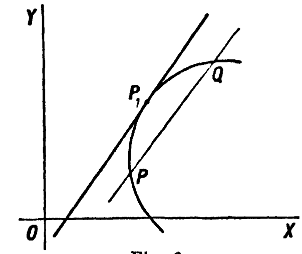

Fig. 2.

The **slope** of the tangent to a curve at a point P_1 is often called the slope of the curve at P_1.

If the equation of a curve in rectangular coordinates is $y = f(x)$, then the slope of the tangent to the curve at a point (x_1, y_1) is given by the value of the **derivative** $f'(x_1)$ at the value $x = x_1$. The equation of the tangent at (x_1, y_1) is then

$$y - y_1 = f'(x_1)(x - x_1).$$

If the equation of a curve is given in **polar coordinates** as $r = f(\theta)$, the direction of the tangent at a point (r_1, θ_1) is determined by $\tan \psi_1 = r_1/f'(\theta_1)$, where ψ_1 is the angle between the **radius vector** to the given point and the tangent at this point; the angle α, which the tangent makes with the X-axis (or polar axis) is then $\alpha_1 = \theta_1 + \psi_1$. (Fig. 3).

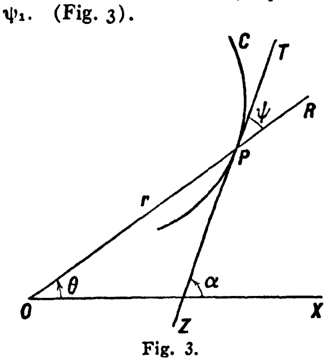

Fig. 3.

A normal to a curve is a straight line perpendicular to a tangent to the curve; its slope is the negative reciprocal of the slope of the tangent. If the equation of the curve in rectangular coordinates is $y = f(x)$, then the equation of the normal at the point (x_1, y_1) is

$$y - y_1 = -\frac{1}{f'(x_1)}(x - x_1).$$

If the tangent and normal at P_1 intersect the X-axis at T and N respectively, then we define: P_1T = length of tangent at P_1, and P_1N = length of normal, at P_1 (Fig. 4).

The projections on the X-axis of the length of tangent P_1T and the length of the normal P_1N are called the **subtangent** and **subnormal** at P_1. Then subtangent =

TM_1, subnormal $= M_1N$, where M_1 is the projection of P_1 on $X'X$.

If m is the slope of the tangent at $P_1(x_1, y_1)$, then subtangent $= -y_1/m$, subnormal $= my_1$. (L.L.S.)

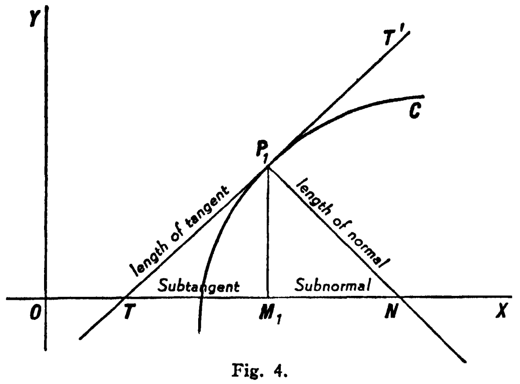

Fig. 4.

TANGERINE. Citrus Fruits.

TANIPAN. Carapato.

TANK. Pressure Vessels.

TANK CIRCUIT. This is the name often given to the inductance-capacitance parallel circuit in the grid or plate circuit of a vacuum tube **oscillator** or class C **amplifier.** It is the resonant frequency of this circuit which determines the output frequency of the vacuum-tube stage. In this type operation the tube is operating in pulses rather than continuously as in Class A service but the tank circuit provides the electrical fly-wheel action needed to keep the circuit operating between pulses. (L.R.Q.)

TANNING DEVELOPMENT. The use of a tanning developer to obtain a hardened gelatin relief for use in color photographic printing. The oxidation products of certain developing agents, such as pyrogallol and hydroquinone, tan gelatin, thus making it insoluble in warm water. The oxidation products are released during the development of a silver image in a photographic emulsion and are in the position occupied by the image and proportional to the density of developed silver. The hardened gelatin thus corresponds in position with the silver image which caused it. If such a film is treated with hot water, the gelatin not in contact with the silver washes away leaving a hardened gelatin-relief image.

Such a relief image may be dyed and the dye transferred to another support by **imbibition.** The silver may be left in the relief or it may be removed. It is also possible to put colored pigments into the emulsions during manufacture in which case the image obtained after washing in hot water will be properly colored. Such a pigmented relief image may be stripped off onto another support in register with the other colorant images making up the color reproduction or it may be used as part of a color transparency. (H.C.C.)

TANNINS. Tannins are substances generally related to one of the **phenols,** pyrogallol or catechol, and they are found in many plants. By their action on animal skins they cause changes which make the skins resistant to decomposition and at the same time leave them flexible and very strong, greatly improved in wearing qualities. Skins so treated are said to be tanned, and are called leather. Tanning is a very old art, having been practiced in China since long before the Christian era. It was also known to the American Indian before the arrival of the white man.

Tannins are found in various parts of the plant, appearing frequently in leaves, and in the cortical tissues of stems. Tannins may be found in the walls of cells or in the **vacuoles;** often their presence causes the cell to appear dark-colored. Many fruits, such as the persimmon, contain large amounts of tannin, especially before they are ripe. Wound tissues, and especially the **hypertrophied** tissues known as **galls,** which result from the bites of certain insects, are particularly rich in tannins. Tannins appear to be by-products of the **metabolism** of the plant. When present in the epidermal cells they are seen as a deterrent to snails, which might injure the leaf by feeding on it, to parasitic fungi which might otherwise enter the leaf tissue, and as a protection against desiccation, since they form substances impervious to water.

An important source of tannin is the bark of various trees, especially that of the hemlock, and several species of **oaks.** The bark is removed from the tree in sheets approximately 4′ long. Stripping from the tree is usually done in the spring, when the **cambial** cells are most active and the bark separates easily. To remove the bark two rings are cut completely through the bark and round the tree. A longitudinal slit is made through the bark from one ring to the other. Using a blunt long-handled implement the bark is then pried loose from the tree and allowed to dry. By felling the tree, the entire trunk may be stripped of its bark in this way. The dried bark is shipped to mills which extract the tannin. Tannins from these barks are used to tan leather for shoe-soles and other heavy leathers. The wood of the chestnut tree yields a tannin similarly used. The available supply of tannin from these sources does not meet the demand; so many foreign plants are now being used.

Of these the most important are small trees of the genus *Schinopsis,* natives of the southern part of South America, including southern Brazil, Bolivia and other southern countries. These trees are known by the name "quebracho," which means "ax-breaker," because of their very hard, dense, heavy, dark-red wood, which is cut with difficulty. The heartwood of the tree contains 20–27% tannin, which is obtained by cutting the wood into small chips and extracting with water. This tannin is often used in combination with tannins from other plants.

The bark of many other trees yields large amounts of tannins. Among these are the **mangrove,** and several species of *Acacia,* known as wattles, natives of Australia. Fruits also may be a source of tannin. The fruits of *Terminalia chebula,* called myrobalans, are an important tannin source. The tree is a native of tropical Asia. Another fruit rich in tannin is divi-divi, the pods of a legume, *Caesalpinia coriaria,* which is native in tropical America and the West Indies. Sumac leaves, especially those of *Rhus coriaria,* a shrub or small tree native in Mediterranean Europe, are rich in tannins. To obtain the tannin, the plants are cut down and spread out to dry. The leaves are then removed from the stems and packed into bags which are shipped to the mills. There the leaves are first cleaned and then ground up. The tannins from this source are used in manufacturing fine leathers, like glove leathers. Leaves of other species of sumac, including the various American sumacs, also contain tannins which, however, are not so valuable and are little used.

Tannins are solids, soluble in water or alcohol, usually extracted by hot water, insoluble in **ether, chloroform, carbon** disulfide, **benzene,** soluble in alcohol-ether mixture, and in ethyl acetate, possessing a bitter astringent taste. Tannins (1) yield precipitates with gelatin, proteins (connected with the property of making leather from hides), **alkaline** salt solutions of many heavy metals, e.g., **lead** acetate, **copper** acetate (precipitate brown), **antimonyl** tartrate, concentrated dichromate solution, also by **chromic** acid (1% CrO_3), (2) yield dark blue or green coloration with **ferric** salt

solutions, (3) in alkaline solution, absorb **oxygen** and yield dark colored solution, (4) with iodine in potassium iodide plus small proportion of ammonium hydroxide, yield red color, (5) with dilute solution potassium ferri**cyanide** in ammonium hydroxide, yield a red to brown coloration (care not to use excess reagent).

REACTIONS OF TANNINS

Reagent	Pyrogallol Tannins	Catechol Tannins	Phloroglucinol Tannins
	1. Oak wood 2. Chestnut wood 3. Galls 4. Sumac 5. Myrobalans 6. Divi-divi	1. Pine barks 2. Oak barks (but not oak wood, fruit or galls) 3. Acacia 4. Quebracho wood 5. Cassia bark 6. Mangrove bark 7. Cutch 8. Gambier	1. Gambier
With ferric salt solution	Dark blue color	Greenish-black color	
Bromine water	No precipitate	Yellowish to brownish precipitate (excess reagent)	
Sulfuric acid concentrated		Water extract yields dark red or crimson layer at the junction, on diluting turns pink	
On leather	Forms a bloom	No bloom formed	
Acid, boiled		Red insoluble phlobaphenes	
Moisten pine wood with water extract, add concentrated hydrochloric acid.			Red to purple color

Tannins are used (1) in making hides and skins into leather, after preparation of the hide, e.g., dehairing, (2) in the manufacture of inks, (3) in dyeing, as a mordant, (4) in the clarification of solutions, e.g., wine, and (5) as a source of gallic, pyrogallic, and tannic acids. (R.K.S., R.M.W.)

TANTALITE. A mineral oxide of iron, manganese, columbian, and tantalum. Crystallizes in the orthorhombic system. Hardness, 6–6.5; specific gravity, 5.20±; color, brown to black; transparent in thin sections. (Compare with **Columbite.**) (R.M.F.)

TANTALUM. Symbol: Ta. Atomic number: 73. Atomic weight: 181.4. Density: 16.6. Melting point: 2850° C. No isotope, but of single atomic form: 181.

Tantalum is a slightly bluish metal; ductile, malleable, and when polished resembles **platinum**; burns upon being heated in air; insoluble in **hydrochloric** or **nitric acid,** but soluble in hydrofluoric acid or a mixture of hydrofluoric and nitric acids. Tantalum metal was used as a filament for the incandescent electric lamp, but has been superseded by **tungsten.** Ductile tantalum and tantalum-clad steel are used for chemical apparatus as a substitute for platinum; for surgical instruments; as a resistant **electrode;** in electric current rectifiers; in vacuum technique because of its high capacity for absorbing carbon monoxide, nitrogen, hydrogen, and oxygen. Tantalum carbide is an important *abrasive.* Discovered by Ekeberg in 1802.

Tantalum occurs, usually with **columbium,** in **tantalite** ($Fe(TaO_3)_2$, 85% Ta_2O_5), **samarskite** (20% Ta_2O_5) chiefly found in Western Australia, and South Dakota. Recovered along with columbium by fusion with **potassium** hydrogen sulfate in the residue after subsequent extraction with water. Tantalum and columbium are separated by fractional crystallization of the **potassium** fluorides, tantalum concentrating in the crystals and columbium in the mother liquid. Tantalum metal may be obtained by **electrolysis** of fused potassium tantalum fluoride, or by reduction of the pentoxide with **carbon** in the **electric furnace.** On heating, the metal absorbs large volumes of **nitrogen** and **hydrogen,** which are only removed by heating to fusion in a vacuum. Chemically related to **vanadium** and columbium.

Chloride: Tantalum pentachloride ($TaCl_5$), white crystals, melting point 221° C., boiling point 242° C.

Fluoride: Tantalum potassium fluoride (K_2TaF_7).

Oxide: Tantalum dioxide (TaO_2), brown solid; tantalum pentoxide (Ta_2O_5), white solid.

Tantalates: (tantalum of valence plus 5).

Tantalic acid: ($HTaO_3$), gelatinous precipitate by addition of water to tantalum pentachloride. (R.K.S.)

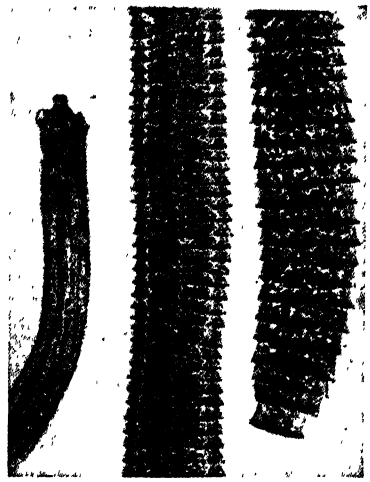
TAPACULO. Aves, Passeriformes. *Pteroptochus.* A South American bird (**Aves**) superficially like the wrens. The several species are distributed over the entire continent. (A.W.L.)

TAPE WORM. Tape worms (**cestodes**) are parasitic flat worms, segmented in form, and having a head portion (**scolex**) which can continually give rise to new segments. As long as this head remains in the human intestine the worm has not been destroyed, for from this an entire new body can grow. These worms do not possess a digestive canal and are usually **hermaphrodites.** Nourishment is absorbed from the host through the surface of the worm's body. Fertilization is accomplished between segments of different worms or between different segments of the same worm.

Certain tape worms apparently do not greatly harm the host while others may produce marked symptoms such as severe anemia. Larval forms of the worm may invade the various tissue of man in certain forms of cestode infestation and cause serious trouble.

The kinds of tape worms commonly found in man are as follows: 1. The fish tape worm (*Diphyllobothrium latum*) is found throughout the world and infests humans when infected fish, which has not been thoroughly cooked, is eaten. Serious symptoms may not develop

for years, but often a condition resembling pernicious anemia develops. Recovery follows the expulsion of the worm. 2. The Dwarf tape worm (*Hymenolopsis nana*) is also found throughout the world and is the most common of tape worms occurring in the United States. It is of small size, being only a few centimeters long, but when present in large numbers the worms cause diarrhea, loss of weight and appetite, and nervous



Dwarf Tapeworm, head, middle segments, and terminal segments. From stained and mounted specimens (photographs ×30). (*Todd and Sanford, Clinical Diagnosis by Laboratory Methods, W. B. Saunders Co.*)

manifestations. The symptoms disappear when the parasites are expelled. 3. The pork tape worm (*Taenia solium*) is large, measuring 9 to 12′ in length. Most of the symptoms and dangers of this worm are due to the invasion of the tissue by its larval forms. This form is rare in the United States. 4. The beef tape worm (*Taenia saginata*) is common in the world wherever beef is eaten. Cold storage will kill the parasite. The adult forms are extremely large worms, some having been found that measure 30 to 50′ in length. Colic and pain may be present in patients infected with this worm. Spontaneous discharge of a long piece of worm may inform the patient of his guest.

The diagnosis of worm infestation is made by finding either segments of worms or eggs in the feces. The white blood count often reveals an eosinophilia.

Treatment with various antihelminths is usually successful if correctly employed. The drugs most frequently used are oleoresin aspidium, carbon tetrachloride, and hexylresorcinol. (D.M.H.)

TAPER. In conical parts, taper is the difference in diameter per unit of length. A part having diameters of 3″ and 2⅝″ at either end of a 6″ length, is said to have a taper of ¾″ per ft. Twist drills and some shank-type milling cutters are equipped with self-holding taper shanks where the degree of taper is so small that the frictional force between the shank and the socket is sufficient to drive the tool. The Morse Taper is used for lathe centers and twist drill shanks, and is approximately ⅝″ per ft.; the Brown and Sharpe Taper is used for milling cutters, and is approximately ½″ per ft. The Jarno Taper is used on profiling and die-sinking machines, and has a taper of .600″ per ft. Standard taper pins or dowels have a taper of ¼″ per ft. Taper sizes are usually designated by numbers, as a No. 7 B&S, or a No. 3 Morse. Since there is little or no uniformity, it is necessary to refer to tables for machine tool taper dimensions. (H.C.H.)

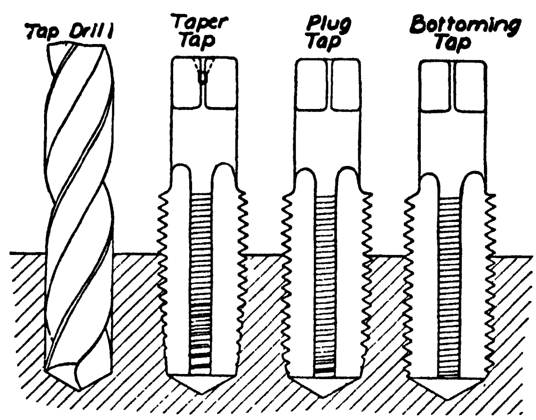
TAPER TURNING. Lathe.

TAPIOCA. Spurge Family.

TAPIR. Mammalia, Perissodactyla. *Tapirus.* Moderately large animals found in the neighborhood of water in the forests and Central and South America and the Malayan region. They reach a length of 8′ and a height of a little over 3′ and are stoutly built. Their most conspicuous characteristic is the short trunk into which the snout is prolonged. Only one of the five species occurs in the Old World.

The natives of the American tropics hunt tapirs for their flesh and hides, although the value of the latter for leather is limited. (A.W.L.)

TAPPING. Tapping is an internal threading process and may be accomplished by hand or by machine. The figure shows the necessary tools and the sequence of operations in threading a blind hole (one which does not



go through the work). The bulk of the metal in a threaded hole is removed by a tap drill which has a diameter equal to or slightly greater than the root diameter of the thread. The threads may be cut by using several taps in succession. The taper tap has from seven to ten chamfered threads. The long chamfer serves as a guide in aligning the axes of the tap and the hole. The plug tap has from three to five chamfered threads and is the most frequently used tap, particularly in machine tapping. In hand tapping it is not as easy to start as the taper tap. The bottoming tap has a chamfer on the first thread only and is never used as a starting tap. It is only employed for finishing blind holes which require threading to the bottom.

Taps are made of carbon or high-speed steel. High-speed steel taps permit more rapid production and hold their cutting edge longer. Carbon steel taps give satisfactory service for occasional jobs and are much less expensive. Taps are made with two, three, or more flutes. The flute serves to form the cutting edge, and provides room for chips. Taps are made with squared shanks for use with a tap wrench, or they may have straight cylindrical shanks for use in chucks in machine tapping.

Through holes may be tapped with a taper tap if the length of the hole does not exceed twice its diameter; in such an instance the taper tap has too much cutting edge in contact at one time, which requires excessive tapping torque and may result in tap breakage. Plug taps or so-called serial taps may be used for long holes. Serial taps are made in sets of three, the first two of which are undersize in outer diameter. The first tap roughs out the thread; the second cuts the thread a little fuller; and the third is used for finishing and bringing the hole to size, thus distributing the work of tapping among three taps. (H.C.H.)

TARANTULA. 1. Arachnida, Araneina. A name applied indiscriminately to many of the large hairy **spiders** of the warmer parts of the Americas, perhaps most commonly to the forms so often imported into temperate latitudes in bunches of bananas. The name comes from the generic name *Tarantula,* which has been applied to an entirely different group of spiders. 2. Arachnida, Pedipalpi. A genus of **whip scorpions.** The application of this name is dependent upon rules of nomenclature which have apparently received no authoritative interpretation. It will undoubtedly remain in popular usage as a name for many large spiders, whatever its scientific disposition. (A.W.L.)

TARDIGRADA. The bear animalcules, a group of minute animals with four pairs of short legs bearing claws. The mouth has piercing stylets and is formed for sucking. Neither respiratory nor circulatory organs are present. Bear animalcules occur in water and in moist places on land, and while they are evidently arthropods, their relations within this **phylum** are uncertain. They are commonly regarded as a separate class. (A.W.L.)

TARN. Cirque.

TARO. Aroids.

TARPAN. Mammalia, Perissodactyla. A wild **horse** of the steppes of central Asia. This species has been regarded as feral rather than a natural species, but this interpretation has been disputed by other authorities. It is in any case closely related to the domestic horse and may be the ancestral form. (A.W.L.)

TARPON. Pisces, Teleostei. *Tarpon.* A large marine fish (**Pisces**) of silvery color, found in the waters of the West Indies, along the Gulf Coast, and northward to a limited extent along the Atlantic coast. It reaches a length of 6′ and is known for its very large scales, which may be 3″ across. Also known as the silver fish, silver king, savanilla, and sabalo.

The tarpon is among the great game fishes but is not commonly regarded as desirable for food. It is eaten in Central America. (A.W.L.)

TARRAGON. Artemisia.

TARSIER. Mammalia, Primates. *Tarsius.* A peculiar animal found on some islands of the Oriental region. It is about as large as a rat and has a very short muzzle and enormous eyes. The hind legs, particularly the ankles, are long, and the tips of the digits are expanded into fleshy disks. The tarsier moves about on its hind legs by springy leaps. It is one of the extreme forms related to the lemurs. (A.W.L.)

TARSUS. 1. The terminal division of the leg of an insect. It consists of five segments in the typical form, the terminal segment bearing a pair of claws. Tarsi are modified in various species by the fusion or loss of segments, and in one genus, *Bittacus,* the terminal joint folds back on the next to form a grasping organ. 2. The shank of the leg of a bird (**Aves**). 3. The proximal portion of the foot of **vertebrates,** containing several tarsal bones. 4. The framework of connective tissue which gives shape to the eyelid. (A.W.L.)

TARTAR EMETIC. Tartaric Acid.

TARTARIC ACID AND TARTRATES. Tartaric acid ($H_2 \cdot C_4H_4O_6$ or COOH·CHOH·CHOH·COOH) is a white solid, melting point of dextro or laevo 170° C. (of racemic, dextrolaevo, about 205° C., of mesotartaric, inactive, 140° C.) (see **Isomerism**), soluble in water, slightly soluble in alcohol, insoluble in ether. Tartrates (like **citrates**) in solution change silver of ammonio-**silver** nitrate into metallic silver. **Potassium** hydrogen tartrate, and **calcium** tartrate, on account of their solubility characteristics, are of importance in the separation and recovery of tartaric acid. The former salt is readily converted into the latter, and the resulting calcium tartrate plus dilute sulfuric acid yields tartaric acid plus calcium sulfate, and the latter may be separated by filtration. Tartaric acid may be obtained by evaporation of the filtrate. Ester: Diethyl tartrate ($COOC_2H_5(CHOH)_2COOC_2H_5$), melting point 17° C., boiling point 280° C. Tartaric acid may be obtained (1) from some natural products, e.g., in the juice of grapes and acid fruits, often in conjunction with citric or **malic acid;** potassium hydrogen tartrate, "argol," in the residue of wine vats, (2) by synthesis. Tartaric acid is a dibasic acid, that is, two series of salts and esters are known. Tartaric acids is used (1) in **baking powders** as potassium hydrogen tartrate ("cream of tartar") with **sodium** hydrogen carbonate ("baking soda"), (2) in medicine, e.g., potassium antimonyl tartrate ("tartar emetic"), (3) in effervescent medicinal salts, (4) in **blue printing** as ferric tartrate, (5) in silvering mirrors—ammonio-silver nitrate yielding smooth deposit of silver. Sodium potassium tartrate ("Rochelle salt," $NaKC_4H_4O_6 \cdot 4H_2O$) is used in medicine, and in the preparation of **Fehling's solution,** which is an alkaline cupric solution made by mixing **copper** sulfate solution, sodium potassium tartrate solution and **sodium** hydroxide solution, and is used as an oxidizing reagent in the case of many organic compounds, such as **glucose** and reducing sugars, and **aldehydes,** with which cuprous oxide, red to yellow precipitate, is formed. (R.K.S.)

TASMANIAN DEVIL. Mammalia, Marsupialia. A Tasmanian animal, *Sarcophilus ursinus,* resembling the badger in its stout build and large head. It is nocturnal in habits, hiding during the day in a burrow or in natural crevices. It eats all kinds of living animals, even killing forms much larger than itself. The species is grouped with the **dasyures** of Australia. (A.W.L.)

TASMANIAN WOLF. Mammalia, Marsupialia. *Thylacinus.* A pouched animal closely resembling the wolves and of similar habits. It is related to the **dasyures.** Also called the thylacine.

Like the wolves of the northern hemisphere, this species has been killed in large numbers for its attacks on domestic animals and is now restricted to the wilder mountainous parts of Tasmania. (A.W.L.)

TASTE BUD. A sensory organ of the **vertebrates,** sensitive to contact with substances in solution and those in a liquid state. A taste bud consists of a spindle-shaped group of cells in the **epithelium** of the vertebrate tongue and in some species in the lining of the mouth and **pharynx.** Taste buds have been reported in the skin of some aquatic animals. The bud includes supporting cells of thick spindle shape and slender taste cells ending with a short taste hair which projects into a minute pit at the free end of the bud. The interpretation of these two types of cells is a subject of disagreement; it is possible that they represent stages in the development of a single form of cell.

The action of taste buds results in four fundamental taste sensations: sweet, sour or acid, salty, and bitter. Perception of these chemical properties is localized in the tissues containing organs of taste, but differentiation of the organs accompanying this localization has not been demonstrated. (A.W.L.)

TATLER. Aves, Charadriiformes. A north American **sandpiper.** *Heteractitis incanus,* the wandering tatler, is found along the Pacific coast of North America,

where it breeds in northern latitudes, and on some of the Pacific islands. (A.W.L.)

TATOUAY. Mammalia, Edentata. The broad-banded **armadillo** of South America, *Cabassous unicinctus*. It is similar to the 6-banded armadillo in many ways. The largest of the group with the exception of the giant armadillo of the same region. (A.W.L.)

TAURUS (The bull) (Map, page 380). Taurus, the second sign of the **zodiac**, is a constellation of very great antiquity, two of its open **clusters, the Pleiades** and the **Hyades**, being frequently referred to in the Bible, and **Aldebaran**, its brightest star, is mentioned by both Homer and Hesiod.

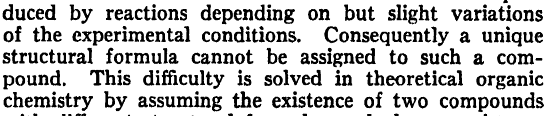
Aldebaran (Alpha Tauri) is the standard first **magnitude** star of the northern hemisphere. The star is distinctly yellowish in appearance and has a measured diameter about 60 times that of the sun. It is a **double** star, but difficult to resolve except with moderately large instruments.

The two asterisms, the Pleiades and the Hyades, are both open clusters, i.e., groups of stars moving through space together. The Pleiades group is also noteworthy in that it is filled with diffuse **nebulous** material.

There are a number of double stars avaible for observers with small telescopes. With a wide-field instrument, such as an opera glass, the two doubles Sigma and Theta can both be seen at once and, with the surrounding stars, make a very interesting spectacle. (W.K.G.)

TAUTOMERISM. This is a phenomenon observed in organic chemistry when a substance has one molecular formula but must be assigned two structural formulae. (**Chemical Formulae.**) Two sets of reactions characteristic of two mutually incompatible groups in the **molecule** and two sets of derivatives can be produced by reactions depending on but slight variations of the experimental conditions. Consequently a unique structural formula cannot be assigned to such a compound. This difficulty is solved in theoretical organic chemistry by assuming the existence of two compounds with different structural formulae and also an existence of a dynamic **equilibrium** between these two forms. The latter differ in their structural formulae in general by the position of a hydrogen **atom** and that of a double bond. The following are the more important cases of tautomerism.

1. Ethyl ester of acetoacetic acid.

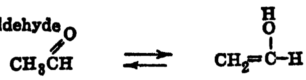


keto form — enol form

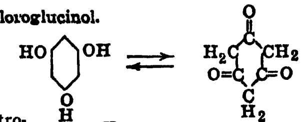
The equilibrium mixture at room temperatures consists of 7% keto and 93% enol form. The enol form can be obtained in the free state by treating the **sodium** derivative with dry **hydrogen chloride** and distilling. The enol form can be preserved in the pure state at low temperatures but at room temperatures it is converted into the equilibrium mixture in two weeks. The enol form gives characteristic reactions with **ferric chloride**. The keto form can be obtained by **crystallization** at low temperatures of the **ester** from an **alcohol**, ether, or **hexane** solution. It does not give the ferric chloride reaction and at room temperatures is gradually converted into the equilibrium mixture.

2. Acetone and similar ketones containing a hydrogen on the carbon atom next to the carbonyl group.

3. Acetaldehyde



4. Phloroglucinol.



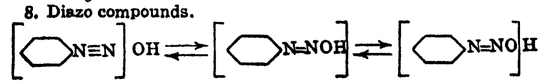
5. Nitro-paraffin compounds. $R_2CH-NO_2 \rightleftharpoons R_2C=N(O)OH$

6. Nitrous acid. $HONO \rightleftharpoons HNO_2$

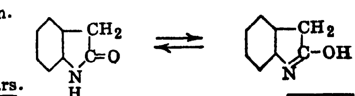
7. Hydrogen cyanide. $HCN \rightleftharpoons HNC$

Two sets of derivatives can be formed CH_3CN methyl cyanide and CH_3NC methyl isonitrile.

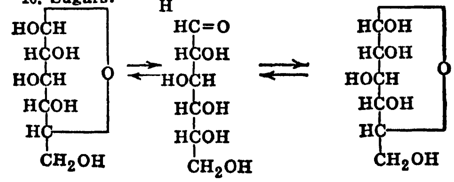
8. Diazo compounds.



9. Isatin.



10. Sugars.



The existence of this tautomerism is invoked to explain mutarotation. [See Carbohydrates (glucose)].

(R.K.S.)

TAXIS. Tropism, and also **Movement in Plants.**

TAXONOMY. The science of **classification.** In dealing with the many details involved in classifying the half-million known species of animals, it has been found necessary to adopt rules of procedure in order to secure approximate uniformity and stability of results. The work of the earlier naturalists was without such restrictions, hence much of the confusion of modern taxonomy has arisen from the interpretation of these early contributions.

Of the several codes of taxonomic procedure the International Rules of Zoological Nomenclature, drawn up by the International Commission on Zoological Nomenclature, is commonly regarded as authoritative in its field. These rules establish many principles relating to scientific names of all ranks. Among them is the provision that all zoological nomenclature shall start with the tenth edition of Linnaeus' "Systema Naturae," published in 1758. All prior works are discarded. A second important provision is the law of priority, which states that the valid name first applied to a group or species shall stand, all names subsequently applied to the same category becoming synonyms. All names, to be accorded consideration, must be published by printing or by a similar permanent form of reproduction and distributed to other scientists either in a recognized periodical or by private enterprise.

All scientific names are latinized, although the range of choice of names is not limited to the Latin; it is, in fact, practically unlimited. The Rules make several specific provisions. Restrictions are placed on the formation of names of superfamilies, families, and subfamilies, which are formed of the stem of the type genus plus the ending -oidea, -idae, or -inae, respectively. The type genus is the included genus regarded by the author of the greater group as typical.

The rules relating to genera have been the source of most confusion. Once applied, a generic name is not to

be used again in the animal kingdom, and if inadvertently used a second time, the later usage becomes a homonym of the name as first applied and is replaced by a new name. In naming a genus the author is supposed to indicate a type species which shall be the embodiment of the characteristics of the genus. Types were designated long before the formulation of these rules but many genera were erected without stated types before their value was appreciated. To meet these cases rules for the citation of types of genera described without them are available. The type species must be among those included in the original description of the genus, and the first designation of such a type takes precedence over all others. As a result historical research has been necessary to fix the older generic names and some are still in a state of confusion. Such cases may be submitted to the Commission for special ruling.

The International Rules of Botanical Nomenclature agree in the main with zoological procedure. The essential differences are summarized under **nomenclature.** See also **Paleobotany.**

In naming species the specimens available, or a selection of them, should be labeled as types and preserved, preferably in the permanent collections of a museum. The species bears the name of the genus to which it belongs, followed by its own name, and for completeness the name of the author of the species should be appended. The generic name is capitalized and both it and the specific name are underlined or in printing are italicized. The use of two names for each species is the principle of binomial nomenclature.

Many other details of taxonomic procedure, based on written and unwritten laws, are of interest only to specialists. A minimum of knowledge in this field is essential to any well-rounded biological training. (A.W.L.)

TAYLOR'S THEOREM. **Expansion of Functions in Series.**

TAYRA. Mammalia, Carnivora. *Galera.* A South American animal of the weasel family. It is among the larger species, comparing with the otter in size, and has the characteristic long body and short legs of the weasels, with a long and rather heavily furred tail. These animals range from white to black in color. (A.W.L.)

TCHEBYCHEFF'S INEQUALITY. Let x be a variable, either **discrete** or **continuous,** whose **probability function** possesses a **mean** $\bar{X}$ and **standard deviation** σ_x, then the probability of obtaining a **deviation** as much as or greater in absolute value than $t\sigma_x$ is less than or equal to $1/t^2$. In symbols

$$P[\,|\,x - \bar{X}\,|\geq t\sigma_x] \leq \frac{1}{t^2}.$$

This inequality is often useful in testing for **significant differences.** A better inequality is due to B. H. Camp. (L.A.A.)

TEA. *Thea sinensis.* Theaceae. The tea plant is an evergreen shrub probably indigenous to China, where it has been cultivated since early times. The plant possesses alternate elliptical leaves which when mature are tough, and vary in length from 2 to 5 in. The flowers are axillary (see **Axil**) and appear singly or in small groups. They are white, slightly fragrant, and about an inch in diameter. Each flower has numerous **stamens** and a single **pistil** composed of three **carpels.** The fruit is a woody **capsule** containing three large seeds.

For successful growth tea must be planted in regions having abundant rainfall. In China most of the tea plants are grown on small farms. The plants are grown from seed or from nursery stock and begin to yield crops when 3 or 4 years old, continuing to do so thereafter for 50 years. The young shoots appear in flushes, growing rapidly for a time. From these flushes are picked the young leaves used for tea. Several flushes occur each year. Picking is done entirely by hand, necessitating an abundant supply of cheap labor.

After picking the leaves are spread out and allowed to wilt for some time. The limp leaves are then rolled and crushed in machines, so that the cells are bruised and certain enzymes freed. The crushed leaves are again spread out and allowed to ferment, after which they are again rolled and dried until crisp. They are then sorted and graded. While still warm the leaves are packed in lead-lined chests partly to conserve the aroma of the leaf and partly to prevent absorption of any odor which might spoil the product. This method of preparation produces black tea, which when brewed yields a rich orange-colored drink. Black tea is principally obtained from China and Ceylon. The best grade is known as Orange-Pekoe.

The preparation of green tea differs in several particulars from that of black tea. After picking, the leaves are at once steamed so that no oxidative **enzymes** remain. Steaming tends to bring out the aroma. After steaming, the leaves are rolled and dried, usually by machine. They are then sifted, graded and packed. Green teas are principally produced by Japan and largely exported to the United States.

Oolong is a slightly fermented tea produced in Formosa, and is intermediate between green and black tea.

In China tea is often delicately scented by exposing the leaves to the odors of flowers. Large quantities of Jasmine flowers are used for this purpose, the product being known as Jasmine Tea.

Tea is principally used as a beverage. Great Britain and its dominions consume by far the greatest amount used outside the producing countries. (R.M.W.)

TEAK. *Tectona grandis.* Verbenaceae. The teak tree is tall, with very rough-surfaced oblong leaves from 10–20″ long and 8–15″ broad, and small white or blue-tinted flowers borne in large panicles. The tree is native in the tropics of Asia and is frequently grown in plantations in India, Java, and other Asian countries for its hard wood. This wood is very durable and much used in shipbuilding and in the making of fine furniture. The wood is very heavy and dries slowly. Drying is hastened somewhat by girdling the tree at the base and leaving it standing for a year or more. During this time it dies and dries out, after which it is felled and floated to the shipping port. (R.M.W.)

TEAL. Aves, Anseriformes. A small **duck** whose beak has almost parallel sides. The several species are beautifully marked. Teals are found throughout Europe, Asia, and North America. The common European species migrates into Africa and is sometimes found in northern and eastern North America, while other species have a much more limited range. In North America the blue-winged teal, *Querquedula discors,* is common east of the Rockies, the green-winged teal, *Nettion carolinense,* throughout the continent, and the cinnamon teal, *Q. cyanoptera,* west of the Mississippi. (A.W.L.)

TEASER TRANSFORMER. **Transformer.**

TECTIBRANCHIATA. **Gasteropoda.**

TECTOGENE. A hypothetical complete down-fold of the **lithosphere** or **sial** as intimated by the sinuous linear strip of strong negative gravity anomalies which follows the East Indian and West Indian island arcs. (See also **Geosyncline.**) (R.M.F.)

TECTONITE. A term proposed by Backland, for a variety of **mylonite** produced from **para**-schists. (R.M.F.)

TEE BOLT. A bolt with a carefully finished square head designed to fit tee-shaped slots in milling machine or planer tables and in lathe faceplates; used for holding machine vises or clamps for work parts. (H.C.H.)

TEGMEN. For the use of this term in botany, see **Seed.** In zoology, it has two meanings. 1. A thickened forewing of the kind found in the **grasshoppers** and related forms. These wings are less thickened than the **elytra** of many beetles but they also serve as wing covers under which the hind wings are folded when at rest. Most tegmina vary from scarcely thickened membranes to leathery appendages. 2. The leathery top of the **calyx** of crinoids. (A.W.L.)

TEJU. Reptilia, Sauria. *Tupinambis.* A large **lizard** of the West Indies and South America. Lives in the forests near water but is not aquatic. Reaches a length of a yard, with long slender tail and heavy forequarters. It is chiefly olive and black. (A.W.L.)

TELEGONY. A supposed influence of a scrub sire on the offspring of a blooded dam by later mating with a blooded sire. Many animal breeders suppose that the accidental mating of a choice female with a mongrel makes it impossible to be sure of securing pure-bred young at subsequent births. There is nothing in the findings of geneticists to support this view. Influence of the sire is limited to the hereditary potentialities of his **germ cells,** and once his own progeny have been born, the female carries no residual influence of the mismating. (A.W.L.)

TELEGRAPHY. Communication by telegraph, whether the older manual type or the more recent automatic or printing type, is done by a code of electrical pulses. In the manual type the operator sends a certain combination of pulses for each letter of his message and the receiving operator then transcribes them into the characteristic letters. In the more complicated automatic types the sending operator uses a keyboard similar to that of a typewriter, and the equipment transforms the striking of a key into the proper signals (not the same code as for manual operation) and a machine at the receiving end selects the proper letter and the message is typed. The message may be transcribed to a punched tape and then transmitted automatically.

In its simplest form the telegraph consists of **battery,** key, and sounder, with connecting wire or wires. The telegraph key is a type of switch designed for easy operation by hand. The sounder is similar to a **relay,** the essential difference being that the sounder has no electrical contacts to close, but its armature strikes a stop at each end of its travel, giving a sound characteristic of the stop. Thus a skilled operator can tell the position of the armature by the sound and can interpret the code message.

A system commonly used in this country is the closed-circuit, so named because the electrical circuit is normally closed, current flowing when no message is being sent. Several stations are usually connected in series, with two common batteries serving all. A circuit is shown in Fig. 1. Since the stations are all in series the

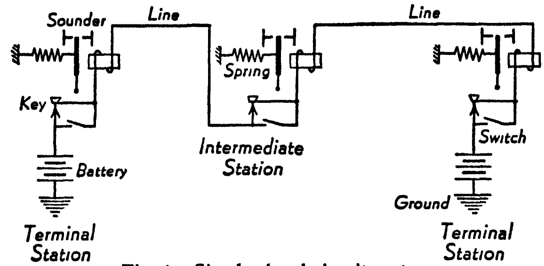


Fig. 1. Simple closed circuit system.

keys must be short-circuited when not in use, hence a switch is attached to each key. To operate, the switch is opened and the key is tapped in accordance with the code. This sends pulses of current through the wire and ground circuit, causing all sounders to operate. These hit the stops on either side of the armature and give the message to the receiving operator.

While the single-current system just described is older and somewhat simpler, a better arrangement is the double-current system of Fig. 2. In this system cur-

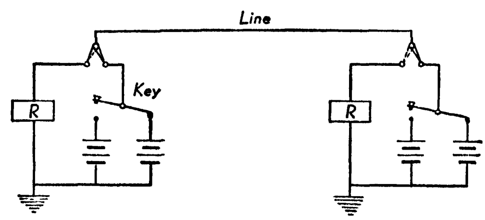

Fig. 2. Double current system.

rent flows in one direction for a signal and in the opposite direction for a space. The operation is more positive than with single-current circuits. These currents may be sent as illustrated with two batteries oppositely connected or a means may be provided for reversing the connections to a single battery The system requires a special relay, known as a polarized relay, between the line and the sounder. A polarized relay is one so designed that current flowing in its windings in one direction will close the contacts in one direction, and current flowing in the opposite direction will close the contacts in the other direction. The combination of relay and sounder is shown as *R* in Fig. 2. The connections are set for transmission of signals from left to right, the operation of the key at the left station sending

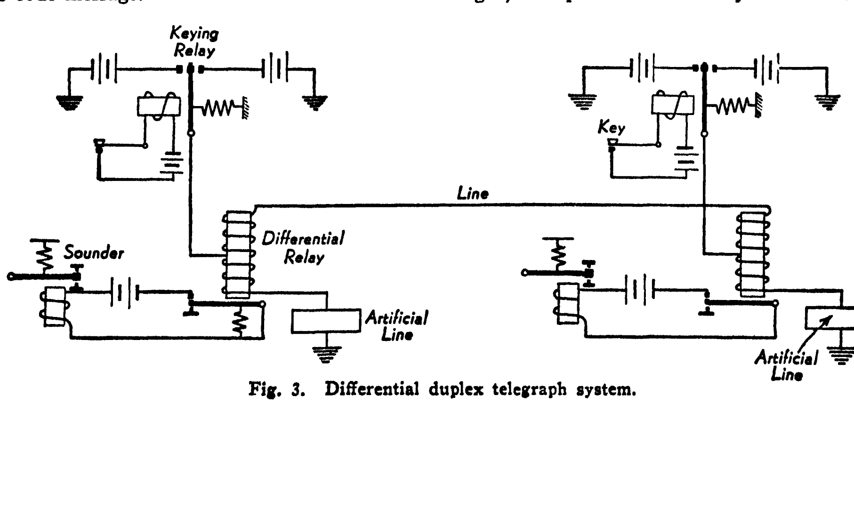

Fig. 3. Differential duplex telegraph system.

pulses of current to the receiver *R* at the right station. There may be intermediate stations.

Both circuits shown allow transmission in only one direction at a time, but there are several arrangements providing simultaneous transmission in both directions. This is known as duplex service as opposed to the previously described simplex service. The differential duplex system is shown in Fig. 3. The duplex operation depends upon a split-winding relay and a balancing of the actual **line** with an artificial one. An artificial line is a circuit designed so that its electrical characteristics are the same as those of the actual line. Therefore, when it is connected to the relay at one end and the line at the other, the two halves of the relay winding and associated connections are electrically identical. Operation of the key at the left station causes the keying relay to send current in first one direction and then the other into the differential relay. Since the two sides of the relay are equal electrically, the current divides, half flowing upward and half downward. The **magnetic flux** of the windings oppose and cancel. This prevents the relay picking up and operating the sounder. However, current coming into the relay from the line all flows through the winding in the same direction, the flux is not neutralized, and the relay picks up, operating the sounder. Thus both transmission and reception may occur at the station at the same time, and only the incoming signals operate the sounder. The half of the transmitted current which flowed upward in the relay goes out over the line to the right station and operates its relay as just described. (See also **Telephony** and **Teletype.**) (F T.M., L.R.Q.)

TELEODESMACEA. Bivalve mollusks, including the soft-shelled **clam,** the **shipworms,** and many other marine species. The group is included as an order in one of the classifications now widely used. Equivalent to the order Eulamellibranchiata. **Lamellibranchiata.** (A.W.L)

TELEOSTEI. Bony fishes of the vast majority of existing species. The group is regarded in most classifications as a very large order of the class **Pisces,** divided into many suborders and families, but a tendency also exists to elevate it to a higher rank and to make its principal subdivisions orders. The principal subdivisions are well established, whatever the rank accorded to them. In North America they number about a score, containing above 3000 species of fresh-water fishes. The principal forms among these many species and the more important food and game species are treated under their vernacular names in this work, as **bass, eel, killifish, salmon, shad, trout,** etc. (A.W.L.)

TELEOSTOMI. The true fishes, a subclass of the class **Pisces.** (A.W.L.)

TELEPHONE EXCHANGE. **Exchange, Telephone.**

TELEPHONY. Telephony is the science of communicating speech by electrical means over wire circuits. The complete system has at least three fundamental components, the transmitter which converts the sound variations into electrical variations, the transmission circuits and the receiver which converts the electrical variations back into sound.

A successful system must meet certain requirements in order to reproduce the speech with a satisfactory degree of fidelity. Ordinary sound may cover a range of frequencies from 20 cycles per sec. to almost 20,000 cycles per sec., the exact range varying from person to person. To transmit this complete band would be a complicated and expensive process so considerable research has been applied to the problem of just how much is really necessary for different services. For simple speech transmission it has been found that a band from about 250 to 2800 cycles is ample. This gives good intelligibility with enough of the characteristic overtones of the voice to make most voices easily recognizable over the phone and yet it is not wide enough to offer serious technical problems. The absence of the frequencies below 250 cycles greatly reduces the amount of power necessary in the system since an abnormal proportion of the total sound power is included in the lower end of the audio band. When telephone circuits are used for special purposes such as program lines for radio networks this range must be considerably extended, introducing many special problems in designing the transmission circuits. Wired circuits for **television** networks are still more difficult to obtain, but can be worked out satisfactorily if cost is not a factor.

The transmitting equipment for the ordinary telephone consists of a single-button carbon **microphone,** called a transmitter. This is connected to a **battery** whose current passes through the transmitter and is modified by the sound waves. It is this modified current which is transmitted over the wire circuits, often through several intermediate pieces of equipment, to the receiver where the sound is reproduced.

Since no special line problems are involved in the local telephone circuits we may start a discussion of the various telephone systems with this relatively simple one. The local service is handled through central offices where the various lines are arranged so they may be interconnected at will to make the desired connections between the subscribers. The exact nature of the equipment in the office and at the subscriber's location depends upon whether the source of d.c. is a battery located at the customer's instrument or whether it is located at the office. Many rural telephones where fairly long **lines** are involved use the first method in order to avoid excessive losses which would result if the d.c. were transmitted from a central location. All modern city service is of the common battery type, all telephones served by a given central office being supplied from the same main battery located at the office Special connections are used to avoid interference between the many circuits using this same battery. A brief outline of the major operations occurring in making a call through a manual office (this is an office in which the connections are made by the telephone operator rather than automatically as in a machine switching office) will illustrate the principles. At the subscriber's premises the telephone equipment (commonly called a subscriber's subset) consists basically of the transmitter, the receiver, a signal bell and an induction coil or **transformer.** The latter is used to connect the receiver to the line so better matching can be secured and so d c. can be kept out of the receiver windings. (See **Anti-Side Tone** for typical connections.) Removing the receiver from the hook, or, for hand sets, the removing of the hand set from the cradle, closes switch contacts connecting the instrument across the line, the circuit between line wires being completed through the induction coil primary and the transmitter. This connection causes a signal lamp associated with this particular phone to light on the switchboard. The operator responds by plugging into the corresponding answering jack on the board, asking for the number, and then completing the connection by means of another plug cord. Ringing is then usually done automatically until the called party answers or the calling party hangs up. When the call is over and the parties hang up other supervisory lamps on the board light and indicate to the operator that the connection should be removed.

Since complete service requires the connection of any phone with any other phone a limit in the number of phones which can be handled is obviously reached. For rapid service this limit is the point at which the operator cannot reach the jack for every phone served by the office. With present equipment the board can hold 10,-

000 jacks within the reach of the operator. When a community has more than this number of phones additional offices must be provided to handle them. The various offices serving a community constitute an exchange or exchange area. Calls from one office to another can be handled by an extension of the simple process given above, the calling party's operator passing his call on to an operator in the called office who completes the connection. Separate switchboards are used for taking calls, i.e., answering a calling party and requesting the number, and for connecting to the called line. The first is called the A board and the second the B board.

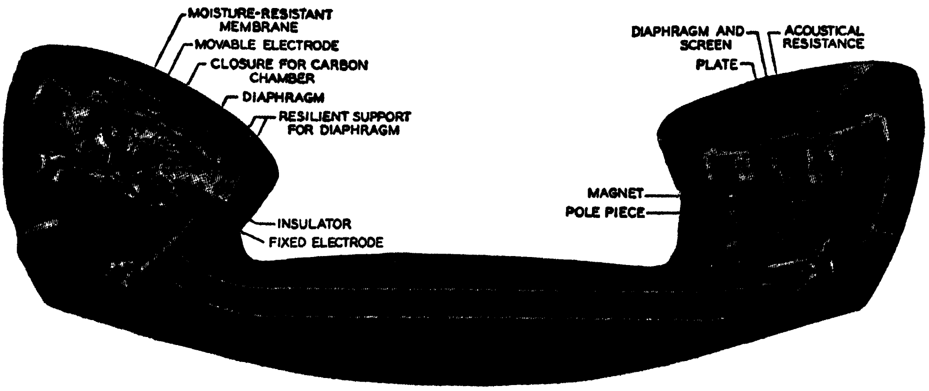

Fig. 1. Sectional view of a modern telephone hand set.

Dial or, more accurately, machine switching performs the connecting functions automatically under the direction of the dial of the calling telephone. This type service is replacing the manual equipment in many localities as it gives quicker and more reliable service at a lower operating cost. It is, however, higher in initial cost. The transmitting equipment is modified to include a dial which is used by the subscriber to indicate the desired number. The dialing operation consists of placing the finger in the dial at the desired numbers and rotating the dial to a stop, then allowing it to return freely, repeating this for each letter or digit. This operation, through the action of the freely returning dial, sends pulses to the central office, these pulses being used to control the necessary switching. The simplest dial system is the rotary selector or step-by-step system which will be outlined to illustrate the principles involved. When the calling party removes his receiver from the hook, the line circuit is closed through the dial contacts. Instead of a lamp lighting on a board as in the manual system, a line finder starts searching for the calling line. This searching is initiated by the closing of the hook switch contacts at the calling subscriber's phone and is terminated when the finder locates the line (indicated by the connection at the phone). The subscriber then hears the dial tone indicating that the office circuits are ready to receive his call. Reference should be made to Fig. 2. The subscriber then dials his number, one digit at a time. For each digit a number of pulses are sent over the line, the number corresponding to the number being dialed. These pass through the line finder connections to a switching device called a selector. This is a notching relay mechanism, which will be notched up one step for each pulse, there being ten steps to handle the range of possible values for each digit. When the even sequence of pulses stops (this happens when the subscriber rotates the dial for his second digit), the selector automatically rotates by steps until it connects to a second selector which is not busy. This second selector responds to the second digit pulses in a similar manner. This process is repeated for all but the last two digits. For the next to the last digit the selector (which in this special application is commonly called a connector) notches up, but does not rotate automatically. However, when the last digit is dialed the connector rotates step by step to the dialed position. Connection is now all but complete to the called line, and, if it is not busy the connection is completed automatically and the called phone is rung. Upon completion of the conversation the parties hang up and all switches return to normal. For large exchange areas a system more complicated in the electrical sense but more rapid in service is used. This is the panel system. A more recent development, the cross-bar system, is also

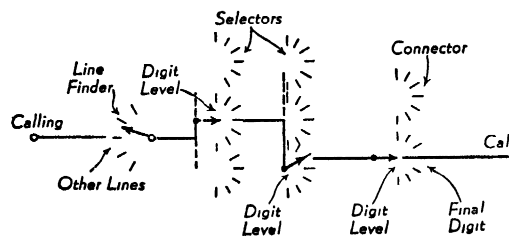

Fig. 2. Simplified dial connections.

designed for large service areas. Neither of these latter systems does its switching under the direct control of the dial pulses but rather through an intermediate mechanism.

Long distance, or inter-city, service introduces many new problems. The electrical signals traversing the lines are subject to attenuation, frequency distortion, interference and various other undesirable effects. Additional equipment must be used to avoid these. The lines themselves are expensive and much has been done to utilize them to the fullest, **phantom** and **carrier circuits** being means of doing this. The lines may consist of the familiar open wire lines, of lead sheathed **cables** containing many lines or of lead sheathed **coaxial cables**. The cables may be overhead or underground, the coaxial being universally underground. Cables are often operated filled with dry nitrogen under a slight pressure, thus decreasing the losses. While open-wire lines are no longer loaded, cable lines for voice frequencies (lines not having carrier channels) are usually loaded. This process, developed by Pupin, consists of inserting at fairly frequent intervals (ranging from a fraction of a mile to a little over a mile) lumped inductances to increase the over-all inductance of the lines. This loading improves transmission by decreasing distortion and attenuation but it also puts a definite upper limit to the frequency which the line will pass. It is this latter limit which prevents its use with the usual carrier circuits. Even for radio program circuits it becomes necessary to insert

the loading coils at very close intervals, since the closer the spacing the higher the cut-off frequency.

To extend further the range of communication over lines it becomes necessary to insert **amplifiers**, or repeaters, at intervals along the line to build the signal strength back up. The spacing of these amplifiers varies with the line and its use, ranging from around 200–300 miles for open-wire lines, 50–100 miles for many cables, down to 5 miles for coaxial cables used for wired **television** programs. Basically these repeaters are vacuum-tube amplifiers but they must be inserted in the circuits in such a way that no energy can feed back from the output to the input. In some cases separate lines are used for the conversation in the two directions so no special problem is encountered except at the terminals where both directions must be brought together on a single line for transmission to the subscribers. In many other cases, however, the same line serves for both directions just as it does in local service. Here special care must be exercised to prevent feedback and consequent distortion. This is accomplished by the bridging transformer or hybrid coil in a manner shown in Fig. 3. The circuits are

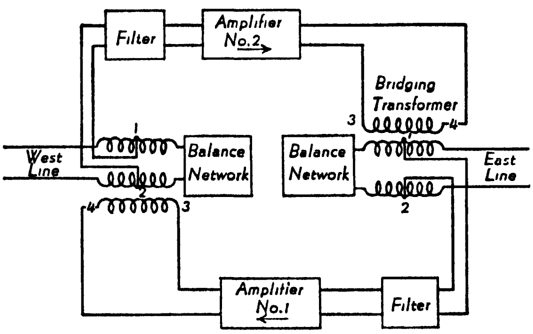

Fig. 3. Repeater station.

so balanced that no signal from the output of one amplifier is introduced in the input of the other. The **filters** limit the range of signals which may go into the amplifiers and hence make the balancing problem less severe since balance need not hold over such a wide range of frequencies. The amplifiers are conventional vacuum-tube circuits and the balancing networks are combinations of capacity, resistance and inductance which will present the same **impedance** as the line over the usable frequency range.

Transpositions are used extensively to decrease interference from various sources. (See **Inductive Interference.**) (L.R.Q.)

TELESCOPE. The name telescope implies that it is a device for "seeing at a distance." There are two modern methods for accomplishing this purpose: (1) the refracting telescope which uses a **lens** for gathering light and forming a real image of a distant object, and (2) the reflecting telescope which employs a concave mirror for the same purpose. In both of these types an eyepiece is employed to "magnify" and study the image. In this article the development of the modern instrument will be briefly treated from the historical point of view.

It is probable that experiments on the accomplishment of "seeing at a distance" were carried out from the time of introduction of lenses into Europe during the thirteenth century for the purpose of correcting defective vision. However, it is not until 1608 that we find definite evidence of the discovery of telescopic vision, for in October of that year Jan Lippershey applied to the States-General of Holland for a patent to an instrument for seeing at a distance. The States-General appreciated the importance of the instrument for military and naval purposes and refused to grant the patent, but did commission Lippershey to continue his experiments and purchased the rights to his instrument. The news of Lippershey's discovery spread like wildfire over Europe, and by May, 1609, Galileo had heard of the discovery and set about to construct an instrument for himself based upon Lippershey's design. Galileo immediately applied his instrument to astronomical observing, and before the middle of 1610 had made and announced a number of important discoveries.

The type of instrument first built by Galileo is shown diagrammatically in Fig. 1 and is now known as the

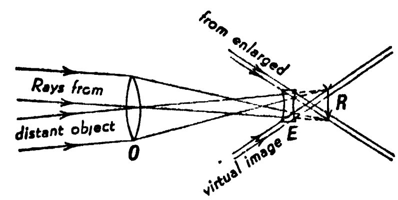

Fig. 1.

Galilean telescope. A converging (convex) lens, O, known as the objective, forms at its principal focus a real inverted image, R, of a distant object. Before reaching the focal plane of the objective the converging rays are intercepted by a divering (concave) lens, E, known as the eyepiece. If the eye is placed behind E an enlarged virtual image of the distant object is observed. This image is in the same orientation as the distant object (i.e., it is an erect image), and the **magnifying power** of the instrument depends upon the relative focal lengths of O and E.

The Galilean type of telescope now survives only in the form of opera and field glasses, usually of from 2- to 5-power. The principal advantages of this type are (1) the erect image, (2) the brilliant illumination of the field of view, (3) the diminished distance between O and E which gives a more compact instrument, and (4) the partial correction of **spherical** and **chromatic aberrations** by the combination of convex and concave lenses. Set against these advantages there are the important difficulties that (1) no **reticle** (cross-hairs) can be used, and (2) the field of view with such an instrument is very limited. In Galileo's instrument the field of view was only 7′ 15″, less than ¼ the diameter of the moon.

To overcome the disadvantages of the Galilean form of telescope, Johann Kepler in 1611 described the type of instrument shown diagrammatically in Fig. 2, which

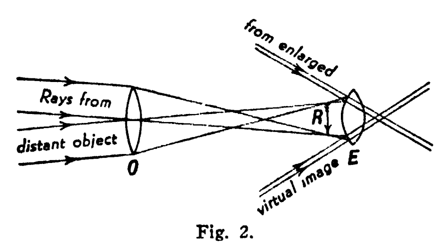

Fig. 2.

is now known as the Keplerian telescope, or, more commonly, as the astronomical telescope. The real image R of a distant object is formed by the objective O as is the case with the Galilean telescope. The difference between the two types of instruments is found in the eyepiece, E, which, in the original Keplerian instrument, was a relatively short-focus convergent lens set in such a position that R is close to its principal focus. The eye is placed behind E and an enlarged, inverted, virtual image of the distant object is observed. This instrument overcomes the fundamental disadvantages of the Galilean instrument, for a reticle or a **filar micrometer** may be used, with the wires placed at R, and the field of view is large. The chromatic and spherical aberrations are very severe when simple convex lenses are

used, and the correction of these defects requires the construction of complicated objectives and eyepieces.

In addition to its use in astronomical observing, the Keplerian form of telescope has a multitude of other uses such as fixing a line of sight (as in surveying instruments or in gunsights) and for reading scales on leveling rods, **galvanometers**, etc. The inverted image is frequently a disadvantage for terrestrial observing, and erecting eyepieces of various designs have been invented. These require the addition of extra lenses with consequent loss of light, both by reflection from the lens surfaces and also by absorption in the glass itself. Such erecting systems are never used in astronomical obverving. The increased length of tube of the Keplerian form over the Galilean is compensated for in prism binoculars by reflecting the rays back and forth parallel to the tube. The use of the prism system has the additional advantages of providing an erect image and also increasing depth perception by increasing the distance between the two objectives.

For astronomical observing an object glass of large diameter is of fundamental importance both for the purpose of gathering more light, and hence increasing the brightness of faint objects, and also to diminish the size of the **diffraction** rings and thus increase the resolving power. Telescope builders of the 17th and 18th centuries were unable to obtain glass disks of sufficient clearness and homogeneity for the construction of large object glasses, and turned to the reflecting type of telescope. In such instruments a concave mirror is used to form the real image to be examined with the eyepiece. This image will be formed in the open end of the tube, and to examine it the observer would have to put his head directly in the path of the incoming rays and seriously reduce the light-gathering power of the instrument. To avoid this difficulty a number of different schemes have been evolved. Newton placed a small mirror in the path of the rays, slightly inside the focus and inclined at an angle of 45° so that the image would be formed at one side of the tube where the eyepiece was located. Cassegrain, and others, adopted the scheme of reflecting the light from the objective mirror back through a hole cut out of the center of the mirror. The relative advantages, in the Cassegrainian type, of using convex hyperbolic mirrors inside the focus of the objective, concave elliptical mirrors outside the focus, etc., are far too complex to be considered in a work of this character. However, by the use of different types of secondary mirrors, the focal length and efficiency of a telescope using one objective mirror may be altered to suit the requirements of a particular problem at hand. In general, it may be said that when the principal focus of the main mirror is used, either by placing a photographic plate at this point or reflecting the image out to one side, the instrument is being used in the Newtonian focus. When the image is formed through a hole in the objective mirror the instrument is said to be used in the Cassegrainian focus.

One fundamental disadvantage of the reflecting telescope is the spherical aberration of the concave mirror. Even though this may be corrected along the axis by the use of a concave paraboloidal mirror instead of a spheroidal mirror, nevertheless, the field of good definition is limited. Recognizing this difficulty, glass makers and lens designers continued their endeavors to produce large aperture refracting telescopes, culminating in 1897 with the dedication of the Yerkes Observatory telescope, with an objective diameter of 40″. It seems highly improbable that any refractors will ever be made with lens diameters greater than this. Not only are telescope builders faced with the difficulty of obtaining the large, clear glass disks and grinding the four surfaces of the achromatic objective, but also there is the difficulty of maintaining the lens figure as the telescope is moved to different positions, since, of necessity, the glass must be supported at the edges. For photographing large areas of the sky the refractor still has its place, and compound objectives are continually being designed and built for the purpose of improving definition over large angular fields.

Another difficulty with reflecting telescopes has been the tarnishing of the reflecting surface. In the original reflectors, in which the mirrors were built of metal, this tarnishing of the surface required the complete regrinding of the figure of the mirror at frequent intervals. These metal mirrors were also subject to serious changes in figure due to expansion and contraction of the metal with changes of temperature. Both of these difficulties have been overcome by making the mirror of glass and depositing a metallic coating on the figured concave surface. The glass does not have to be clear or transparent, can be supported at the back, and has such a low temperature coefficient of expansion that the figure does not change seriously with temperature variation. Originally, the glass mirrors were coated with silver, which was chemically deposited on the surface. This could readily be dissolved off and replaced after it had tarnished. The 200-in. reflector, and probably all the reflectors of the future, will be coated with **aluminum** deposited by evaporation and recondensation in a vacuum. When such a surface is first exposed to the air a transparent oxide of aluminum is immediately formed which protects the surface from tarnishing for a considerable period of time.

In 1930, a new type of telescope was invented which has revolutionized certain phases of astronomical research. This instrument, known as the Schmidt telescope, is a combination of the reflecting and refracting instruments. Its reflecting mirror is ground as a hollow sphere. To eliminate the spherical **aberrations** of such a mirror, a thin correcting lens is placed in front of the mirror. The curvature of the mirror and the figure of the lens may be so adjusted that a working field as large as 20° may be used without appreciable aberrations at the edges, and the effective focal length may be reduced to such a point that the f-ratio (see **Camera**) may be as low as 0.5. The image is formed between the mirror and the lens, and the photographic plate, or film, must be curved by pressing it against a convex spherical surface. Since the telescope cannot be used for visual work, it is sometimes referred to as the Schmidt camera. During World War II, the Schmidt camera was successfully used for high-altitude reconnaissance photography. (W.K.G.)

TELESCOPING GAUGE. **Measurement.**

TELETYPE. Teletype is the transmission and reception printing of messages by electrical means, being in principle a receiving typewriter whose keys are operated from the transmitting station, either by means of a keyboard or previously prepared tape. While there are two systems in use in this country, the simplex and the multiplex, they differ more in details than in principle.

Both systems utilize the Baudot code which employs 5 equal length pulses in various combinations to give the letters, numerals, punctuation, etc., necessary for operation of such a system. The nature of this code will become clear as we discuss the operation of the simplex or start-stop teletypewriter. Referring to Fig. 1, we have a sending device, the connecting line and a receiving device. In addition to the schematic parts shown, there are, of course, many other components such as transmitting key board, **relays**, receiving printer, etc. When a key is pressed at the transmitter the sending brush arm is released and starts revolving (clockwise in the diagram), sweeping over successive segments of the sending commutator. Pressing of the key (this is not the conventional telegraph key, but rather a key of a typewriter-like key board) also causes certain of the transmitting contacts to close, the ones

selected being determined by the letter being transmitted, i.e., "a" closes contacts 1 and 2, "b" closes 1, 4 and 5, etc. As soon as the sending arm starts revolving it operates the receiving end relays so the receiving brush arm starts revolving at practically the same speed as the transmitting one. Thus the two arms cross corresponding commutator segments together. If the letter "a" is being transmitted, battery is connected to the line as the sending arm crosses segments 1 and 2. This in turn causes the receiving magnets of 1 and 2 to operate. Other segments are dead for this letter.

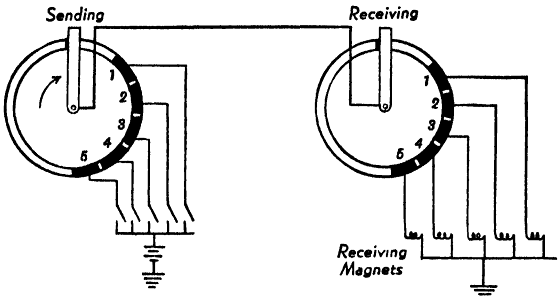

Fig. 1.

After crossing the 5 code segments, the transmitting arm is stopped and the receiving arm operates a printing relay and then is stopped, ready for starting on another letter. The receiving magnets, operating a mechanical selector mechanism set up the selection of the "a" type bar and when the printing circuit is actuated by the receiving arm, the letter is printed. Other letters cause other magnet combinations to pick up and thus select the proper type bars. The start-stop method allows the two arms to be synchronized for each revolution and thus the corresponding segments of the commutators are crossed at the same time. The multiplex system is much faster and does not stop and start the arms but uses other means of synchronizing.

A great part of the telegraph traffic is handled by various kinds of printers and there is also available to private subscribers a teletypewriter service on a basis somewhat similar to the familiar telephone service. In this service any teletype subscriber can be connected through teletype switchboards to any other teletype subscriber just as a telephone subscriber can connect with any other phone. Business houses operating on a national basis make extensive use of the system for transmitting orders, etc., from branch to home office or home to branch. (L.R.Q.)

TELEVISION. Television is the transmission of scenes, either still or motion, by electrical means, commonly by radio, for instantaneous viewing without permanent recording. For a practical system certain fundamental components or functions are necessary:

1. Camera device to pick up the scene.
2. Transducer to convert the light impulses of the scene to corresponding electrical pulses.
3. Transmitter to convert the electrical pulses into proper form to be transmitted to the receiver.
4. Receiver to pick up the transmitted signals and convert them to the proper form to apply to a transducer.
5. Transducer to convert the electrical pulses back into light in a reproduction of the original scene.

While in both still and motion pictures the entire scene is utilized at the same time to produce the film image, in all the present practical systems of television it is necessary to break up the scene into minute elements and utilize these elements in an orderly sequence. This process is called scanning and is very similar to the process of reading line by line the printed page. In reading the eye progresses along the line word by word, relatively slowly, and then returns rapidly to the beginning of the next line, and repeats this process on down the page. In scanning the picture must be broken down into lines of successive elements just as the eye breaks down the printed page into words. While there have been various methods developed for performing this function all those in use at the present time utilize some electrical means. However, since it gives a rather clear idea of the basic process, we might consider one of the earlier mechanical methods using a revolving disk. This disk had a series of small holes along a spiral near its outer edge as shown in Fig. 1. Suppose, now, the

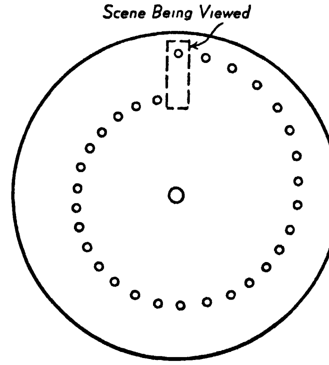

Fig. 1. Mechanical scanning disk.

picture is viewed through these holes as the disk is rapidly revolved. The outermost hole passes across the top of the picture so if the observer is looking through it he sees successively the parts of the picture opposite the hole as it passes across the scene. As the first hole moves beyond the edge of the picture, the second comes to the other edge, and since it is one hole diameter nearer the center of the disk than the first, it covers a second line across the picture. Then the third hole crosses a line just below the second and so on until the disk has made a complete revolution when the entire picture has been covered. This is repeated at the rate of revolution of the disk. If these successive small sections of the picture as seen through the disk can be made to produce corresponding electrical effects the entire picture can be reproduced in an orderly sequence of electrical pulses. When the disk was the standard means of scanning this was accomplished by replacing the eye of the above discussion by a phototube. Modern television, as has been said, utilizes an electrical scanning method.

The received scene must be reconstructed from these electrical pulses, or their received equivalents. If we assume that the original scanner broke the picture down into ten lines and each line had ten elements side by side (this is determined by the width of the hole, being the width of the picture divided by the hole width) then we have 10 times 10 or 100 elements in the scene and our reproduced picture must be built of 100 blocks. It can readily be seen that this would give a very coarse mosaic effect to the picture since each element is fixed in intensity of light. More lines would give more elements and finer detail in the receiver scene. A close comparison may be drawn between this and the printed pictures of newspapers and magazines. The relatively coarse newspaper pictures are lacking in detail while the usual magazine half-tones give very good detail. The difference between these pictures is the number of dots or elements (clearly visible if the printed picture is viewed through a magnifying glass) of which they are composed. Various technical considerations dictate the exact number of lines into which the television scene may be broken, but at present it is of the order of 500, while the future holds promise of much higher numbers and consequently much better detail.

Besides the number of lines per scene, the engineer must decide upon the repetition rate. In moving pictures at present the action effect is produced by projecting upon the screen successive scenes taken and projected at the rate of 24 per sec. The persistence of vision of the eye then gives the effect of smooth motion. The television pictures must also be repeated at a rate high enough to give the illusion of smooth motion. While the motion picture rate of 24 frames per sec. would be satisfactory for this the standard power supply frequency of 60 cycles dictates the use of 30 frames per sec. for television. Further to improve the quality of the reproduced picture, the scanning is not done for adjacent lines in order, but the picture is scanned over alternate lines first and then scanned again over those missed the first time. This double scanning, known as interlaced scanning, is done in the thirtieth-of-a-second period of one frame.

A block diagram of a complete television system is shown in Fig. 2. The original scene is focused on the picture carrier. Both are then picked up by the receiving antenna, amplified and fed through the first detector and intermediate frequency amplifiers of a **superheterodyne receiver.** The two types of signal are then separated and each is fed to its proper **detector** or demodulator. The sound signals, now at audio frequency, are further amplified and drive the **loudspeaker.** The picture signal circuits are much more complex. In order to reproduce the scene at the receiver, it is necessary for the receiver transducer, whatever its nature, to follow exactly the operation of the camera tube. Thus when the camera scans the scene at a given rate, each scanning line starting at a definite time after the preceding one, the picture tube must retrace the scene in exactly the same order, each line starting at the same time interval after the preceding one. Otherwise the various lines might get badly skewed or out of synchronism and a badly distorted picture would result. To insure accurate synchronization between the transmitting end and the receiving end, syn-

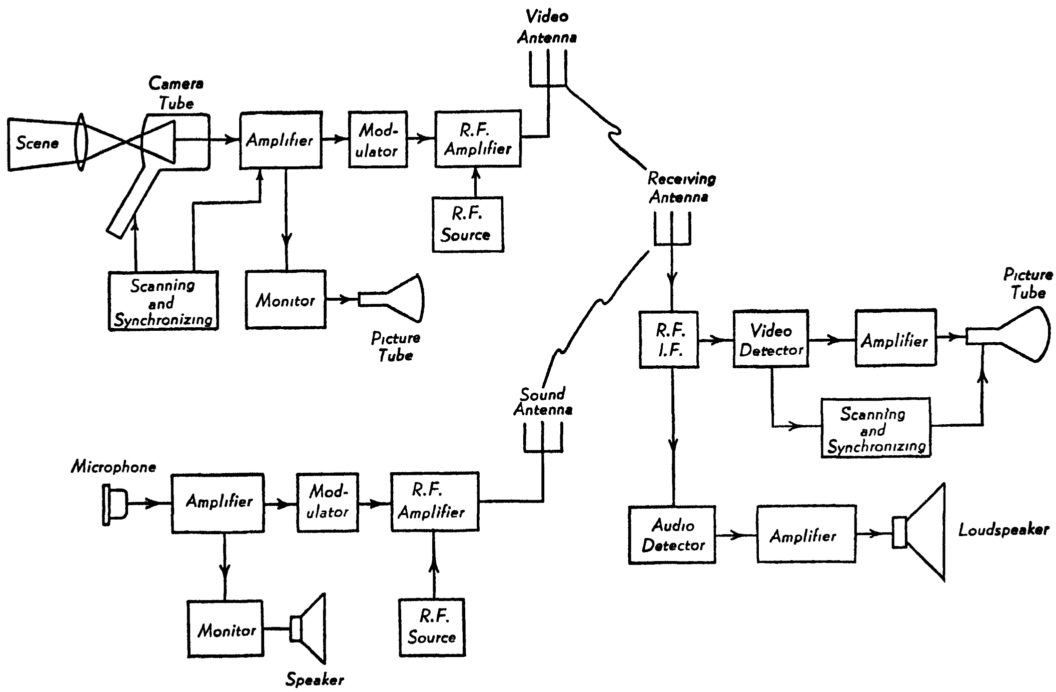

Fig. 2. Block diagram of television system.

camera tube by a light lens system. The camera tube converts this light picture into the sequence of electrical elements necessary for transmission. (For the operation of two of the various types of camera tube see **Iconoscope and Image Dissector.**) The very minute electrical signals coming from the camera tube are amplified by wide band **amplifiers,** the wide band being necessitated by the great range of frequencies produced by the modern multi-line systems. This wide band amplifier feeds a monitor circuit which reproduces the televised scene on a picture tube so the operator can check the camera circuit operation continuously. It also drives the modulator which modulates the picture signals on the radio-frequency **carrier** in a manner very similar to that of the audio **modulation** of conventional broadcasting. The modulated radio frequency is then fed to the **antenna** and radiated into space. At the same time the **microphone** is picking up the sound associated with the scene. This signal is amplified and impressed on the radio frequency sound carrier just as for any amplitude modulated **transmitter.** The sound-modulated carrier is radiated simultaneously with the chronizing pulses are transmitted at the end of each scanning line. In addition synchronizing pulses to govern the return of the scanning to the top of the scene are also transmitted. These various pulses are impressed on the signal in the transmitter during the short time interval while the scanning is returning from the end of one line to the beginning of the next. In the receiver these synchronizing pulses must be separated from the detected signal and routed into the proper channels. They are then used to synchronize the sweep **oscillators** which give the reversed scanning at the receiver or picture tube. The video signals without the synchronizing pulses are amplified in the proper channels of the circuit and also fed to the picture tube. The electronic picture tube is the **cathode ray tube.** The electron beam issuing from the gun is modulated in intensity by the picture or video signal so the intensity of the fluorescent spot produced by it on the tube screen is a reproduction of the intensity of the corresponding part of the original scene. The synchronizing and scanning circuit produces a sweep signal which is applied to the picture tube by plates or coils just as in

the oscilloscope discussed in the section on cathode ray tubes. This sweep action carries the electron beam relatively slowly across the screen, then blanks it and returns it rapidly, moves it down and repeats, the time for each operation being the same as for the corresponding operation in the camera tube, the two operations being linked together by the synchronizing pulses. After completing the scanning of alternate lines of the picture, the beam is deflected back to the top of the picture and repeats this operation, now filling in the alternate lines which were skipped on the first scanning, again in exact synchronism with the same process in the camera tube. It can be seen, then, that since the intensity of the spot corresponds at each instant to the intensity of the original scene and the position of the spot corresponds with the position of the original scanning position at the original scene, the reproduced effect on the screen of the picture tube is the scene which was picked up by the camera.

While the various systems of television in current use are all electronic in nature and differ in details rather than principle, the systems are highly complicated and are subject to certain limitations. The frequency band of the video signal is proportional to the number of lines, the width of the elements in any line and the number of frames per second, giving a band width of several megacycles for satisfactory reproduction. Since this requires a correspondingly wide radio-frequency **channel** it is entirely impracticable to use carrier frequencies in the ordinary broadcast band, both because the entire band could accommodate less than one station, but also because of complications in designing suitable selective circuits at these frequencies. These factors have forced television to the very high frequency region. Further to aid in the problem of getting the most out of the available spectrum space, both **sidebands** are not transmitted, but one is eliminated except for the components nearest the carrier. This is known as vestigial transmission and is a compromise between conventional double sideband and single sideband transmission. The audio signal band is transmitted on adjacent frequencies, the spectral arrangement being shown in Fig. 3. Because of the nature of propagation at

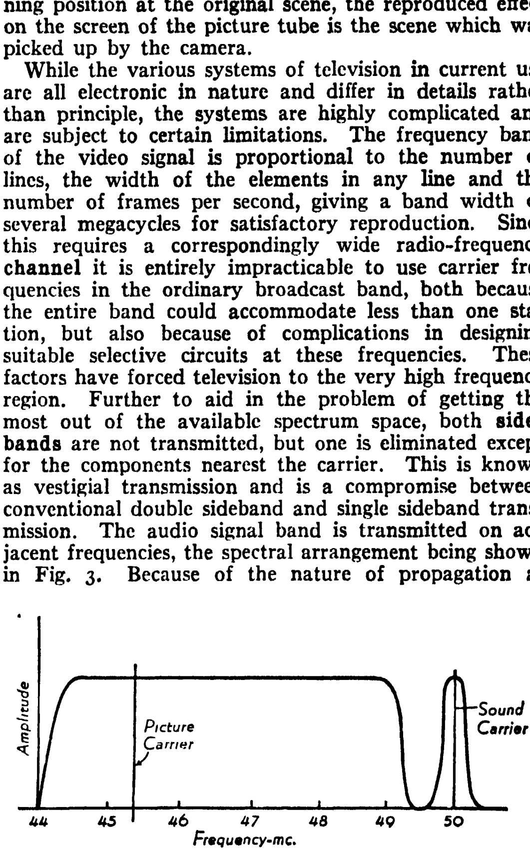

Fig. 3. Spectral distribution of signal.

these high frequencies the range of television stations is very limited, reliable reception being possible over distances very little greater than **line-of-sight** distances. Under abnormal atmospheric conditions reception can be secured over greater distances, sometimes even running into hundreds of miles, but this is extremely erratic and occurs only rarely. The reflection and diffraction problems which accompany these high frequencies also enter the problem and limit the satisfactory reception of television. It seems doubtful if reliable reception will be available for years for any but the residents of urban and suburban areas. The conventional chain service of standard broadcasting is also unlikely since the wide band of video frequencies introduces grave problems in wire transmission. The **coaxial cable** is the only possibility for wired program connections and it is very expensive. Automatic relay transmitters and receivers operating on ultra high frequencies offer the possibility of radio-linked networks. However, the entire transmitting procedure is so expensive at present it is doubtful if smaller communities will justify the expense so television service for these and rural areas must wait for technical advances to bring down the costs. In spite of these limitations, the service which can be rendered in large population centers is at present satisfactory and within the very near future bids fair to be greatly improved, both by development of systems using more lines and even giving color television. (L.R.Q.)

TELIOSPORE. Rust Fungi.

TELLURIUM. Symbol: Te. Atomic number: 52. Atomic weight: 127.61. Density: 6.25. Hardness: 2.3. Melting point: 452° C. Boiling point: 1390° C. (**Isotopes**: page 290.)

Tellurium is a silver-white brittle semi-metal; stable in air, and in boiling water; when heated in air burns with a greenish flame to form the dioxide; insoluble in **hydrochloric acid**, but dissolved by nitric acid or **aqua regia** to form telluric acid; dissolved by **sodium** hydroxide solution; combines with chlorine upon heating to form tellurium tetrachloride. Discovered by Reichenstein in 1782.

Tellurium occurs chiefly as telluride in **gold, silver, copper, lead,** and **nickel** ores in Colorado, California, Ontario, Mexico, and Germany, and infrequently as free tellurium and **tellurite** (tellurium dioxide, TeO_2). The **anode** mud from copper and lead refineries, or the flue dust from roasting telluride gold ores is treated by fusion with sodium nitrate and carbonate and the melt extracted with water. The resulting solution is acidified carefully with **sulfuric acid,** whereupon tellurium dioxide is precipitated, and the dioxide reduced to free tellurium by heating with carbon. Chemically related to **selenium.**

Acids: Tellurous acid (H_2TeO_3), white crystals, only slightly soluble in water; telluric acid (H_2TeO_4), white crystals, soluble in water, forms telluric oxide upon heating to a red heat.

Chlorides: Tellurium dichloride ($TeCl_2$), black solid; tellurium tetrachloride ($TeCl_4$), white solid, melting point 224° C., formed by reaction of tellurium and excess chlorine.

Hydride: Tellurium hydride, hydrogen telluride (H_2Te), by reaction of aluminum telluride with water or hydrochloric acid, gaseous, unstable, of unpleasant odor, chemically related to hydrogen selenide.

Oxide: Tellurium dioxide (TeO_2), white solid, sublimes at 450° C., only slightly soluble in water, soluble in acids, and in sodium hydroxide; tellurium trioxide (TeO_3), orange crystals, insoluble in water, in nitric acid, and in cold **hydrochloric acid,** soluble in hot concentrated sodium hydroxide solution.

Tellurides: Metallic tellurides are formed by combination of tellurium and the metal, or by precipitation of the metallic salt solutions with hydrogen telluride.

Numerous organic compounds of tellurium have been prepared. (R.K.S.)

TELOGONIA. Nematoda.

TELPHER. An electric **hoist** suspended from a wheel carriage which rolls on an overhead track is called a telpher. The operator rides on a platform, also supported by the carriage, and controls the hoisting as well as the horizontal movement of the telpher. The telpher can be employed to lift and transplant all material which can be suspended from a hook, and is suitable for a variety of service in industrial plants, being able to transport lumber, pipe, iron (usually with electromagnet), partially or completely manufactured parts, packages, and bulk material (with grab bucket). The carriage may roll on an I-beam suspended from an overhead structure. In building interiors it may be sus-

pended from the roof trusses. Outside, of course, a special supporting structure must be built. (See **Crane.**) (F.T.M.)

TELSON. The hind part of the body of an arthropod, beyond the segmented abdomen. The **anus** opens in this structure, which is otherwise extremely varied. In the **lobster** it is a flap associated with a pair of broadened appendages to form a powerful fanlike swimming organ and in the **scorpions** it is the sting. The telson of the **horseshoe crab** is the spine-like terminal appendage. (A.W.L.)

TEMPER. Temper has two distinct meanings in metallurgy. Hardened steels are tempered after quenching to increase their toughness. (See **Heat Treatment.**) In the heat-treatment of small tools the "temper" may be drawn by observing the "temper color" of a brightened area as it becomes oxidized during heating. The first indication is a light straw color which appears at about 425° F. The piece may be quenched to arrest the tempering process. At higher temperatures brown, purple, blue, and dark blue to black oxides form. At the higher temperatures the hardness decreases appreciably. In the production heat-treatment of both tool and machine steels, tempering is carried out in batch or continuous-type furnaces in which the heating cycle is carefully controlled by pyrometers. Under these conditions much more uniform results are obtained than by the old temper color method.

Temper also refers to the degree of hardness induced by a **cold-working** process such as sheet rolling or wire drawing. Tempers are expressed as soft, ¼ hard, ½ hard, etc., or in **gauge numbers** reduction in thickness or diameter. The following table applies to copper alloy sheet and strip.

Commercial Temper Designation	B. and S. Nos. Hard	Reduction of Thickness, %
Soft (annealed)	0	0.0
Quarter hard	1	10.9
Half hard	2	20.7
Three-quarter hard	3	29.4
Hard	4	37.1
Extra hard	6	50.0
Spring	8	60.5
Extra spring	10	68.7

Reduction in thickness of an annealed brass sheet from 0.0808″ (12 gauge) to 0.0508″ (16 gauge) by cold rolling would result in a hard temper. (R.H.H.)

TEMPER CARBON. Cast Iron.

TEMPER ROLLING. Soft annealed low-carbon steel and ingot iron sheets tend to form stretcher-strains, a rough surface condition, when drawn into autobody components or similar parts. Stretcher-strains, also called Lüder lines or orange peel, are formed when the material reaches the **yield point.** In areas where the total stretch is greater than the yield point elongation, the surface again becomes quite smooth. In order to prevent stretcher-straining, annealed sheets are temper-rolled to eliminate the yield point elongation. A reduction by cold rolling of only 0.5–2.0% is sufficient. In the case of iron or steel made by the rimming process the yield point elongation gradually returns, making it necessary to draw or stamp the sheet within a limited time after temper rolling. **Roller leveling and stretcher leveling** also aid in the prevention of stretcher-straining. (R.H.H.)

TEMPERATURE. Fundamentally, temperature is a manifestation of the average translational kinetic energy of the molecule of a substance due to heat agitation, and is measurable by any one of many physical effects due to changes or differences in this energy. Thus, substances expand, their electrical resistivity changes, gases and vapors exert varying pressure, the viscosity of fluids alters, etc., as the temperature varies; and the state of aggregation of any substance (whether solid, liquid, or gaseous), under a fixed pressure, depends primarily upon the temperature. Very imperfectly, also, our special temperature sense is able to judge whether one body with which we come into contact is warmer or colder than another. Heat energy always transfers itself spontaneously from the warmer to the cooler parts of any body or system of bodies, never in the reverse direction, and the transfer ceases when the temperatures become equalized. The temperature of a vacuum may be defined as the temperature of a small body placed in it and in thermal equilibrium with it. All measurements of temperature, upon whatever principle they are based, are comprised under **thermometry.** (See also **Temperature Scales.**) (L.D.W.)

TEMPERATURE GRADIENT IN THE ATMOSPHERE. The maximum rate of decrease of temperature with distance in the atmosphere is known as the thermal gradient. Temperature gradients directed vertically are known as lapse rates. (P.E.K.)

TEMPERATURE, HUMAN. The normal temperature of the human body is usually said to be 98.6° F. Actually this normally varies in the course of 24 hours, so that variation between maximal and minimal temperatures during this period is about 1.8° F. The above figures are those obtained when the temperature is taken by mouth. The rectal temperature is 1° F. higher.

The body temperature is determined by the relation of two factors: the amount of heat produced and the amount of heat eliminated. The amount of heat produced depends on the basal **metabolism.** Additional heat is produced by muscular activity. Extra heat is eliminated by increase in radiation, condensation, or evaporation on the skin surface, and by more rapid and deeper breathing. When insufficient heat is eliminated the temperature rises and **fever** is said to be present. Normally the delicate adjustment in the body between heat production and heat elimination is under control of the temperature centers in the brain. If the body temperature falls below 86° F., life is seriously threatened. The highest temperature compatible with life is between 109 and 110° F. (D.M.H.)

TEMPERATURE IN THE ATMOSPHERE. Atmospheric Structure.

TEMPERATURE SCALES. Temperature is usually reckoned both ways from an arbitrarily chosen zero. When it had become known that **heat** is a form of **energy** and that temperature is determined by the mean transitional energy of molecular agitation, the concept of an **absolute zero** of temperature became possible; but since such a condition is apparently unattainable and is inconveniently far removed from temperatures of everyday experience, a more practicable reference point, such as the melting point of ice, is preferable for ordinary purposes.

Starting at such a zero, it would seem logical to base the temperature scale upon equal quantities of some selected effect caused by temperature change. For example, a change of one Fahrenheit degree in the temperature of ice-cold mercury increases its volume by almost exactly one ten-thousandth, so that each ten-thousandth might be taken as indicating one degree of temperature. However, a different plan has been followed. Instead of one fixed point, two are chosen, and the temperature interval between them divided into aliquot parts.

Thus, for the centigrade scale, the fixed points are the freezing and the boiling points of water, and the

interval is divided into 100 parts, so that the freezing point is 0° C. and the boiling point is 100° C. On the Fahrenheit scale, these points are marked 32° and 212° respectively, the zero point having no obvious physical significance. The ratio of the Fahrenheit to the centigrade degree is therefore 5:9; and if t_F and t_C are respectively the Fahrenheit and the centigrade value of the same temperature, their relation is easily seen to be

$$t_F = \tfrac{9}{5}t_C + 32^\circ, \quad \text{or} \quad t_C = \tfrac{5}{9}(t_F - 32^\circ).$$

The original of the centigrade scale was the Celsius scale, on which the boiling point was zero and the freezing point 100°. The Réaumur scale, with freezing as zero and boiling at 80°, is still used in parts of Central Europe. Special limited scales have been adopted for certain purposes; for example, the Leyden low-temperature scale (or low-temperature range of the centigrade scale), taking the boiling point of hydrogen at −252.74° and that of oxygen at −182.95° as its fixed points and using the centigrade degree.

Since the centigrade value of absolute zero has been determined as −273.16°, it follows that if we wish to express an "absolute temperature" in centigrade degrees, we have but to add 273.16° to the centigrade temperature:

$$T = t_C + 273.16^\circ.$$

This is the basis of the Kelvin scale, and therefore 0° C. is 273.16° K. (degrees Kelvin). (See **Thermochemistry.**)

It will be noted that nothing is here said as to the basis upon which equal subdivisions or "degrees" of a fixed temperature interval are established. For this the reader is referred to **Thermometry.** (L.D.W.)

TEMPLATE. **Press Working; Sheet Metal Processes.**

TEMPORAL. A bone of the vertebrate skull. In the human skull it lies at the side, centering about the ear. It forms the posterior part of the cheek bone with the articulation of the lower jaw, and bears the mastoid process behind the ear. It includes the squamosal bone and the bones of the ear. (A.W.L.)

TENCH. Pisces, Teleostei. A European fresh-water fish (**Pisces**), *Tinca tinca.* It is found in ponds, lakes, and other quiet waters, particularly those with a muddy bottom. The species is known to reach a weight of 5 lbs. in some cases. (A.W.L.)

TENDON. Connective tissue structures connecting muscles with their skeletal supports. They are composed of parallel white fibers, closely bound into bundles between which the cells of the tendon are compressed. The entire tendon is surrounded by a fibrous sheath known as the vagina fibrosa which is split in some cases to form a cavity containing a mucoid liquid. Such a sheath is called a vagina mucosa. It develops where a wide range of movement is necessary.

Aponeuroses, ligaments, and **fasciae** are fibrous structures resembling tendons in structure. The first are broadly expanded and usually bind down muscles. The second connect bones. The third are fibrous coverings of muscles and other organs. When tendons are severed they must be sutured together again. At least 6 weeks are required for union between the cut ends. (A.W.L., R.S.M.)

TENDRIL. A tendril is a slender elongated structure which either twines around any supporting object or is attached thereto by means of small disks. Tendrils may be modified **stems,** as in the grape, **leaves,** or leaflets as in various peas, or **stipules.** (R.M.W.)

TENON. **Dado.**

TENORITE. A mineral oxide of copper, CuO. Crystallizes in the monoclinic system. Hardness, 3.5; specific gravity, 5.8–6.4; color, gray to black with metallic luster. Named after M. Tenore (1780–1861), Naples. (R.M.F.)

TENOSYNOVITIS. An infection of the membranous sheaths which envelop tendons in various parts of the body. The sheaths most commonly involved are those which surround tendons controlling movement of the fingers, wrist, and hand, and provide frictionless movements of these parts. Normally there is a small amount of fluid within the sheaths to provide lubrication. When infection takes place, more fluid accumulates with the production of pus. The only treatment that will save the function of the tendon is very early surgical drainage.

The symptoms of tenosynovitis are acute pain, swelling, and redness over the affected part. (D.M.H.)

TENREC. Mammalia, Insectivora. *Centetes.* An animal of Madagascar. This species resembles the other members of the order in its compact body, short legs, and long sharp muzzle. It is the largest of the group, attaining a length of 16″, and is clothed with a mixture of spines, bristles, and hair. Tenrecs are nocturnal burrowing animals. (A.W.L.)

TENSILE LOAD. **Load.**

TENSILE STRESS. **Stress.**

TENSION. In structural engineering tension is used to denote the longitudinal force which causes the fibers of a member to elongate, thus giving rise to tensile stress. (C.W.C.)

TENSION MEMBER. Any member of a structure which is subjected to a primary tensile **stress** is called a **tension** member. The analysis or design depends on that part of the cross-sectional area which is effective in resisting the tensile stress. The effective area at any section is called the net section. It is the gross area minus the area of any holes including those filled by **rivets** or **bolts.** The net section may be based on a right section or a zig-zag section. The net section of a threaded member such as a bolt or **tie rod** is the area at the root of the thread. The strength of a tension member is a function of the minimum net section.

If the member is composed of two or more independent parts other than **eye bars,** the parts may be connected by **tie plates** or by tie plates and **lacing bars** to equalize the stress and prevent excessive distortion during fabrication, shipping or erection. (C.W.C.)

TENSION TEST. Next to **hardness** tests, tension tests are the most frequently used to determine the **mechanical properties of metals.** Tension test specimens necessarily vary in form with the product to be tested. A machined cylindrical specimen with threaded or shouldered ends for gripping is used when the material is sufficiently thick. Standard flat specimens are used for flat-rolled products. While both types of specimens have a reduced central section to insure breaking within a measured gauge length, wires and certain special shapes such as steel reinforcing bars for concrete are tested in full section without preparation. Special cast test specimens are often attached to castings, or cast separately, and these are generally tested without machining.

The significant loads determined in the test are reported as unit stresses based on the area of the original section. (Stress = load ÷ area.) The elongation is expressed as % increase in length of the gauge-marked section. The initial gauge length is generally 2 in., although an 8-in. gauge length is used for certain flat

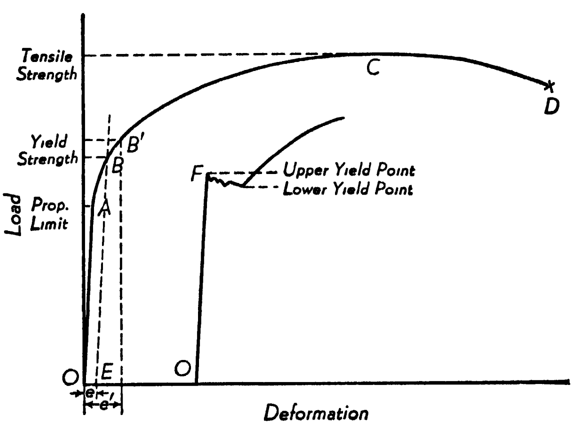
specimens and other gauge lengths are used for special specimens. The gauge length should be specified when elongation is reported since % elongation values are higher for short than for long gauge lengths.

The elongation measured over a fixed gauge length, and the reduction of area of the section at the fracture are measures of ductility. In cylindrical specimens the area is readily determined from the final diameter at the fracture. The % reduction of area is then determined as (original area − final area) ÷ original area.

Autographic load-deformation curves are often drawn during the test. From such a curve the modulus of elasticity, proportional limit, and yield strength can be determined.

A typical curve has an essentially linear portion (OA) in which the deformation is proportional to the applied load. It follows that the unit stress (load ÷ original area) is proportional to the unit strain (deformation ÷ original gauge length) in accordance with Hooke's Law. The numerical value of this ratio (e.g., in lbs. per sq. in.) is known as Young's Modulus or Modulus of Elasticity. (See **Elasticity.**)

The maximum stress that is developed without deviation from proportionality of stress to strain is the proportional limit (the stress corresponding to load A).



Stress-strain diagram.

The maximum stress that can be applied without causing permanent deformation upon release of the load is the elastic limit. Usually there is little difference between the proportional limit and the elastic limit. Both are dependent on the sensitivity of the measuring devices used and certain details of testing technique. For this reason the yield strength is generally used as a practical measure of the elastic properties of metals.

The yield strength is the stress at which the stress-strain curve deviates from the initial straight line by a specified increment of strain. The yield strength corresponding to the load at B is based on the specified strain deviation or offset e. The value of e may be as low as 0.0001 in. per in. of gauge length but the most commonly used value is 0.002 in. or 0.2% strain.

If the load should be released after reaching B, the load-deformation relationship will follow the line BE, or a curved line terminating between O and E. Thus the permanent strain will be e or a somewhat smaller value. When the final or permanent strain is specified, the stress is known as the proof stress.

An alternate type of yield strength is based on a specified total extension under load, such as 0.5%. If the specified extension is e' the load B' determines the "extension-under-load" yield strength. Load B' may be greater or less than B.

The tensile strength, or ultimate tensile strength, is the maximum stress developed in the tension test. (Load C ÷ original area.)

The breaking stress, corresponding to load D, is seldom determined or reported.

In loading tension specimens of many soft irons and steels a point is reached where stretching continues without increase in load. The unit stress obtained by dividing this load, F, by the original area of the section is called the yield point. The elongation of the specimen at the yield point may reach 8% in some instances, after which the load will again increase to a maximum in the normal manner. Upper and lower yield points are indicated at F; both are used but the upper yield point is influenced by variations in testing technique such as alignment of the specimen in the testing machine and speed of test. Yield points occur only rarely in the non-ferrous metals.

Conventional stress-strain curves are necessarily similar to the load-deformation curves from which they are derived. True stress-strain curves can also be derived in which the stress is based on the actual or instantaneous area of the cross-section. Such curves do not have a maximum corresponding to C but increase continuously to the breaking load. (R.H.H.)

TENSION-FIELD THEORY OF BEAM ANALYSIS. The analysis of **plate girders** and other built-up beams of structural engineering is based on the assumption that the web does not buckle along diagonal lines under the action of the diagonal compressive stresses. (See **Stress, Principal Stress.**) Although these stresses vary through the depth of web (see **Web Plate**) between **flanges** at any section, they are usually assumed to be constant and equal to the value at the **neutral axis.** The diagonal compressive stress at a point on the neutral axis is equal numerically to the **shearing stress** at that point. Design procedure is such that these webs will not buckle if the **intermediate stiffeners** are properly spaced.

In **airplane** structures the webs of built-up beams are very thin. Consequently the possibility and the effect of diagonal buckling must be investigated even though the webs are supported by closely spaced stiffeners. These stiffeners divide the web into a series of panels in which buckling may occur. After a web has buckled there is a complete redistribution of stress at the section. The web within the panel acts as a series of inclined strips subjected to **tensile stress.** The flanges must resist both vertical and horizontal components of this diagonal tension at the junction of the flange and web. The horizontal component causes **direct stress** in the flange and the vertical component produces flexural stress (see **Flexure**) in the flange which acts as a **beam** continuous over the stiffeners. Buckled webs which carry the shear by means of inclined tension only are called tension-field webs. Beams whose webs are designed to buckle are known as Wagner Beams.

If the shear at the neutral axis is less than a certain critical value at which buckling takes place, the web is said to be shear resistant and the usual formulae for beam analysis are applicable. The critical stress at which a braced panel will buckle may be obtained by analytical or experimental means. Formulae which are applicable to beams with shear resistant webs cannot be used for beams with tension-field webs. (C.W.C.)

TENSION-FIELD WEB. Tension-Field Theory of Beams.

TENSORS. The tensor concept is a generalization of that of a **vector**, and requires for its specification more than three components.

A tensor may be defined as a set of n^r components which are functions of the coordinates of any point in space of n dimensions, which is transformed linearly and homogeneously, according to certain rules, when a transformation of coordinates is made. Tensors are called covariant, contravariant or mixed, according to the law

of transformation. The number r is called the rank or order of the tensor. (L.L.S.)

TENTACLE. A slender fleshy protuberance of the body wall, in the region of the mouth and usually arranged as a group surrounding the mouth. Tentacles are well developed among the **coelenterates**, the marine **annelids**, and the **cephalopod** mollusks, and are present in all **Bryozoa, Brachiopoda**, and **Phoronidea**. In the coelenterates they contain stinging cells and are capable of wrapping around the prey to bring it to the mouth. They also act to secure food by ciliary movement; in the Bryozoa the cilia covering them apparently carry a food-bearing current down the funnel that they form about the mouth. Cephalopod tentacles also enfold the prey but in addition they are provided with cuplike suckers which enable them to grip even very smooth surfaces. In this group and to a limited extent in the coelenterates they are used for locomotion.

In the **echinoderms** a sensory appendage at the end of each radial water vessel is called a terminal tentacle and, in the sea cucumbers, tube feet in the region of the mouth are developed into tentacles of various forms, sometimes finely branched. (A.W.L.)

TENTACULOCYST. A sense organ of the jellyfishes and a few allied forms. It consists of a reduced tentacle at the margin of the body, hooded by a small projection of the margin. The tentacle bears a pigment spot which may be a light-sensitive organ and is flanked by two pits regarded as olfactory organs. Tentaculocysts lie at the ends of the interradial and perradial canals. (A.W.L.)

TEOSINTE. **Corn.**

TEPHRITE. A term proposed by Cordier, in 1816, for a variety of **basalt** containing both **plagioclase feldspar** and **nepheline** or other soda-feldspathoids. Tephrite differs from **basanite** because of the absence of **olivine.** (R.M.F.)

TERBIUM. Symbol: Tb. Atomic number: 65. Atomic weight: 159.2. No isotope, but of single atomic form: 159. Type of compound: Tb_2O_3. Color of salts: Colorless. Discovered by Mosander in 1842. A member of the **yttrium** sub-group of the rare earth metals. (R.K.S.)

TERGITE. **Skeletal System.**

TERMINAL EFFICIENCY. The structural efficiency with which stresses may be transmitted through the terminal connection of a structural member is called "terminal efficiency." This is of more importance to tension than compression members. Near the point of connection of a member such as a tie-rod, a cable, or a rolled or drawn section, the connecting device will usually alter the distribution of stress over the cross-section of the member. Threads or rivet holes may be cut to develop the type of connection desired. Eccentric loadings and short radius bends may have to be introduced. The terminal efficiency may be defined as the safe working stress of the member, including terminals, divided by the safe working stress of the section used for the member. It is possible to have terminal efficiencies greater than 100%. For example, by swaging the ends of a rod its diameter at the terminal fitting can be increased sufficiently to provide greater strength than that possessed by the normal section of the rod. (F.T.M.)

TERMINAL MORAINE (END MORAINE). When balance is maintained between the melting of a **glacier** and its forward advance, the debris carried on (superglacial); within (englacial); and dragged along the bottom (subglacial); is dumped at that point and builds up a heterogeneous mass of the transported material called the terminal moraine. If a glacier is slowly retreating and makes successive halts farther and farther up the valley, a series of terminal moraines are formed which are spoken of as recessional moraines. (R.M.F.)

TERMINAL TEMPERATURE DIFFERENCE. Two fluids not having the same temperature and being on opposite sides of a heat-conducting surface cause a temperature difference to exist across the surface, a difference that may vary from point to point on the surface. If one of the fluids is in motion the temperature difference where it joins or leaves the conducting surface is the terminal temperature difference. Water flowing through a tube which is surrounded by steam whose temperature exceeds that of the water will receive heat by conduction through the tube and become heated. The temperature difference between steam and water dwindles as the water traverses the tube, becoming minimum at the discharge end of the tube. The minimum temperature difference is often called the terminal temperature difference. (F.T.M.)

TERMITE. **Isoptera.**

TERMITOPHILE. An insect of another form living in the nest of **termites.** Both ant and termite colonies are inhabited by other insects, some apparently living as scavengers and profiting by the supply of food and by the protection afforded by the colony while others produce secretions used by their hosts and so live in a commensal relationship. Even in the latter cases the termitophiles may eat the young of the termites, but since they render some return they are not to be regarded as parasitic on the colony. Some, however, are nourished by food supplied by the termites in return for the desired secretion. Insects of such habits are often very strangely formed, differing conspicuously from other members of the orders to which they belong.

Among the known termitophiles are **flies, larvae** of **moths,** one species of **Homoptera,** and many **beetles.** (A.W.L.)

TERN. Aves, Charadriiformes. A bird (**Aves**) resembling the gulls but with a more slender and tapering beak. The tail is forked. Terns are very like gulls in habits and are usually seen in flight over water, both on the coasts and near ponds and lakes. About 10 species are normally found in the United States. (A.W.L.)

TERNE PLATE. An iron or steel sheet coated by the hot-dip process with a lead-tin alloy containing up to 25% tin.

There are two classifications known as "short ternes" and "long ternes." Short ternes are produced in certain small sheet sizes in light gauges only and usually carry heavy weights of coating. They are used principally for roofing purposes.

Long terne sheets are produced in sizes 24" x 60" and larger in a wide range of thicknesses and usually carry much lighter weight coatings than short ternes. Long terne sheets are often supplied in deep drawing grades, in which case the coating acts as a carrier for lubricating oils or compounds in the drawing dies and also provides protection from rust during processing and storage. The alloy coating also greatly facilitates soldering and is a good base for paint. Among the principal applications of long ternes are metal caskets and automotive parts such as gasoline tanks, radiator side walls, oil filters, and mufflers. (R.H.H.)

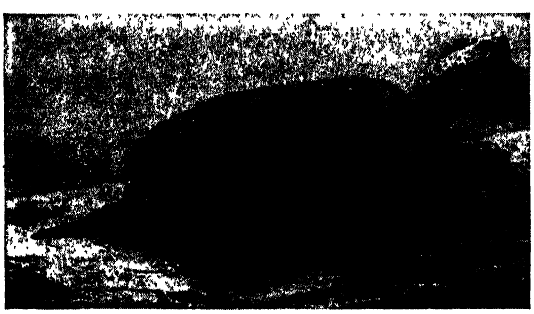
TERRA COTTA. Terra cotta is the name given to a product made of burnt clay which has been fired at

a high temperature. It is employed in building construction as a decorative feature, and is to be found in copings, cornices, facades, and other trim. It is used both on exteriors and interiors. Terra cotta is one of the most permanent of building materials, and a great deal of distinctive individual ornamentation of buildings of present and past times has been achieved by liberal use of terra cotta. A standard building material used to construct interior partitions, to back up exterior face brick in a masonry wall, or to form a complete exterior wall for an industrial building, is known as hollow building tile. The aim in manufacturing this product, of course, is to produce a cheap fireproof building material, but not an especially decorative one.

A great deal of terra cotta work is special, i.e., in its shape and surface decoration, as well as color and method of attachment. Models of the separate pieces are made and plaster casts taken. These casts are then used to mold the clay body of the terra cotta. When the molded clay has dried it is removed from the mold and fired at high temperature until it has become hard and unaffected by moisture. It is known now as a bisque, and is ready for the application of liquid glazes, known as slips. The minerals which produce the color are incorporated in this slip. The bisque is either sprayed or dipped in the slip, and returned to the kiln for firing of the glaze. Terra cotta is set in mortar, with carefully pointed joints, and in some cases may be reinforced by metal ties or by shelves or caps. (F.T.M.)

TERRA ROSSA. A red **ferruginous**, residual earth derived from the surface alteration of limestones. A characteristic soil of the *Karst* lands surrounding the Adriatic Sea. (R.M.F.)

TERRAPIN. Reptilia, Chelonia. Certain of the pond and land **turtles**, especially those of the genera *Malaclemmys* and *Pseudemys*. The related genus *Terrapene* includes the box turtles, and the common painted turtles are also closely connected forms. The species whose flesh



Diamond back terrapin. (*N. Y. Zool. Soc.*)

is so highly esteemed is the diamond-backed terrapin or salt-marsh turtle found in salt marshes along the Atlantic coast from Massachusetts to Florida. This and a related species of the Gulf coast make up the genus *Malaclemmys*. The species of *Pseudemys* are commonly called sliders or cooters, one species bearing the name red-bellied terrapin. They are edible but are less highly valued than the diamond-back. Terrapins are widely distributed in the northern hemisphere. Elsewhere they are limited to a few species in Central and South America. (A.W.L.)

TERRESTRIAL COORDINATES. The position of a point on the surface of the earth may be defined to a high degree of precision by considering the earth as a sphere and establishing on that sphere a reference frame for **spherical coordinates**. The most common system is to consider the line joining the poles of rotation of the earth as a fundamental line. The plane perpendicular to this line, and passing through the center of the earth, is the plane of the **equator** and cuts out on the surface of the earth a great circle known as the terrestrial equator. Great circles on the earth perpendicular to the plane of the equator and passing through the poles of rotation are known as terrestrial **meridians**. The fundamental direction selected in the plane of the equator is the direction of the point of intersection of the meridian through Greenwich, England, with the equator.

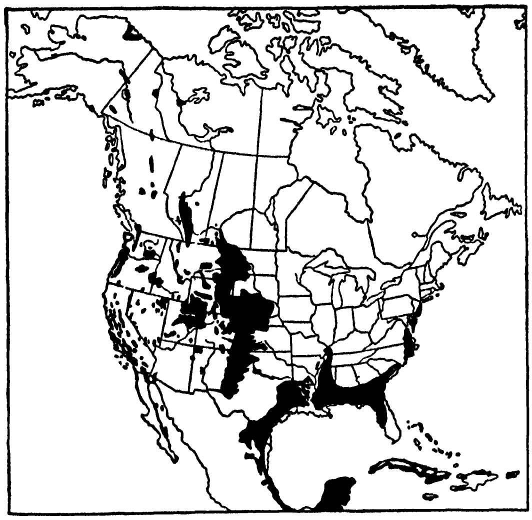
Terrestrial **longitude** of a point on the earth is the spherical coordinate measured in the plane of the equator either east or west from the point of intersection of the meridian through Greenwich to the point of intersection of the meridian through the point in question. **Latitude** is the spherical coordinate measured from the equator north or south along the meridian to the point in question. (See **Latitude, Longitude, Celestial Navigation,** etc.). (W.K.G.)

TERRESTRIAL MAGNETISM. The outstanding facts of the earth's magnetism were investigated by William Gilbert about 1600. He recognized that the earth acts as a huge bipolar magnet, and anticipated by many years the actual discovery of its magnetic poles. These are located, respectively, on the Boothia peninsula about 500 miles northwest of Hudson's Bay and on the Antarctic Continent some 750 miles northwest of Byrd's "Little America." (The pole north of Hudson's Bay is, of course, one of the negative or south-seeking kind, since the positive poles of compasses point toward it.) Our direct knowledge of the terrestrial magnetic field is confined near the earth's surface, and is usually represented by maps showing lines of equal magnetic **variation** (departure from the true north), lines of equal **inclination** or dip (see **Dip Needle**), and lines of equal magnetic intensity (see **Magnetometer**). The inclination at middle latitudes approximates 70°, while the total intensity in this region is usually something like 0.6 **oersted,** with a horizontal component of about 0.2 oersted. There is a line of zero variation (agonic line) at all points of which the compass indicates the true north; this line passes down through the United States and traverses the globe in each hemisphere from northwest to southeast.

The terrestrial field has certain variations, chief among which are: 1. The diurnal variation, in which the compass swings back and forth through an angle of many minutes once a day. 2. The secular variation, a slow periodic movement of many degrees with a period of several centuries. 3. Random variations, sometimes very great, when they are called "magnetic storms." These last are unquestionably associated in some way with those solar activities which result in **sun spots,** since their occurrence is almost simultaneous with the appearance of sun spots, and they have the same 11-year cycle. The **aurora borealis** seems to be similarly involved. The mechanism behind terrestrial magnetic phenomena has not been fully explained; though the rotating earth's electrical condition (see **Lightning**), together with thermoelectric earth-currents, doubtless contribute to some of the effects. (L.D.W.)

TERRESTRIAL PHOTOGRAMMETRY. **Photogrammetry.**

TERTIARY. A major subdivision of the **Cenozoic,** or last geologic era. The periods of the Tertiary from the oldest to the youngest are: **Paleocene, Eocene, Oligocene, Miocene, Pliocene.** (R.M.F.)



Map showing the surface distribution (areas of outcrops) of Tertiary strata in North America.

TESCHENITE. Theralite.

TESLA COIL. A type of **induction** coil in which the primary has a high-frequency spark gap instead of the usual interrupter, and whose secondary yields an intense high-frequency discharge. A typical arrangement is shown in the figure. A high-voltage transformer T, or sometimes an ordinary induction coil, sends sparks across the primary gap G_1, which is in circuit with a condenser C_1 and the primary air-core coil P, composed of a few turns of heavy copper wire or tubing. Because of the oscillatory nature of the condenser discharges, this circuit is the seat of powerful high-frequency oscillations. The secondary, S, consists of many turns of fine wire. The secondary circuit may be "tuned" by means of a variable condenser C_2, and when it is in **resonance** with the primary, the oscillations in it are very intense. A torrent of high-frequency sparks plays across the secondary gap G_2; or one terminal may be grounded and sparks drawn from the other. (L.D.W.)

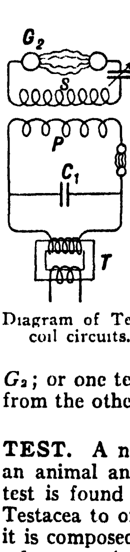


Diagram of Tesla-coil circuits.

TEST. A non-cellular structure enclosing the body of an animal and formed by the outer layers of cells. A test is found in some 1-celled animals, giving the name Testacea to one division of the phylum. In these forms it is composed of various materials, including **chitin** and calcareous (see **Calcium**) deposits. It may be either rigid or flexible. Foreign particles such as grains of sand are incorporated into some of these tests.

A tough enveloping test is also formed about the body of the **tunicates**, giving them their name through the synonymous term tunic. In this group the structure is formed of a material closely related to cellulose, which is a common plant product. (A.W.L.)

TEST OF INDEPENDENCE IN A CONTINGENCY TABLE. It is frequently desired to test whether items in contingency tables of r rows and c columns are independent. If we represent the actual number of **variates** in the cell formed by the intersection of the rth row and the cth column by n_{rc} and the theoretical number by n'_{rc} we know that on the hypothesis of independence

$$n'_{rc} = \frac{n_c n_r}{N}$$

where N is the number of items in the whole table and n_c is the number of items in the cth column and n_r is the number of items in the rth row. Then we compute

$$\chi^2 = \sum \frac{(n_{rc} - n'_{rc})^2}{n'_{rc}}$$

summed over all cells, $n'_{rc} \geqq 5$. For a test of significance we use the χ^2 distribution with $(n-1)(r-1)$ **degrees of freedom.** If the hypothesis is rejected we may if desired compute the **coefficient of mean square contingency.** If $n'_{rc} < 5$, special methods must be used or certain cells must be combined. If $n'_{rc} > 5$, χ^2 is found somewhat more easily by

$$\chi^2 = N\left[\left(\sum \frac{n^2_{rc}}{n_r n_c}\right) - 1\right],$$

the summation being extended over all cells. (L.A.A.)

TEST OF THE DIFFERENCE OF TWO MEANS. Student's t Distribution.

TESTA. Seed.

TESTACEA. Sarcodina.

TESTICARDINES. Brachiopoda.

TESTICLE. **Testis.** The testicles are the two **male** sex glands which are suspended from the groin by the spermatic cords, and are supported and enclosed by the **scrotum.** Each gland measures about 1½" in length, 1" in width and about ¾" in thickness from side to side. The testicle is joined to the spermatic cord by means of the epididymis which is a coiled duct lying at the upper portion of the testicle. When uncoiled this duct measures 20' in length. The function of the testicle is to produce **spermatozoa** and the male **sex hormone.** If both testicles are removed before puberty, secondary sex characteristics fail to develop, due to the absence of testosterone. The skin remains smooth, the voice is high-pitched, fat develops around the breasts and buttocks, and the pubic hair is scanty. Erections are feeble, and no ejaculation occurs. The individual is timid, lacks ambition, normal combativeness and aggressiveness. Such an individual is known as a eunuch. Eunuchoidism usually results from failure of development of the testes, which is usually secondary to a **pituitary** disorder.

In early fetal life both the ovaries and the testicles lie in front of and below the kidneys. During fetal growth they descend. The ovaries finally lodge on the side wall of the pelvic cavity. The testicles normally continue downward and descend through and out of the abdomen in the region of the groin to the scrotum. This descent may be arrested along any portion of this pathway, and one or both testicles may remain in the abdominal cavity, in its wall or in the groin. The condition is known as **cryptorchidism.** Men with undescended testicles are sterile, but are sexually normal otherwise. The situation is corrected by an operation in which the undescended testicle is brought down to its normal scrotal position. This operation is best done at or shortly after puberty. In some cases glandular injections will cause the testicle to descend without operative interference.

Diseases affecting the testicles are tumors, which are rare, and infections. These include **tuberculosis, syphilis,** and acute staphylococcal, gonococcal, or other pyogenic infections. The testes are involved as a complication of **mumps,** and atrophy and sterility may be the end result. (R.S.M., D.M.H.)

TESTIS. Testicle.

TESTUDINATA. The **turtles** and **tortoises**, constituting an order of the class **Reptilia**, also known as the order Chelonia. These animals have a short broad body enclosed in a shell composed, in most species, of closely joined bony plates covered with thin plates of horn or tortoise shell. The bony plates are flattened ribs and vertebrae, with supplementary dermal plates. The upper part of the shell is the **carapace** and the plate below the body is the plastron; the two are firmly united along the sides in most species. The skin is covered with scales and the jaws are without teeth, forming a horn-sheathed cutting beak.

Most species of the order are partially aquatic but some are strictly terrestrial. The marine turtles are the most thoroughly aquatic species, but even they come to shore to lay their eggs. These species have all four limbs developed as paddlelike flippers while the other members of the group merely have webbed toes. (A.W.L.)

TETANUS (Lock-Jaw). An infectious disease caused by *Clostridium tetani* which liberate a toxin having a peculiar affinity for nervous tissue.

Tetanus has been known since ancient times. No specific treatment was available until the development of an antitoxin by Behring and Kitasato in 1890. In 1922 in the United States, 1480 persons died from tetanus, but in World War I, when tetanus antitoxin was given to all wounded American soldiers, among 224,089 wounded, only 36 developed the disease.

Tetanus bacilli are **anaerobic bacteria, spore-forming** rods which are found in the excreta of man and many domestic animals. They thrive well in soil and manure; the spores are extremely resistant to heat and chemicals. The disease usually follows an injury of the puncture or penetrating type. Blank cartridge wounds are particularly dangerous in this respect. Infection occurs by the introduction of spores into the wound. The organisms will not grow unless there is devitalized tissue present. If they gain a foothold, they multiply deep in the tissues and produce an extremely potent neurotoxin which is responsible for the signs and symptoms of the disease.

Following an incubation period of 5–10 days, the earliest symptoms appear. They are restlessness, irritability, stiffness and tightness of the various muscles. The jaw muscles are usually affected first, and later become fixed in a spasm which gives the disease its name—lockjaw. In severe cases, extreme rigidity of the muscles and painful **convulsions** set off by the slightest noise or other stimuli occur. Death may result from spasm of the respiratory muscles and asphyxia. Often, however, the immediate cause of death is not apparent.

All wounds of the dirty, deep lacerated type should be given immediate surgical care and tetanus antitoxin should be given at once. After the disease once develops, the important factor in treatment is to control the convulsions and to give sufficient antitoxin to neutralize the effect of the poison produced by the tetanus organisms. Before the use of antitoxin the mortality from tetanus was from 80–100%. At present the mortality is only about 25%.

Recently a tetanus toxoid has been produced. This is a preparation of treated toxin which produces active immunity when given in small doses subcutaneously. It is given to those who work in the soil, and may also be given to children routinely as a prophylactic measure. (D.M.H.)

TETANY. Increased neuromuscular irritability manifested by spasm of the muscles, particularly of the extremities, and sometimes convulsions. It is commoner in children than in adults. Tetany is due to an upset in the inorganic salt metabolism which may be caused by a number of factors. There are two common types: one resulting from low serum **calcium**, and the other by an upset in acid-base balance with resultant alkalosis. Conditions resulting in low calcium include **parathyroid** deficiency, inadequate calcium in the diet, loss of calcium through **diarrhea**, and **rickets**. Alkalosis and tetany may follow hyperventilation (excessive blowing off of the acid CO_2 from the lungs), excessive bicarbonate ingestion, and loss of hydrochloric acid by persistent vomiting. (See **Acidosis; Alkalosis.**)

Treatment of tetany depends on its cause. If low calcium must be corrected, calcium chloride or calcium gluconate may be given intravenously. Alkalosis is compensated by the ingestion of hydrochloric acid, ammonium chloride or acid phosphates. (D.M.H.)

TETRABRANCHIATA. Cephalopoda.

TETRACHORIC CORRELATION. Tetrachoric correlation is a technique for finding the **correlation** in a 2×2 contingency table with entries, a, b, c, d, and $N = a + b + c + d$.

a	b	$a+b$
c	d	$c+d$
$a+c$	$b+d$	N

y increasing

x increasing

In the table above we have the standard form. We determine h and k by the following equations

$$\int_h^\infty \frac{e^{-\frac{t^2}{2}}}{\sqrt{2\pi}}\,dt = \frac{b+d}{N}, \quad \int_k^\infty \frac{e^{-\frac{t^2}{2}}}{\sqrt{2\pi}}\,dt = \frac{c+d}{N}$$

such that $h \geq 0$ and $k \geq 0$. This can always be accomplished if the contingency table is put into the standard form above. We then calculate $\frac{d}{N}$ and find r, the tetrachoric coefficient of correlation from the tables of Pearson for volumes of the normal bivariate surface where

$$\frac{d}{N} = \int_h^\infty \int_k^\infty P(t_1, t_2, r)\,dt_1,\, dt_2$$

having found h and k by the previous equations, $P(t_1, t_2, r)$ being the normal probability function in two variables. These tables are given in "Tables for Statisticians and Biometricians, Part II" edited by Karl Pearson in the section Volumes of the Normal Bivariate Surface, pp. 78–137. The tetrachoric coefficient of correlation is based on the assumption of a normal distribution in both variables. Hence, it cannot be compared to the usual **coefficient of correlation.** (L.A.A.)

TETRADYMITE. The mineral tetradymite is a **bismuth tellurium sulfide** corresponding to the formula $Bi_2(TeS)_3$. It is **rhombohedral.** Occurs usually in gold **quartz** veins. Found in Norway, Sweden, England, Bolivia, British Columbia, and in the United States in Virginia, North Carolina, Georgia, Montana, Colorado and elsewhere. It derives its name from the Greek word meaning fourfold in reference to the double twin crystals occasionally developed. (E.S.C.S.)

TETRAGONAL SYSTEM. Crystallography.

TETRAHEDRITE. The mineral tetrahedrite is a **copper-antimony sulfide**, the formula being $Cu_8Sb_2S_7$. The copper may be replaced in part by **iron, lead, zinc,** mercury, etc., and the antimony by **arsenic**. This mineral is **isometric** and the crystals are **tetrahedrons** often highly modified. It is also found massive. It has no **cleavage**; uneven fracture; brittle; hardness, 3–4; metallic luster; color, gray to black; streak, gray to black but may be brown or red; practically opaque. There are many European **localities** for tetrahedrite among which might be mentioned Rumania, Czechoslovakia, France, and Cornwall, England. It is found in

Algeria and Bolivia; and in the United States in Colorado, Arizona and Utah. While chiefly an ore of copper it may be also mined for **silver** or other replacing metals. (E.S.C.S.)

TETRAPHYLLIDEA. **Cestoda.**

TETRAPLASY. A theory of the origin and **evolution** of living things formulated by Henry Fairfield Osborn. According to this theory, also known as the tetrakinetic or tetraplastic theory, four complexes are the foundation of all that exists and occurs in the organic world. These were designated as the inorganic environment, the organism, the Heredity-germ, and the life environment. In more recent publications they have been discussed under the terms physical environment, internal environment, heritage, and organic environment. The theory is distinctly mechanistic, since it postulates that vital phenomena are adequately explained as the results of interaction among these complexes. (A.W.L.)

TETRARHYNCHIDEA. **Cestoda.**

TETRATHIONIC ACID AND TETRATHIONATES. Tetrathionic acid ($H_2S_4O_6$) is a colorless solution formed by reaction of **barium** tetrathionate and dilute **sulfuric acid,** and filtering off barium sulfate. Dilute solution of tetrathionic acid may be boiled without decomposition but the concentrated solution decomposes yielding sulfuric acid, **sulfur** dioxide and **sulfur.**

Sodium tetrathionate ($Na_2S_4O_6$) is made (1) by reaction of sodium thiosulfate and **iodine** with accompanying formation of iodide, (2) by reaction of sodium thiosulfate and **ferric** salt solution, lead dioxide, barium peroxide, or sodium peroxide, (3) by **electrolysis** of sodium thiosulfate. No visible reaction takes place when sodium tetrathionate is mixed with (1) ammoniacal **silver** nitrate, (2) **ammonium** sulfide, (3) sodium hydroxide (although thiosulfate, trithionate, sulfite and sulfide may be formed). (R.K.S.)

TETRAXONIDA. A division of the sponges (**Porifera**) included in some classifications as an order characterized by the presence of spicules with four axes. These sponges belong to the **Demospongiae** of this work. (A.W.L.)

TETRODE. **Tube, Electronic.**

TEXTURE. This term, as used by **petrographers,** denotes primarily the absolute and relative size and shapes of the visible constituents of a rock. In an igneous rock the texture of the mineral aggregate depends upon its crystallinity, **granularity,** and **fabric.** Texture, when applied to clastic sedimentary rocks should include the surface characteristics of the constituent particles, or **clasts.** (R.M.F.)

THALAMUS. A great nuclear center in the **brain,** formed just behind the portion that gives rise to the cerebral hemispheres. Communication between the outlying parts of the body and the cerebral cortex is established by the routing of nerve impulses through the thalamus, where the redistribution of impulses is accomplished. Thus the center is important in the types of nervous control that are highly developed in man. (A.W.L.)

THALIACEA. The salpians or salps. A group of transparent marine animals related to the ascidians but drifting freely in the water in contrast with the sessile habits of that group. They constitute a class of the subphylum Urochordata (**Chordata**).

This class is closely related in fundamental characters to the ascidians, showing a high specialization of structure with an enclosing test of material similar to cellulose. It is divided into two orders:

Order Multistigmatea. Barrel-shaped animals with muscle bands forming complete rings about the body.

Order Astigmatea. Body usually flattened. Muscle bands incomplete. (A.W.L.)

THALLIUM. Symbol: Tl. Atomic number: 81. Atomic weight: 204.39. Density: 11.86. Melting point: 303.5° C. Isotopes 203 (29.4%), 205 (70.6%).

Thallium metal is bluish-gray upon fresh exposure, changing to dark gray on standing, this oxidation increased with temperature above 25° C.; soft, and may be easily cut with a knife; malleable but of low tenacity so that it must be extruded to form wire; **nitric acid** is the best solvent; forms alloys with many metals, e.g., **mercury, cadmium, zinc, silver, copper, magnesium.** Discovered by Crookes in 1861.

Thallium occurs in small amounts in **pyrite, zinc blende,** and **hematite** of certain localities, and in a few rare minerals in Sweden and Macedonia. For the recovery of thallium from flue dust of pyrite burners, the dust is boiled with water, allowed to stand some time, filtered, and **hydrochloric acid** added to the filtrate, whereupon crude thallous chloride is precipitated. This is purified by further treatment, and thallium metal obtained (1) by **electrolysis** of the sulfate solution or (2) by fusion of the chloride with **sodium** cyanide and carbonate. Thallium compounds are poisonous, and as such used as rat poison, as insecticide, as a depilatory.

Hydroxides: Thallous hydroxide (TlOH), chemically similar to sodium hydroxide, reacts characteristically with traces of ozone to give brown coloration, when on filter paper; thallic hydroxide ($Th(OH)_3$), brown precipitate (possibly TlO·OH) by reaction of **sodium** hydroxide and thallic salt solution, insoluble in excess sodium hydroxide.

Oxides: Thallous oxide (Tl_2O), black solid, melting point 300° C., when molten attacks glass and porcelain; thallic oxide (Tl_2O_3), brown to black solid.

Salts: Thallous. Thallous sulfate (Tl_2SO_4), soluble; thallous carbonate (Tl_2CO_3), soluble; thallous **alum** ($Tl_2SO_4 \cdot Al_2(SO_4)_3 \cdot 24H_2O$). These compounds are chemically similar to those of sodium. Thallous chloride (TlCl), white resembling silver chloride in appearance and formation and used in an electrical **cell.** Thallous chromate (Tl_2CrO_4) yellow precipitate; thallous sulfide (Tl_2S) black precipitate in acetic acid, neutral or alkaline solution. These compounds are chemically similar to those of lead. Thallous chloroplatinate (Tl_2PtCl_6), pale orange precipitate. Thallous cobaltinitrite ($Tl_3Co(NO_2)_6$), pale red precipitate. These compounds are chemically similar to those of potassium.

Thallic. Thallic chloride ($TlCl_3$), nitrate ($Tl(NO_3)_3$), sulfate ($Tl_2(SO_4)_3$) all white to colorless soluble solids.

Volatile thallium salts, such as the chlorides, color the bunsen flame green. (R.K.S.)

THALLOPHYTES. This division, the second largest of the plant kingdom (the seed plants being the largest) is considered to be the oldest and to contain the most primitive types of plants.

Plants of this division vary from minute forms composed of a single cell to seaweeds 200′ or more in length. These plants do not have any root, stem or leaves, though some have structures which resemble these parts in form. However, with a few exceptions in the brown **algae,** all these plants are composed of aggregations of **cells** which show very little differentiation. A plant body thus not differentiated into true roots, stems and leaves is called a thallus.

Several methods of reproduction are found in the thallophytes. The simplest is **cell division,** which occurs in the unicellular forms. A second method is by spores. These are single cells set apart for reproductive

purposes. Many spores are provided with protective cell walls which keep them alive in unfavorable environments. Reproduction by spores is either sexual or asexual. Several kinds of spores are found in this division. In many thallophytes, asexual reproduction is by means of zoospores; these are reproductive cells provided with one or more cilia, thread-like objects which by their beating propel the spore through the water.

Another form of reproduction is sexual. This occurs in many thallophytes. The cells which function in sexual reproduction are called **gametes**. As a rule gametes are incapable of developing until they unite in pairs, forming cells called zygotes. From the latter new plants develop. Such zygotes usually acquire thick walls and become resting spores. If they are produced by fusion of gametes of equal size (isogametes) they become zygospores; if by fertilization of an egg by a sperm (heterogametes) they become oöspores.

There are two main groups of thallophytes, the **algae** and the **fungi**. Algae have **chlorophyll** in their cells and so are separated from fungi, which always lack chlorophyll. In addition to these two groups, there is a third, composed of plants which are formed by an intimate union of an alga with a fungus. These are the **lichens**, which in spite of their dual nature are usually described as separate plants, and classified as such. (See also **Paleobotany.**) (R.M.W.)

THALLUS. A thallus is a plant body having no differentiation into roots, stems or leaves. (R.M.W.)

THEBAINE. Alkaloids.

THECA. The outer ridge surrounding the depression in the hard deposit of a stony **coral** in which the **polyp** lives. The deposit is formed by the basal disk of the polyp, first as a flat plate and later in a series of ridges as the ectoderm of the disk is thrown into folds. The theca is a circular ridge in most species. (A.W.L.)

THEELIN. Sex Hormones.

THEOBROMA CACAO. Sterculiaceae. A medium-sized tree growing wild in the lowlands from Mexico to northern South America. It has shining evergreen leaves about a foot long and small flowers, which grow from buds on the trunk or large branches of the tree. The fruits are 6–12″ long and about 4″ in diameter, and have a ribbed rough surface. Each contains from 20–50 flattened seeds, or beans, embedded in a gelatinous pulp. The tree is extensively cultivated in low humid climates in regions where there is a rich soil. It has been introduced into various Old World countries, and is grown extensively in tropical Africa. The cultivated tree is somewhat smaller than the wild one and begins to bear in 4 or 5 years when grown from seed.

The mature pods are cut from the tree and split open. The seeds are then scooped out and fermented for a week or so. During fermentation the color of the seeds darkens to a reddish tone and a rich aromatic odor develops. The pulp surrounding the seeds liquefies and runs off. After fermentation the seeds are dried and shipped to the manufacturers, located chiefly in the United States and Europe.

In the factories, the seeds are cleaned and then roasted for a short time (1–2 hours). After roasting, the seeds are cracked and the shell separated from the **cotyledons.** The shells may be ground up and used in the manufacture of cheap grades of cocoa, or they may be burned as fuel. From the cotyledons is ground out by heated mills an oily liquid which hardens into the familiar chocolate. If part of the oil is squeezed out and the residue ground to a powder, it is cocoa. When chocolate is mixed with sugar and flavored with **vanilla,** it becomes sweet chocolate.

The vegetable fat removed from the pressed beans is known as cocoa butter, and is used in the manufacture of various pharmaceutical preparations, and also in the preparation of confections. (R.M.W.)

THEOBROMINE. Purines.

THEODOLITE. Altazimuth; Meteorological Instruments.

THEOPHYLLINE. Alkaloids.

THEORETICAL PLATE. Distillation.

THEORY OF EQUATIONS. The name "Theory of Equations" usually is applied to the study of the properties of **polynomial equations** and of methods for the numerical solution of such equations. (L.L.S.)

THEORY OF ESTIMATION. Given the **statistics** in a **sample,** it is necessary from these to make some inference concerning the **population parameters** or values. Two methods of estimation will be discussed, that of Markoff and that of R. A. Fisher. Markoff stated that estimates of population parameters which are unbiased and have minimum **variance** should be used. Ordinarily this principle cannot be utilized for all values of the parameter.

R. A. Fisher stated that an estimate should at least be a **consistent statistic** and if possible should be efficient and sufficient. Usually such statistics which are at least consistent and efficient may be found by the method of **maximum likelihood.** It appears then that a particular estimate depends on the **probability function** of the **variates.** Examples of some estimates are the **mean** of a sample for the mean of a population and the **variance** of a sample for the variance of a population. These are point estimates. Estimation by intervals is accomplished in the theory of **confidence limits.** (L.A.A.)

THEORY OF SAMPLING. In the theory of sampling we are interested in the study of **samples** drawn from a population. Among topics covered by such a theory are the **theory of estimation,** methods of finding the **moments** of **statistics,** methods of obtaining the distribution of statistics, **stratified samples,** random samples, **Snedecor's *F* distribution, Fisher's *z* distribution, Stuent's *t* distribution, confidence limits,** the χ^2 test, and the **Neyman-Pearson theory of testing a statistical hypothesis.** The problems involved in sampling theory are sometimes very difficult. (L.A.A.)

THEORY OF SIMILARITY. Similitude.

THERALITE. Theralite is a granular intrusive **igneous** rock composed chiefly of **labradorite, nephelite** and **augite.** Duppau, Bohemia, is the type locality. If **analcite** is present instead of nephelite the rock is called teschenite from Teschen, in Moravia. The name theralite is derived from the Greek meaning eagerly sought for, because such a rock type was believed to exist and sought for before its actual discovery. (E.S.C.S.)

THERIODONTIA. Fossil Reptiles.

THERMAL CAPACITY. Specific Heat.

THERMAL CONDUCTION. Every substance is in some measure a conductor of heat, though liquids are generally poor conductors and gases almost non-conductors. The best conductors are metals. The flux of heat through a layer of any substance by conduction is proportional to the temperature gradient (fall of temperature per unit thickness), and to a factor called the "thermal conductivity" of the substance, defined as the

quantity of heat transmitted per unit time per unit cross section per unit temperature gradient. The thermal conductivities of a few solids are given below, in calories per cm. per sec. per °C.:

Aluminum	0.480	Iron (cast)	0.161
Copper	.918	Lead	.083
Cork	.0001	Paraffin	.0006
Glass	.002	Quartz	0.033 or 0.017
Ice	.005	Silver	1.006

(It will be noted that quartz, a highly birefringent crystal, has different conductivities along and perpendicular to its optic axis, as do such crystals in general.)

The mechanism of thermal conduction is probably at least three-fold. Thermally agitated atoms and molecules doubtless actually jostle each other and thus mechanically pass along the heat energy. Thermal radiation between neighboring atoms or molecules should have a similar result. But neither of these explains the enormous difference in conductivity between, say, copper and glass, both of which are dense, fine-grained solids; or between silver and lead, both soft, crystalline metals of similar chemical properties. If, however, we examine the electric conductivity of these substances (see **Electric Conduction and Resistance**), we discover that good thermal conductors are also good electrical conductors, and we are led to suspect that thermal as well as electrical conduction may depend upon the activity of electrons. The relationship is brought out quantitatively by the **Wiedemann-Franz law.**

The speed with which a temperature wave progresses by thermal conduction depends upon the "thermal diffusivity" of the conductor, which is its thermal conductivity divided by its thermal capacity per unit volume. (L.D.W.)

THERMAL CONVECTION. This is a familiar phenomenon, consisting in the transfer of heat by the automatic circulation of a fluid (liquid or gas) due to differences in temperature and density. While water and liquids generally are poor conductors, a kettle of water is quickly heated throughout by applying heat at the bottom. The warmer water, being less dense, is compelled to rise by the colder, which, sinking to the bottom, is warmed in its turn. The process is more clear-cut when a definite circuit is provided, as in the heating coil attached to a hot-water tank or radiator system. Gasoline engines are cooled by a similar circulation, either entirely automatic or augmented by a small rotary pump. Gases likewise exhibit convection. A chimney "draws" when the air inside it is warmer than that outside, so that the greater pressure difference outside forces the air inward at the bottom. (The term "draw" is manifestly misleading.) The motion of the air in hot-air furnaces and in the **winds** of the atmosphere are good examples. There is a type of **pressure gauge** which depends upon the cooling effect of convection currents in the gas upon a hot filament immersed in it, the rate of cooling being a function of the gas density. (L.D.W.)

THERMAL DEGREE. Temperature Scales.

THERMAL DIFFUSIVITY. Thermal Conduction.

THERMAL EFFICIENCY. Thermal efficiency is output, in heat units, divided by the heat supplied or chargeable. Thermal efficiency may partially define the operating condition of both a machine or a static piece of equipment. In the case of static equipment, if it is well insulated it may have very high thermal efficiencies. A machine which converts heat supplied into work output (the **steam engine, Diesel engine,** etc.) is always characterized by low thermal efficiencies because the conversion of the low-grade type of heat energy into high-grade energy of mechanical work is accomplished with considerable difficulty. The thermal efficiencies of the best prime movers today rarely exceed 35%, and are not found higher than 40% even when optimum conditions of loading, maintenance, and fuel employed are present. Thermal efficiency of a prime mover may be based on the output at the shaft per unit of heat supplied, or upon the electrical output in the case of a generator drive. It may also be based on cylinder hp. in piston and cylinder prime movers. Heat supplied and chargeable to internal combustion engines is the heat in the fuel. Heat supplied to steam prime movers is the heat in the **steam** at the throttle; the heat chargeable is the heat supplied after deducting the heat of condensate in the exhaust. (F.T.M.)

THERMAL EQUATOR. The belt of maximum temperature surrounding the earth which moves north and south with (but lagging) the sun's motion. It is also spoken of as the center of the area bounded by the yearly mean isotherms of 80° F. (P.E.K.)

THERMAL METAMORPHISM. Metamorphism.

THERMAL RADIATION. All bodies that are not at absolute zero emit radiation excited by the thermal agitation of their molecules or atoms, whether there are other causes of **excitation** or not. This thermal radiation ranges in wavelength from the longest **infra-red** to the shortest **ultra-violet** rays, its **spectral energy distribution,** however, depending upon the nature of the body and upon its temperature. The total emissive power of a surface at any temperature is the rate at which it emits energy of all wavelengths and in all directions, per unit area of radiating surface. The flux density (per unit solid angle) in various directions obeys the **cosine emission law** approximately; but strictly only in the case of a **black body.** Thermal radiation is observed and measured by means of different types of **radiometer,** by the **bolometer,** and by the **radiomicrometer;** also, in the shorter wavelengths, by its photographic and photoelectric effects.

In ordinary surroundings bodies not only emit but receive radiation. The net transfer of energy depends upon the relative rate of emission and absorption, and this, in turn, upon the temperature of the body and that of its surroundings. The dependence of this rate upon the two temperatures was investigated by Newton, by Dulong and Petit, by Stefan, and by Boltzmann. (See **Newton's Law of Cooling** and **Stefan-Boltzmann Law.**) **Wien's laws** have to do with the dependence of the spectral energy distribution of black-body radiation upon temperature, the last word upon which at present, however, seems to be **Planck's equation** developed through the **quantum theory.** Kirchhoff pointed out that the absorptivity of a surface (ratio of absorbed to incident radiation) and its emissivity (ratio of emissive power to that of a black body at the same temperature) are equal. It follows that good radiators are good absorbers. The reflectivity (ratio of reflected to incident radiation) is equal to one minus the absorptivity; hence good radiators and absorbers are poor reflectors.

Most surfaces exhibit "selective" emission, absorption, and reflection; that is, their emissivities, absorptivities, and reflectivities for different wavelengths are not proportional to those of a black body, and the proportion differs for different surfaces. Thus copper has abnormally high reflectivity and low absorptivity in the red; silicon, in the ultra-violet.

A substance transparent to thermal radiation is said to be "diathermanous." A material could be completely described in this respect by giving its **absorption coefficient** in the various parts of the spectrum. Thus, rock salt is very diathermanous throughout the infra-red and visible ranges; water and glass only in the visible, filtering out much of the infra-red. Well-defined absorption bands often occur in different regions of the spectrum. (See **Absorption Spectrum** and **Residual Radiation.**) (L.D.W.)

THERMAL RATING. **Speed Reducers.**

THERMAL WAVES. **Long Waves in the Prevailing Westerlies.** (P.E.K.)

THERMEL. The well-known Seebeck effect (see **Thermoelectric Phenomena**) is the principle underlying a large class of thermoelectric thermometers. The essential feature is a circuit composed of two different metals, the two junctions of which are at different temperatures, and in which a net electromotive force develops as a result of this temperature difference. Any device which uses this electromotive force, or the current due to it, as a measure of temperature is called a thermel (a term introduced by W. P. White).

The simplest form is a "thermocouple," composed of two pieces of metal, or wires, soldered or welded together at their ends, the other ends being connected to a **galvanometer** or a **potentiometer**. Various pairs of metals are used, for example, antimony and bismuth, copper and iron, or copper and constantan (an alloy of copper and nickel). High-temperature thermocouples are commonly of platinum, with some other refractory metal such as iridium or an alloy of platinum and iridium, rhodium or chromium. One of the junctions may be enclosed in a protecting tube, the other being kept at zero by means of melting ice. In cases where a temperature difference only is desired, the two copper or platinum lead-wires may be attached to the opposite ends of a single wire of the other metal, and the two junctions placed at the two points to be compared.

A "thermopile" is composed of a number of thermocouples in series, the alternate junctions being assembled in two bunches which are used like the junctions of a single thermocouple. This arrangement multiplies the thermoelectromotive force and gives greater sensitivity. An exceedingly sensitive form of thermel is the **radiomicrometer**. The "thermoelement" utilizes a thermocouple to detect and measure very feeble currents by their heating effect on a fine wire. (L.D.W.)

THERMIONIC PHENOMENA. In view of the commotion among the atoms and electrons of a heated substance, it is not surprising that electric particles, both positive ions and electrons, should be projected from a highly heated body. If the body is electrically charged, particles of the same sign as the charge, when once through the surface barrier (see **Work Function**), are repelled into the surrounding space, where they can be detected. Electric particles thus emerging, either positive or negative, are called thermions. The heated body may be a filament of pure metal, electrically heated, or a layer of some chemical substance spread over and heated by such a filament. The usual experimental arrangement is to enclose the thermionic emitter as an electrode in a tube or bulb, along with another electrode of opposite sign, so that the field between the two will set up a stream of the released thermions, called a thermionic current. With sufficient voltage, this current reaches a maximum or "saturation" value, the ions being then swept away as fast as they are released.

In the early experiments of Becquerel, Guthrie, Edison, Elster and Geitel, and others, it was found that at lower temperatures (up to a red heat) the thermionic emission from metals is predominantly positive, but that at much higher temperatures (white heat) the negative or electronic emission rapidly surpasses the positive and becomes all-important. The positive emission from a pure metal like platinum or tungsten appears to be due to impurities such as potassium, and falls off with prolonged heating; for metallic salts it consists of ions of the metal composing the salt. Some metals emit electrons much more copiously than others; a notable example is **thorium**, an adsorbed film of which on tungsten gives very copious electron emission at high temperatures.

The saturation current for any metal is an exponential function of the temperature, expressed by Richardson's equation

$$I = AT^n e^{-B/T},$$

in which T is the absolute temperature and A and B are constants dependent on the metal. The exponent n appears in some cases to be ½, while in others the value 2 fits better. B, and perhaps A, involves the thermionic work function. The emission is not quite steady, being subject to the so-called **shot effect**. In the various forms of **triode**, the thermionic current is controlled by means of a grid, an arrangement of great practical importance in radio and elsewhere. (L.D.W.)

THERMITE. **Aluminum.**

THERMO SIPHON. The term thermo siphon refers to a method of circulation of a liquid arising from the slight difference of density of the hot and cool liquid. At one time automobile engines were provided with thermo siphon action in the cooling water system. Although the principal portion of circulation of modern automobile engines is achieved by a pump, there is some thermo siphon action aiding the pump. Thermo siphon circulation is used to considerable extent on stationary engines which have an external radiator for cooling the jacket water. When the water leaves the radiator and enters the engine jacket, it is heated and expands slightly. Its decrease in density causes the column of hot water in the engine to weigh less than the equivalent column of cool water in the radiator, so there is a continuous displacement of heated water from the jacket by cool water flowing in from the radiator. This system requires large hose, unobstructed hose connections from engine to radiator, and large radiators having considerable height. (F.T.M.)

THERMOCHEMISTRY. Every chemical reaction is accompanied by a definite change in the heat content of the system. Most reactions evolve heat and are described as exothermic reactions, but some, such as the reaction of **nitrogen** plus **oxygen** to form **nitric oxide** absorb heat and are described as endothermic.

The amount or quantity of heat change in a given reaction is measured in large or small **calories** (number of kilograms or grams, respectively, of water * multiplied by the temperature change in °C.) or in B.T.U. (number of lbs. of water multiplied by the temperature change in °F.). The amount of heat is calculated in various ways, for example, per 1 gram or per 1 lb. of one reacting substance, as in the case of solid and liquid **fuels** and **foods**, per 1 cu. meter or per 1 cu. ft. of gaseous fuels, per 1 equivalent in the neutralization of **acids** and **bases**, or per 1 mol in expressing heats of formation of compounds.

The intensity of heat is measured by the degrees of temperature on the centigrade scale (melting point 0° C., boiling point 100° C. of water), the Fahrenheit scale (melting point 32° F., boiling point 212° F. of water) or the absolute scale + 273° C. (which is also the Kelvin scale) and + 491° F. As stated, 1° C. equals 1.8° F. It is estimated that the temperature of the **hydrogen**-oxygen flame may attain 2000° C., the **acetylene**-oxygen flame 2500° C., and the thermite reaction (**aluminum** plus **iron** oxide yielding aluminum oxides plus iron) even higher temperatures. Coker and Scoble (1913) estimated the temperature attained in coal gas-air mixture in the ratio of 1 to 5.66, as 2250° C. and the pressure observed 433 lbs. per sq. in.

Changes of energy always accompany chemical reaction, and most common of these is heat energy; these

* Temperature of water from 3.5–4.5° C., ordinary calorie; from 14.5–15.5°, normal calorie; from 0–100° C. divided by 100, mean calorie.

have been stated to be "of hardly less importance to the modern chemist than the material changes themselves" (Huddeston).

Thermochemical considerations may be classified as follows:

1. When no change in composition is involved.
   a. No change of state takes place.
      Heat capacity or atomic heat of solid elements (Dulong and Petit, 1819).
      Heat capacity or molecular heat of solid compounds (Kopp, 1864). (See **Chemical Composition.**)
      Heat of dilution of solutions.
      Heat of wetting and adsorption.
   b. A change of state takes place.
      Heat of fusion or solidification (melting point, freezing point).
      Heat of vaporization or condensation (boiling point, condensing point).
      Heat of sublimation (sublimation point).
      Heat of transition (transition point of allotropic substances).
      Heat of solution or crystallization of solids, liquids, gases.
2. When a change in composition is involved.
   a. Temperature effects.
      (1) Temperature of reaction.
         Reactions at ordinary temperatures.
         Reactions at high temperatures.
            The temperature attained depends upon the rate of heat evolution in the system less the rate of heat loss from the system.
         High temperatures attained by combustion of fuels:
            Local, by use of hydrogen—or acetylene—oxygen flame.
            General, by use of fuel gas and pre-heated air, in metallurgical furnaces, ceramic, cement and glass kilns and furnaces, by-product coke ovens. (See **Fuels.**)
            Very high temperatures attained in the electric furnace, producing such products as calcium carbide, silicon carbide, phosphorus, graphite, carbon disulfide, silicon, aluminum oxide fused, silicon oxide fused.

HEAT OF FORMATION OF OXIDES, CHLORIDES, SULFIDES

Element	Oxide	Calories per 16 Grams Oxygen	Chloride	Calories per 35.5 Grams Chlorine	Sulfide	Calories per 32 Grams Sulfur
Hydrogen	H_2O, gas	58	HCl, gas	22	H_2S, gas	5
Sodium	Na_2O	99	NaCl	98	Na_2S	90
Potassium	K_2O	86	KCl	104	K_2S	88
Magnesium	MgO	146	$MgCl_2$	77	MgS	82

(2) Temperature coefficient of reaction.
About 2 for a rise in temperature of 10° C. (See **Chemical Changes.**)

b. Heat effects.
Heat of reaction, general.
Specific cases—heat of neutralization of acids and bases; heat of dissociation; heat of formation.

The initial and final conditions of a reaction or of a series of reactions determine the total heat effect without regard to the intermediate steps. This is the formulation of Hess' Law of Constant Heat Summation. Its usefulness is evident by a simple example. The heat of reaction of carbon to carbon dioxide ($C + O_2 \rightarrow CO_2$) is 94,400 calories obtained by burning a weighed amount of carbon with excess oxygen in a bomb calorimeter. The heat of reaction of carbon monoxide to carbon dioxide ($CO + 0.5\ O_2 \rightarrow CO_2$) is 68,000 calories obtained by burning a measured volume of carbon monoxide in a gas calorimeter. It is not easy to ascertain the heat of reaction carbon to carbon monoxide ($C + 0.5\ O_2 \rightarrow CO$) directly, but since the heat evolved by the two routes

$$\begin{array}{ccc} C & \longrightarrow & CO_2 \\ & \searrow \quad \nearrow & \\ & CO & \end{array}$$

is the same, then the difference between the first and second reactions ascertained above is the desired result, namely, 26,400 calories.

The heat of formation of three grand groups of chemical substances is shown on preceding page. (R.K.S.)

THERMOCOUPLE. Thermel.

THERMODYNAMIC POTENTIAL. Potential.

THERMODYNAMICS. This branch of physics had its origin in the classical discoveries of Rumford, Davy, Joule, and others early in the nineteenth century, which identified **heat** as a form of **energy.** Gradually the mechanism of heat and the statistics of molecular motion were revealed by the researches of such men as Maxwell, Kelvin, Clausius, and Boltzmann, until now, with the added assistance of the **quantum theory,** we discuss the dynamics of **molecules** almost as confidently as that of visible bodies.

The first law of thermodynamics is embodied in the fact of the **mechanical equivalent of heat,** and need be touched upon here only by expressing it in its customary algebraic form $W = JQ$; meaning that Q heat units are equivalent to JQ work units. Our best present value of J is 41,855,000 ergs per calorie. With increasing emphasis upon the fact that heat is kinetic energy, has grown the tendency to express heat directly in ergs or joules and to do away with the **calorie** and the constant J; but the old notation still persists.

The second law of thermodynamics is really a confession of our helplessness in making molecules do what we wish, because of their inconceivable numbers and their submicroscopic size. It states, in effect, that the only way in which we can utilize any of the supply of heat energy in a body, and make it do mechanical work, is to find another body whose molecules have less average heat energy (i.e., a body at lower temperature), set up between them a mechanism (engine) through which the molecules of the warmer body can contribute some of their excess energy to those of its cooler neighbor, and capture part of this donated energy on the way. (No such engine will run on heat energy given by a cooler to a warmer body; it would have to be run from outside as a refrigerating machine.) It is shown that if the warmer and cooler bodies are at the respective absolute temperatures T_1 and T_2, the maximum fraction of the transferred energy that even an ideal engine could capture is $(T_1 - T_2)/T_1$, which is thus the maximum ideal heat-engine efficiency.

The variables commonly chosen in thermodynamic reasoning are temperature, entropy, pressure, and volume, and in terms of these we write the **characteristic equations** of the substances, such as air, steam, etc., used in engines. The purely dynamic aspects are especially concerned with volume and pressure, and thermodynamic diagrams are often drawn with these as coordinates. For example, if a gas expands and its pressure diminishes, this change may be represented by the curve AB and the corresponding work by the area $AB\beta\alpha$ (Fig. 1); while if, as in an engine, the change is a cyclic one, the net

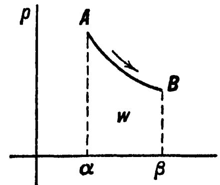

Fig. 1.

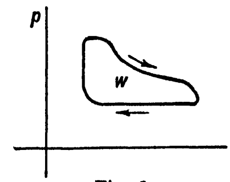

Fig. 2.

Representation of work during a unidirectional or a cyclic change in volume and pressure.

work derived from each cycle on one side of the piston is represented by the area W enclosed by the curve (Fig. 2). A steam engine indicator, for example, automatically draws such a curve at each stroke of the engine, the efficiency of whose performance can thus be deduced. (See **Carnot Cycle, Rankine Cycle, Entropy, Joule-Thomson Effect, Reversible Processes,** etc.) (L.D.W.)

THERMOELECTRIC PHENOMENA. If two strips of different metals are closely joined at one end, and the junction kept at a different temperature from the rest of the strips, an electromotive force develops in the two-part conductor. This thermoelectromotive force, sometimes called the Seebeck effect from its discoverer, depends upon the metals and the temperature distribution in them. The pair of metals is called a thermocouple, and the change in the electromotive force per degree change in temperature at the junction is the thermoelectric power of the thermocouple.

The thermoelectric power is a linear function of the junction temperature; while the thermoelectromotive force itself is a quadratic function, having a maximum value at some point (for iron and copper about 275° C.).

Peltier discovered that when a feeble battery current is sent through a thermocouple, the junction is thereby either warmed or cooled, according as the direction of the current is from the $-$ to the $+$ or from the $+$ to the $-$ metal. (This is altogether apart from the ordinary resistance heating effect.) Kelvin found that a potential difference develops even in a single metal (except in the case of lead) if one end is warmer than the other. The thermoelectromotive force of a thermocouple appears to be a combination of a "Peltier electromotive force" at the junction and the Kelvin or "Thomson electromotive forces" in the two strips.

If several metals are joined to form a circuit of nonuniform temperature, the resultant thermoelectromotive force is the algebraic sum of the several Peltier and Thomson electromotive forces, and gives rise to a thermoelectric current, such as that utilized in any **thermel.**

Kelvin discovered that if a weak current is sent through a wire which is heated at one point, the current causes a flow of heat, sometimes one way and sometimes the other, depending upon the metal.

None of these phenomena is fully understood; but they are believed to be due to the activity of **electrons** which are either free or related in some peculiar way to the **crystal structure** of the metals. (L.D.W.)

THERMOGRAPH. A recording thermometer. A common and very simple form employs a Breguet differential expansion spiral (see **Solid Expansion Thermometer**). One end of the spiral is securely fixed to

a metal post, while to the other is attached a long rod bearing at its end a pen or pencil. As the spiral coils and uncoils with changes of temperature, this marker moves up and down on a drum or disk covered with paper and slowly revolved by clockwork; thus leaving a graph of the temperature changes during a period of several hours or days. Another arrangement is to use a **thermel** connected with a **galvanometer**, the mirror of which reflects a spot of light upon a slowly moving photographic film. Thermographs are in extensive use at meteorological observing stations, for the exploration of the upper air, in deep sea soundings, etc. (See **Meteorological Instruments.**) (L.D.W.)

THERMOLUMINESCENCE. Luminescence.

THERMOMETRY. The measurement of **temperature** and of changes in temperature has been based upon many different heat effects. Among those which have been extensively developed are: (1) the expansion of solids, liquids, and gases, illustrated by **solid expansion thermometers, liquid expansion, thermometers,** and the constant pressure **gas thermometer**; (2) the change of pressure in a gas kept at constant volume (constant volume gas thermometer), or of the saturated vapor pressure of a liquid (see **Vapors**); (3) the change in resistivity of metals (metallic **resistance thermometer**); (4) the Seebeck thermoelectric effect (**thermel**); (5) the brightness of very hot bodies (**optical pyrometer**); and (6) the character of the **thermal radiation** from the heated body (**radiation pyrometer**).

With so many temperature indices, it is necessary to have a standard of temperature measure. For various reasons, it was once found desirable to fix upon gas pressure at constant volume as the practical standard measure of temperature. That is, equal changes of temperature were defined as those corresponding to equal changes of pressure in a selected gas (hydrogen) kept at constant volume. The constant volume hydrogen thermometer thus became the reference instrument for the calibration of other types. In 1927, however, the United States, Great Britain, and Germany proposed, and thirty-one nations represented at the Seventh General Conference of Weights and Measures unanimously adopted, what is now called the international temperature scale. From $-190°$ to $+660°$ C., the measure of temperature is based upon the indications of a standard platinum resistance thermometer, specified and used in accordance with certain formulas. From $+660°$ C. to the melting point of **gold** a platinum-platinrhodium thermel is the reference instrument; and above the gold point, the optical pyrometer is used as standard. The basic fixed points of this scale are the boiling point of **oxygen** ($-182.97°$ C.), the freezing and the boiling points of water, the boiling point of **sulfur** ($+444.60°$ C.), the melting point of **silver** ($+960.5°$ C.), and the melting point of gold ($+1063°$ C.).

Kelvin was long ago impressed with the dependence of such thermometric methods upon characteristic properties of certain arbitrarily chosen substances. Even constant-volume gas thermometers, using different gases, do not quite agree. Kelvin therefore proposed an ideal absolute temperature scale on which changes of temperature, whatever the substance concerned, are strictly proportional to the quantities of heat converted into mechanical work during **Carnot cycles** bounded by the respective temperatures and by the same two adiabatic **entropy** limits. A constant-volume gas pressure thermometer using a gas obeying the **ideal gas law** would perform in exact agreement with this standard. The subsequent researches of Joule and Kelvin on the **Joule-Thomson effect** enabled them to calculate the corrections necessary to convert the hydrogen constant volume standard into this "thermodynamic scale" (more properly, this thermodynamic standard of temperature measure) proposed by Kelvin, which is now used as the basis of the international scale above mentioned. (L.D.W.)

THERMOPILE. Thermel.

THERMOSTAT. The thermostat is a device, the purpose of which is to regulate, automatically, the temperature of a body or of an enclosure, or to maintain the temperature at some predetermined value, or within a certain range. Thermostats are employed widely in heating systems in order to adjust or regulate the temperature of the heating medium. They also have a great many uses in industry, where fluids, chambers, or material must be maintained at predetermined temperatures in order to accomplish the industrial process satisfactorily. There are other scattered uses of thermostats, many of which are very important, and among these might be cited the control of engine cooling water temperature in the modern automotive vehicle, the control of heat-treating furnaces, etc.

Thermostats are actuated mainly either by the expansion of a fluid, or by expansion of a metallic element. A very common example of the former is the wafer-type thermostat, in which thin disk-shaped shells, called sylphons, are filled with gas, or partially filled with a liquid of suitable boiling temperature. Actuated by the developed internal pressure, the expansion and contraction of these sylphons, the cases of which are flexible, constitute a motion which can be mechanically transmitted to a regulating **valve or relay.** While the motion of any one disk is relatively small, a number of them may be made into a group, the motions of which are additive.

Metallic element thermostats employ the well-known principle of linear expansion with temperature change. The element is not always built as a straight rod; satisfactory thermostats are constructed of a bimetallic strip wound in spiral form, which tends to coil or uncoil with changes of temperature.

Thermostats are sometimes actuated by thermoelectric currents or by the varying resistance of conductors, the effects of which, suitably amplified, may be utilized to control heating elements. (F.T.M.)

THICKENING. Classification.

THICK-FILM LUBRICATION. Lubrication.

THICK-KNEES, THICKNEES. Aves, Charadriiformes. A long-legged European bird (**Aves**) whose habits are similar to those of our killdeer. The same genus is represented by African, Indian, South American, and Australian species. The European bird is also called the stone curlew, but there is some question about its inclusion in this order. (A.W.L.)

THIGMOTROPISM. Movement in Plants.

THIN SECTIONS. The term used by **petrographers** and **mineralogists** for slices of rocks or minerals which are cut and ground to the approximate thickness of a thousandth of an inch, and mounted on glass slides for use with the **petrographic microscopic.** The average practical thickness for normal petrographic or mechanical analysis is 0.03 mm. (R.M.F.)

THIN-FILM LUBRICATION. Lubrication.

THINNER. Pigments, Paints, Varnishes.

THIOALCOHOLS AND RELATED COMPOUNDS. Thioalcohols and thioethers are organic derivatives of **hydrogen sulfide** containing the groups —SH and =S respectively. The thioalcohols (and thiophenols) may also be named as mercaptans, hydrosulfides, sulfhydrates, and thiols. The last of these names (thiols) is given priority in the accompanying table. Sulfinic and sulfonic acids are organic compounds containing the groups $—SO_2H$ and $—SO_3H$ respectively.

TABLE SHOWING INTERRELATIONSHIP BETWEEN VARIOUS ORGANIC SULFUR COMPOUNDS

Thioalcohols	Sulfinic Acids	Sulfonic Acids
Boiling Point		
(Hydrogen sulfide HSH −62° C.)		
Methanethiol CH_3SH 6° C. (Methyl hydrosulfide, methyl mercaptan)	Methyl sulfinic acid CH_3SOOH	Methyl sulfonic acid $CH_3 \cdot SO_2OH$ 167° C. dec.
Ethanethiol C_2H_5SH 37° C. (Ethyl hydrosulfide, ethyl mercaptan)	Ethyl sulfinic acid C_2H_5SOOH	Ethyl sulfonic acid $C_2H_5SO_2OH$
Propanethiol C_3H_7SH 67° C. (Normal-propyl hydrosulfide, normal-propyl mercaptan)	•	
Phenylmethanethiol $C_6H_5CH_2SH$ (Benzyl hydrosulfide)		
Dithioglycol $C_2H_4(SH)_2$ (Ethylene mercaptan)		
Benzenethiol C_6H_5SH (Phenyl hydrosulfide, thiophenol)	Benzene sulfinic acid C_6H_5SOOH	Benzene sulfonic acid $C_6H_5SO_2OH$ Benzene disulfonic acid $C_6H_4(SO_2OH)_2(1,3)$ Benzene trisulfonic acid $C_6H_3(SO_2OH)_3(1,3,5)$
Naphthylamine Sulfonic Acids	**Naphthol Sulfonic Acids**	**Sulfonic Acids**
Naphthionic acid $C_{10}H_6(NH_2)(1)(SO_2OH)(4)$	Naphthol sulfonic acid (Alpha acid) $C_{10}H_6(OH)(1)(SO_2OH)(2)$	Alpha-naphthalene sulfonic acid $C_{10}H_7SO_2OH(1)$
Laurent's acid $C_{10}H_6(NH_2)(1)(SO_2OH)(5)$	Naphthol sulfonic acid (Beta acid) $C_{10}H_6(OH)(2)(SO_2OH)(6)$	Beta-naphthalene sulfonic acid $C_{10}H_7SO_2OH(2)$
Tobias' acid $C_{10}H_6(NH_2)(2)(SO_2OH)(1)$	Naphthol disulfonic acid (R-acid) $C_{10}H_5(OH)(2)(SO_2OH)_2(3,6)$	Naphthalene disulfonic acids $C_{10}H_6(SO_2OH)(2,6);(2,7);(1,5);(1,6)$
Bronner's acid $C_{10}H_6(NH_2)(2)(SO_2OH)(6)$	Naphthalmine disulfonic acid (S-acid) $C_{10}H_5(NH_2)(1)(SO_2OH)_2(4,8)$	Methylene disulfonic acid $CH_2(SO_2OH)_2$
		Ethylene disulfonic acid $C_2H_4(SO_2OH)_2(1,2)$
Sulfonyl Chlorides		
Methyl sulfonyl chloride CH_3SO_2Cl	Ethyl sulfonyl chloride $C_2H_5SO_2Cl$	Benzene sulfonyl chloride $C_6H_5SO_2Cl$
Thioethers **Sulfides**	**Sulfinyl-compounds** **Sulfoxides**	**Sulfonyl-compounds** **Sulfones**
Methylene sulfide CH_2S (thiomethylene)	Methyl sulfinylmethane (dimethyl sulfoxide) $(CH_3)_2SO$	Methylsulfonylmethane (dimethyl sulfone)$(CH_3)_2SO$
Dimethyl sulfide $(CH_3)_2S$ (methylthiomethane) M.P. 38° C.		
Diethyl sulfide $(C_2H_5)_2S$ (ethylthioethane) M.P. 92° C.	Ethylsulfinylethane (diethyl sulfoxide)$(C_2H_5)_2SO$	Ethylsulfonylethane (diethyl sulfone)$(C_2H_5)_2SO_2$
Divinyl sulfide $(CH_2{:}CH)_2S$		
Diallyl sulfide $(CH_2{:}CHCH_2)_2S$		
Dichloroethyl sulfide (beta, beta prime) ("mustard gas")$(ClCH_2 \cdot CH_2)_2S$		
Dibenzyl sulfide $(C_6H_5CH_2)_2S$	Benzylsulfinylphenylmethane (dibenzyl sulfoxide) $(C_6H_5CH_2)_2SO$	Benzylsulfonylphenylmethane (dibenzyl sulfone)$(C_6H_5CH_2)_2SO_2$
Diphenyl sulfide $(C_6H_5)_2S$ (phenylthiobenzene)	Phenylsulfinylbenzene (diphenyl sulfoxide)$(C_6H_5)_2SO$	Phenylsulfonylbenzene (diphenyl sulfone)(phenyl sulfene)$(C_6H_5)_2SO_2$
		Diethyl sulfone dimethylmethane (acetone diethyl sulfone, sulfonal) $(CH_3)_2C(SO_2C_2H_5)_2$
		Trional $\begin{matrix}CH_3\\C_2H_5\end{matrix}\!\!>C(SO_2C_2H_5)_2$
		Tetronal $(C_2H_5)_2C(SO_2C_2H_5)_2$
Cyanogen sulfide $(CN)_2S$ M.P. 60° C.	Carbon disulfide CS_2 B.P. 46° C.	Diethylene disulfide $C_2H_4S \cdot SC_2H_4$
Carbonyl sulfide COS B.P. −48° C.	Methyldithiomethane (dimethyl disulfide) $(CH_3)_2S_2$	Phenyldithiobenzene (diphenyl disulfide)$(C_6H_5)_2S_2$
Acetyl disulfide $(CH_3CO)_2S_2$	Ethyldithioethane (diethyl disulfide)$(C_2H_5)_2S_2$	Diphenylene disulfide (thianthrene) $C_6H_4(S)_2C_6H_4$
Benzoyl disulfide $(C_6H_5CO)_2S_2$	Benzyldithiophenylmethane (dibenzyldisulfide)$(C_6H_5CH_2)_2S_2$	
Carbonyl disulfethyl $CO(SC_2H_5)_2$		
Allyl trisulfide $(C_3H_5)_2S_3$		
Sulfonium Compounds		
Trimethyl sulfonium iodide $((CH_3)_3S)I$	Trimethyl sulfonium hydroxide $((CH_3)_3S)OH$	(R.K.S.)

THIOALDEHYDES AND THIOKETONES. Thioaldehydes and thioketones are produced by the action of **hydrogen sulfide** on **aldehydes** and **ketones.** They are ill-smelling liquids, but change on standing to odorless compounds, trithioaldehydes or trithioketones, e.g., thio-acetaldehyde, ethanethial ($CH_3 \cdot CHS$) changes to trithio-acetaldehyde $(CH_3 \cdot CHS)_3$. Trithioacetone $(((CH_3)_2CS)_3)$, alpha, melts at 101° C.; beta melts at 125° C.; gamma melts at 81° C. **Potassium** permanganate causes oxidation yielding sulfonyl compounds. (R.K.S.)

THIOCARBONIC ACID AND THIOCARBONATES. Thiocarbonic acid (H_2CS_3) is a yellow oily liquid, melting point 20° to 30°, with decomposition into **carbon disulfide** plus **hydrogen sulfide,** made by addition of acid, e.g., **hydrochloric acid,** to sodium thiocarbonate.

Sodium thiocarbonate (Na_2CS_3) is made by reaction of sodium hydrogen sulfide and carbon disulfide (similar to the reaction of sodium hydroxide and **carbon dioxide** to form **sodium** carbonate). (R.K.S.)

THIOCYANIC ACID AND THIOCYANATES. Hydrogen thiocyanate (HCNS) is a gas, unstable, and upon cooling it solidifies to an odorous solid, melting point 5° C. to a liquid that soon changes to a yellow solid. Hydrogen thiocyanate is soluble in water, and the solution is thiocyanic acid, moderately stable when dilute and cold, but not otherwise.

Thiocyanic acid is formed by reaction of **barium** thiocyanate solution and dilute **sulfuric acid,** and filtering off barium sulfate.

Sodium, potassium, barium, or **calcium** thiocyanate may be made by reaction of **sulfur** and the corresponding **cyanide** upon heating to fusion. Ammonium thiocyanate (plus ammonium sulfide) may be made by reaction of **ammonia** and **carbon disulfide,** a reaction which probably accounts for the presence of ammonium thiocyanate in the products of the destructive distillation of coal.

Silver, lead, cuprous, and **thallous** sulfocyanates are insoluble, and **mercuric** and **stannous** sulfocyanates slightly soluble. All of these are soluble in excess of soluble (e.g., ammonium) thiocyanate forming complexes. Ferric thiocyanate is a red solution, used in detecting either ferric or thiocyanate in solution, and is extracted from water by amyl alcohol.

When thiocyanic acid is treated with oxidizing agents, e.g., **nitric acid, sulfuric acid, hydrocyanic acid** is formed; when treated with reducing agents, e.g., **aluminum** and dilute hydrochloric acid, hydrogen sulfide plus carbon plus ammonium chloride are formed.

Esters: Ethyl thiocyanate ($C_2H_5 \cdot SCN$), colorless liquid, boiling point 142° C. Formed by reaction (1) of potassium thiocyanate and potassium ethyl sulfate, (2) of cyanogen chloride and ethanethiol. Oxidizable with fuming nitric acid to ethyl sulfonic acid ($C_2H_5 \cdot SO_2OH$), and reducible with zinc and dilute sulfuric acid to ethane thiol (C_2H_5SH). Ethyl isothiocyanate ($C_2H_5 \cdot NCS$), colorless, odorous liquid, boiling point 132° C. Formed by reaction of ethyl **amine** and carbon disulfide. Reducible to ethyl amine ($C_2H_5NH_2$) plus methylene sulfide (CH_2S). Allyl isothiocyanate ("mustard oil," $C_3H_5 \cdot NCS$) liquid, boiling point 151° C., odor of mustard, and causes blisters in contact with the skin.

Soluble thiocyanates give a characteristic red coloration with ferric salts. (R.K.S.)

THIOIC ACIDS. Sulfur.

THIOLS. Thioalcohols and Related Compounds.

THIOPHENE AND RELATED COMPOUNDS. Thiophene ($(CH)_4S$) is a liquid, boiling point 84° C., resembling **benzene** in odor and properties. Thiophene is present in coal tar and is recovered in the benzene distillation fraction (up to about 0.5% of the benzene present). Its removal from benzene is accomplished by mixing with concentrated **sulfuric acid,** soluble thiophene sulfonic acid being formed. Thiophene gives a characteristic blue coloration with isatin in concentrated sulfuric acid.

Thiophene may be formed (1) by passing ethyl sulfide (diethyl sulfide) through a red-hot tube, (2) by reaction of **sodium** succinate and **phosphorus** trisulfide. **Chlorine** and **bromine** yield chloro- and bromo-substitution products, respectively, cold fuming **nitric acid** yields thiophene sulfonic acid. Thiophene aldehyde ($C_4H_3S \cdot CHO$), liquid, boiling point 198° C., resembles **benzaldehyde** chemically rather than furfural. The corresponding primary **alcohol,** and **carboxylic acid** are known. Where sulfur of thiophene is occupied by oxygen, **furane** is the compound, and where by nitrogen (group —NH), **pyrrole.**

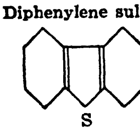
Benzothiophene ($C_6H_4 \cdot (CH)_2S$) is a solid, melting point 31° C., boiling point 221° C., and resembles naphthalene. Where sulfur of benzothiophene is occupied by oxygen, coumarone is the compound, and where by nitrogen (group —NH), indole.

Thiophene  (C_4H_4S)

Benzothiophene (Thionaphthene)  ($C_6H_4(CH)_2S$)

Penthiophene  (C_5H_6S)

Diphenylene sulfide

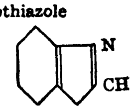


melting point 97°C.
boiling point 332°C.

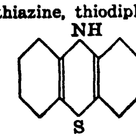
Nitrogen-sulfur ring compounds:
Thiazoles:

Thiazole 
boiling point 117°C.

Benzothiazole

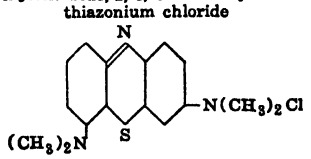


Thiazines:
Phenthiazine, thiodiphenylamine



melting point 180°C.
boiling point 370°C.

Methylene blue, 2, 8, tetramethyldiamino-thiazonium chloride



(R.K.S.)

THIOPHENOLS. Thioalcohols and Related Compounds.

THIOSULFURIC ACID AND THIOSULFATES. Thiosulfuric acid ($H_2S_2O_3$) is possibly formed upon addition of an acid to **sodium** thiosulfate solution, but immediately decomposes into **sulfur** dioxide gas and sulfur, yellow precipitate, the latter appearing gradually (more rapidly with higher concentrations).

Sodium thiosulfate, "hypo" (misnamed hyposulfite) ($Na_2S_2O_3 \cdot 5H_2O$), is used (1) to dissolve **silver** chloride, bromide, iodide in the photographic "fixing" bath, soluble sodium silver thiosulfate being formed plus sodium chloride, bromide, iodide, (2) in reaction with **iodine** in solution, sodium tetrathionate and sodium iodide being simultaneously formed, or with **ferric** salt solution, sodium tetrathionate and ferrous being simultaneously formed, (3) in reaction with **chlorine** as an "antichlor" forming sulfate and chloride. Sodium thiosulfate reacts with silver nitrate solutions yielding silver sulfide, brown precipitate, and with permanganate yielding **manganous. Sodium** amalgam changes sodium thiosulfate to sodium sulfide plus sodium sulfite.

Sodium thiosulfate is formed (1) by reaction of sodium sulfite solution and sulfur upon warming, (2) by reaction of sodium sulfite solid and sulfur upon heating, (3) by complex reaction of sulfur and sodium hydroxide solution upon warming—sulfur yields sodium sulfide plus sodium sulfite and the latter reacts with excess sulfur forming sodium thiosulfate, and the sodium sulfide present may be converted into sodium thiosulfate by passing in sulfur dioxide until the solution changes from yellow to colorless.

Thiosulfates are commonly identified as follows:

1. Dilute acids precipitate sulfur from thiosulfates (difference from sulfides and sulfites).
2. Zinc sulfate and sodium nitroprusside give no color (difference from sulfites). (R.K.S.)

THIOUREA. Thiourea, "thiocarbamide" ($(NH_2)_2CS$), is a white solid, melting point 172° C.; easily hydrolyzed to **ammonia** plus **carbon dioxide** plus **hydrogen sulfide**; chemically analogous to urea; oxidized to **urea** by cold potassium permanganate solution.

Thiourea is formed by heating ammonium **thiocyanate** at 170° C. After about an hour 25% is converted. With **hydrochloric acid** thiourea forms thiourea hydrochloride; with **mercuric** oxide thiourea forms a salt, and with **silver** chloride it forms a complex salt.

Symmetrical diphenyl thiourea, "thiocarbanilide" ($(C_6H_5NH)_2CS$), is a solid, melting point 154° C., and when heated with concentrated **hydrochloric acid** yields **aniline** plus phenylisocyanate. Formed by reaction of aniline and **carbon disulfide.** Symmetrical-diethylthiourea ($(C_2H_5NH)_2CS$) is a solid, melting point 77° C. (R.K.S.)

THOMSON EFFECT. Thermoelectric Phenomena.

THOMSON E.M.F. Thermoelectric Phenomena.

THONGALLEN. Types of **concretions** which occur in **loess.** When these concretions simulate the forms of human figures they are called *Loessmänchen.* (R.M.F.)

THORACENTISIS. Removal of fluid or pus from the chest or pleural cavity by inserting a needle or trocar through the chest wall between the ribs. (D.M.H.)

THORACOPLASTY. Tuberculosis.

THORAX. 1. The division of the **arthropod** body between the head and abdomen. It consists of three or four metameric segments of the body, often closely united so that their boundaries are difficult to determine. It bears a pair of jointed appendages on each segment, developed for walking or swimming, and in some species for grasping, and in the insects the two posterior segments may bear a pair of wings each. The three segments of the insect thorax are known as the pro-, meso-, and metathorax. 2. A division of the trunk of **vertebrates,** just behind the head and neck. This region is supported by the ribs and contains the thoracic cavity, a division of the **coelom.** In the **mammals** it is separated from the abdominal cavity by the diaphragm and is further subdivided into the pleural cavities containing the **lungs** and the pericardial cavity containing the **heart.** It is a bony cage made of the sternum in front, the vertebral column behind, and the ribs connecting the two. (A.W.L., R.S.M.)

THORIANITE. The mineral thorianite is chiefly composed of **thorium uranium oxide,** occurring in black nearly opaque cubic crystals in Ceylon and Madagascar. It is radioactive, and as such is particularly valuable in helping to date the absolute, as well as the relative, ages of the rocks in which it occurs. (See **Radioactive Minerals; Chronology.**) (R.M.F.)

THORITE. The mineral thorite is a **silicate** of the rare element **thorium** and corresponds to the formula $ThSiO_4$. It is **tetragonal** and exhibits a prismatic **cleavage.** The original thorite was black in color with a specific gravity of 4.4–4.8. A variety orangite, so called from its orange-yellow color, has a specific gravity of 5.19–5.40. It has been found partly altered to thorite. Uranothorite contains **uranium** oxide. Thorite occurs in Norway in **augite syenites.** Thorite and orangite occur in Sweden, and orangite and uranothorite are found in Madagascar. Uranothorite is found in Ontario. (E.S C.S.)

THORIUM. Symbol: Th. Atomic number: 90. Atomic weight: 232.12. Density: 11.5 (11.3–11.7). Melting point: 1845° C. No isotope, but of single atomic form: 232.

Thorium metal is dark gray, dissolves in **hydrochloric acid,** is made passive in **nitric acid,** not affected by fusion with alkalis; at 450° C. combines with **chlorine** and with **sulfur,** at 650° C. combines with **hydrogen** and with **nitrogen.** An outstanding property is the **radioactivity** of all thorium-containing substances. Discovered by Berzelius in 1828.

Thorium occurs in **monazite** sand in Brazil, India, North and South Carolina, which sand contains 3–9% thorium oxide, and is the chief source; also found in thorite containing about 60% oxide and in thorianite, about 80% oxide. When heated with concentrated **sulfuric acid** the minerals form thorium sulfate, from which, by a series of reactions, thorium nitrate, the chief commercial compound, is obtained. Upon ignition the nitrate yields oxide which finds extensive use in the manufacture of gas mantles, where a mixture of 99% thorium oxide and 1% **cerium** oxide gives maximum luminosity at a comparatively low temperature. The oxides are formed in place by ignition of the mantle fiber, which has been previously impregnated with the corresponding nitrates and dried.

Hydroxide: Thorium hydroxide ($Th(OH)_4$), white, gelatinous precipitate, by treating thorium salt solutions with sodium hydroxide solution.

Nitrate: Thorium nitrate ($Th(NO_3)_4$), crystallizes with 5, 6, and 12 molecules of water, and is the chief commercial salt.

Oxide: Thorium oxide (ThO_2), white solid, prepared by ignition of the nitrate, oxalate, or hydroxide. (R.K.S.)

THORN APPLE. **Potato Family.**

THORNY-NOSE. Pisces, Teleostei. A peculiar marine fish (**Pisces**) found near New Zealand. It has very long serrate dorsal and ventral fins and the nose bears two strong spines. (A.W.L.)

THORON. Symbol: Tn. A radioactive element of the thorium series. (See **Radioactive Changes.**) (R.K.S.)

THOULET SOLUTION. An aqueous solution of **potassium mercuric** oxide the specific gravity of which is 3.19. Used by petrologists to separate mineral particles according to their specific gravities. Synonym, Sonstadt Solution. (R.M.F.)

THRASHER. Aves, Passeriformes. Moderately large North American birds (**Aves**) related to the wrens, the mockingbird, and the catbird. They have a long curved beak. Several of the species are among our finest singers.

The brown thrasher, *Toxostoma rufum,* is a familiar bird east of the Rockies. Our 6 other species are western and southwestern. (A.W.L.)

THREAD GAUGE. **Measurement.**

THREE-BODY PROBLEM. If we assume that three or more objects exist in the universe, each of them attracting every other in accordance with the law of **gravitation,** the problem of predicting subsequent positions and motions is commonly referred to as the three-body problem, or the *n*-body problem.

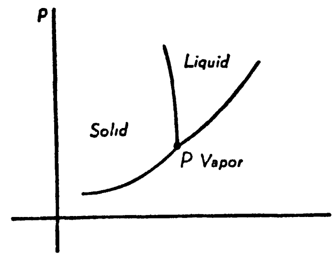
The **two-body problem** has been completely solved and the full solution may be expressed in comparatively few words and symbols. However, if we add one or more other bodies the solution becomes one of exceeding complexity and has never been accomplished in any form which is at all suitable for computational purposes. In fact, only one complete solution has ever been made, in spite of the labors of practically all of the great mathematicians of the past 3 centuries.

Even though no general solution of the problem is available, nevertheless, there are several practical computational methods for determining the positions of **planets** and other members of the **solar system,** taking into account the gravitational attraction of all effective members. Such solutions are all made by successive approximations and various methods of computing **perturbations,** rather than by the application of any general solution.

A number of particular solutions of the three-body problem have been made by mathematicians, notable among them being the solution by Lagrange. He showed that it is possible for an **asteroid** to be stable in a position such that it is equidistant from both the sun and **Jupiter.** In this case the three objects would be on the vertices of an equilateral triangle and the asteroid **orbit** would have the same period as that of Jupiter. This case is illustrated in nature by the members of the so-called **Trojan group.** (W.K.G.)

THREE-HINGED ARCH. **Arch.**

THREE-PHASE EQUILIBRIUM. For every pure, chemically stable substance there is a certain temperature and pressure at which it can exist in all three states or phases, solid, liquid, and vapor, each phase being in equilibrium with each of the others. At higher temperatures and pressures than those at this so-called "triple point," the liquid and vapor states may attain equilibrium; solid-vapor equilibrium (see **Sublimation**) is possible at lower temperatures and pressures; while solid-liquid equilibrium can be obtained at higher pressures and at lower or higher temperatures according as the substance contracts or expands upon melting (see **Fusion**). These three equilibria may be represented by three temperature-pressure graphs which



Triple point (P) on temperature-pressure diagram.

converge at the triple point. The figure illustrates the case of water, which contracts on melting, and for which the triple point is at +0.072° C. and 4 6 mm. of mercury. (L.D.W.)

THREE-WIRE SYSTEM. Much of the domestic and small commercial electric power loads are supplied by a dual-voltage, three-wire system, the voltage between two of the wires being approximately 220 while that between the other two wire combinations is approximately 110 volts. As usually shown schematically the neutral wire (the one common to the two 110-volt combinations) is placed in the center, giving 110 volts between the neutral and either outside wire while the outside wires have 220 between them. In applying the load to this type system an attempt is made to keep it balanced on either side of neutral. For a perfectly balanced load no current flows in the center wire, while for an unbalanced load only the unbalance current (the difference between the currents in the two 110-volt loads) is carried by the neutral wire. Thus there is a reduction in power loss and voltage drop in the line, giving a better, more efficient service. (See **Balance Coil.**) (L.R.Q.)

THRESHOLD SPEED, THRESHOLD DENSITY, THRESHOLD EXPOSURE. In photography the threshold density is the smallest density visible—above the **fog density**—when the image is placed in contact with a sheet of white paper. Threshold exposure is the exposure necessary to produce the threshold density. Threshold speed may be defined in several ways but, basically, it is the reciprocal of the threshold exposure. The use of the term threshold in photographic technology arose from the use of "Schwellenwert" in a similar sense in German literature.

The Scheiner method of measuring and expressing emulsion speeds is the best known of the methods based on the threshold speed. (C.B.N.)

THRIPS. **Thysanoptera.**

THROAT. Internally, the pharynx: the cavity behind the mouth into which the nasal passages open and from which the esophagus and trachea lead. Externally, the ventral part of the neck. (A.W.L.)

THROMBOPHLEBITIS. **Thrombosis** associated with inflammation or **phlebitis** of a vein. There are two general types: (1) Superficial thrombophlebitis in which veins near the surface of the body are involved; and (2) deep thrombophlebitis in which the deep internal

veins are involved. Any vein in the body may be affected, but those of the legs and pelvis are most commonly involved. Varicose veins are more subject to phlebitis than normal ones. With infection of the vein a soft friable clot forms in the involved vessel, blocking the blood flow in this portion of the vein. The condition is then termed thrombophlebitis.

The causes of thrombophlebitis are (1) stasis, or slowing of the blood stream, as occurs when a patient is confined to bed for a prolonged period, as in severe illness or following an operation, (2) infection, chronic or acute, in some other part of the body, and (3) trauma or injury of some kind to the veins. This is especially apt to occur following childbirth due to injury to the pelvic veins. Any of the preceding factors or combination of them are sufficient to produce thrombophlebitis.

The symptoms are local pain, swelling, redness, and heat, over the site of the infected vein. Constitutional symptoms vary; fever and prostration may be marked. In some cases the infection spreads and bacteria and infected material are constantly being poured into the blood stream, resulting in **septicemia.** At times a piece of clot (**embolus**) breaks loose from the infected vein and is carried into the general circulation to the lung. If it is large enough to shut off the main artery to the lung, death results very quickly—at times instantly. If smaller, the clot may travel in a smaller arterial branch to the lung. If the clot is infected, pneumonia results.

The treatment of thrombophlebitis is mainly rest in bed with such general treatment as is given any acute infection. If an extremity is involved, heat is applied, and the part is elevated. Injection of the parasympathetic ganglia along the spine with novocaine is one of the newer and more effective treatments. It acts by dilating the blood vessels of the involved area, improving the circulation and thus clearing up the infection more rapidly. (D.M.H.)

THROMBOSIS. The forming of a clot in a vessel, thereby shutting off the circulation beyond the point of thrombosis. This usually results from infection, injury to the vessel, or almost complete stasis in the vessel. (See **Coronary Occlusion.**) (R.S.M.)

THROMBUS. A clot or plug forming in a blood vessel and attached to the vessel wall. When the thrombus becomes dislodged and is caried by the blood current to some other part of the circulation, it is called an **embolus.** (R.S.M.)

THROTTLE. To throttle means to choke. Throttling a fluid flow is to decrease the cross-sectional area of flow at some point, as by partly closing a valve, damper, or gate in the conduit. (See **Throttling Process.**)

This word is in common usage to denote the adjustable control on the quantity of the working medium entering prime movers and hence has become synonymous, in common usage, with the control of prime mover power. (F.T.M.)

THROTTLING PROCESS. Throttling is the reduction of pressure of a fluid passing a restriction or orifice. During a throttling expansion of a fluid there must be no work done, i.e., the enthalpy contained in the fluid after throttling must be unchanged from the original. Throttling as a thermodynamic process may be used to advantage as in the control of a **steam engine,** where the weight of steam drawn into the engine per cycle is varied by varying the pressure with a throttle valve. The automobile engine is governed in speed by variable throttling of the intake, so that the cylinders receive more or less charge, depending on the extent to which the pressure of the incoming gas is reduced by throttling. (See **Steam Calorimeter.**) (F.T.M.)

THROUGH BRIDGE. Bridge.

THROW. For the use of this term in geology, see **Fault.**

THRUSH. (In zoology) Aves, Passeriformes. In the broad sense a bird (**Aves**) of the family Turdidae, but the term is most widely applied to the members of this family that retain a spotted breast as adults, while other species which lose the spots as their adult plumage develops receive other names. Among the latter are the **robin** and **bluebirds** of North America. The North American thrushes are of moderate or small size, brown, gray, or olive above and white below, with spots similar to the back. The wood thrush, *Hylocichla mustelina,* is widely distributed in the eastern half of the United

Wood thrush, *Hylocichla mustelina.* Bright brown above, white below, with large round spots on the breast and sides.

States, and the hermit thrush, *H. guttata,* is even more widely distributed, though less commonly known.

The family includes the European fieldfare, **redwing,** and **blackbird,** the ring-ouzel, and the Old World chats. In North America it is also represented by the Townsend solitaire and the **wheatear,** in addition to the robin and the several species of bluebirds.

The song-thrush of Europe, *Turdus philomelus,* is also called the mavis, and in America the term thrush is misapplied to the Louisiana water thrush, which is a warbler, because of its similar color and pattern.

In medicine, thrush is a contagious parasitic infection of the mouth due to a **fungus** called *Oidium albicans.* The organism produces white patches (apthae) on the mucous membrane of the mouth and tongue. It occurs primarily in nursing infants who are debilitated from some other infection, but may occur in adults when the oral hygiene has been neglected, or where the gums have been injured by too violent cleansing.

The disease is treated by adopting the proper methods of oral hygiene, and swabbing the mouth with mild antiseptic solutions such as boracic acid, or 1% aqueous gentian violet. (A.W.L., R.S.M.)

THRUST BEARING. Bearings.

THRUST COEFFICIENT, PROPELLER. Propeller Coefficients.

THULIUM. Symbol: Tm. Atomic number: 69. Atomic weight: 169.4. No isotope, but of single atomic form: 169. Type of compound: Tm_2O_3. Color of salts: Green. Discovered by Cleve in 1879. A member of the **yttrium** sub-group of the rare earth **metals.** (R.K.S.)

THUMBLESS MONKEY. Mammalia, Primates. A group of African **monkeys** constituting the genus *Colobus.* They are named from the reduction of the thumb, which is either entirely absent or reduced to a small projection, with or without a vestigial nail. Some of

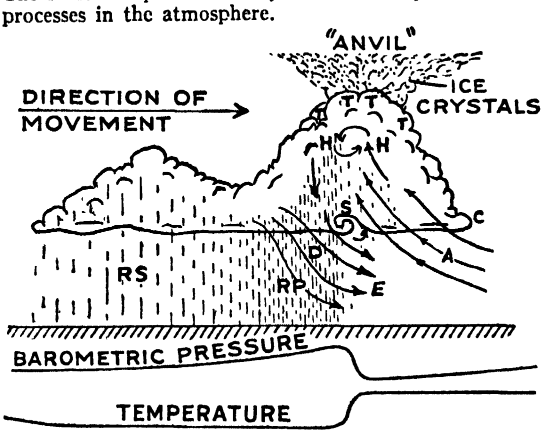
the included species are called colobs, one is a guereza, and one is the king monkey. (A.W.L.)

THUNDER. An electrical discharge in the atmosphere which sets up a sound wave all along the column of air in which the discharge occurred. If the discharge occurs close at hand, there is one sharp burst or "explosion" but if the discharge occurs some distance away then portions of the sound wave reach an observer over a period of time. Echoes of thunder also occur when the sound wave or parts of it are reflected from objects projecting from the earth such as hills and buildings. (P.E.K.)

THUNDERSTORMS. Cumulonimbus clouds accompanied by lightning and thunder. Normally thunderstorms are accompanied by torrential rain for brief moments during the passage of the storm, but occasionally no precipitation reaches the ground. Often they cause hail and gusty surface winds of considerable velocity. Sometimes they are attended by tornadoes which cause great damage. Vertical velocities inside thunderstorms are extremely erratic and as high as 120 m.p.h. Thunderstorms originate as a result of the occurrence of three factors and the absence of any of the three will not permit their formation.

1. Sufficient number of vertical perturbations in the air to cause parcels of air to start upward.
2. Sufficiently unstable air to permit the vertical perturbations to rise with accelerated velocity up to great enough heights to insure penetration of the freezing level.
3. Sufficient moisture to insure the development of cloud droplets and eventually snow and rain in the rising parcels of air.

The first requirement may be fulfilled by mechanical lifting of air over terrain or up a frontal surface, or by heating of the surface air over warm ground or water. The second requirement may be fulfilled by one of four processes in the atmosphere.



A cross-section of a typical cumulo-nimbus (thunderstorm) cloud showing the air currents involved as well as the formation of hail and areas of rain. *A* is the inflowing-ascending air; *D*, the outflowing-descending air; *C*, the storm collar; *S*, roll of "scud," where *A* and *D* meet; *E*, wind gust; *H*, hail; *T*, thunderheads; *RP*, primary rain; *RS*, secondary rain.

a. Heating from below, i.e., along the ground or water.

b. Cooling from above, i.e., advection of cold air at high altitude.

c. Simultaneously heating from below and cooling from above.

d. Differential cooling of a layer of air in such a manner that the top grows colder than the bottom.

Necessary moisture is not always present in the atmosphere to assure thunderstorm development even though the other two requirements are met. Moisture content of the air must be such that saturation can be caused by the two other requirements and its distribution must be such that lower levels reach saturation first. Because moisture is distributed horizontally by large-scale air currents in tongues and islands in the atmosphere, the distribution of thunderstorms often assumes these patterns.

Heating from below normally occurs over land during daylight hours and over water whenever cold air flows from cold continents over warm water, or from cold water over warmer water. Thermal or air-mass thunderstorms of this type are at a maximum over land in the late afternoon and are restricted almost entirely to the spring and summer of the year in countries as far north as the United States and Canada. Thermal or air-mass thunderstorms occur over oceans at any time of day or night and generally are at a maximum during winter and spring. Air-mass thunderstorms are isolated and distributed at random.

Cooling from above by nocturnal radiation from the moist air takes place over ocean areas where the surface water temperature is maintained virtually constant. This creates instability and results in early morning thunderstorms at sea.

Cooling aloft may also occur by advection of cold air over a layer of warm air. Thunderstorms of this type are usually high level with bases 1 or 2 miles above the earth. They occur over both land and water. In North America they are common to the region just east of the Rockies during summer.

On some occasions both heating from below and cooling from above occur simultaneously. Thunderstorms which result may lie as low as a few thousand feet or as high as several miles. Heating from below may arise from any of the processes that raise the temperature of the lower levels of the atmosphere, but high-level cooling is due to advection of cold air.

Differential cooling of an air layer occurs when an entire layer of air is lifted. If the air remains unsaturated the top will cool slightly more rapidly than the base. If the layer remains unsaturated at its top, but becomes saturated at its base, lifting will cool the top rapidly but the base only slowly, causing a rapid trend toward instability. Lifting occurs along cold and warm fronts, along mountains, and at a relatively slow rate in air that is undergoing convergence. (See **Cumulonimbus.**) (P.E.K.)

THYLACINE. **Tasmanian Wolf.**

THYME. **Mint Family.**

THYMUS. A ductless gland situated in the upper anterior portion of the chest cavity. It reaches its maximum activity during **puberty** and thereafter it diminishes in size and activity in most individuals. Its function in the body is not known. It is known, however, that certain children who have an enlarged thymus are subject to sudden attacks of unconsciousness, convulsions, sometimes sudden death. At autopsy a large thymus is found. The condition is described as *status thymicolymphaticus.*

Tumors of the thymus are found in a certain per cent of patients with myasthenia gravis, a disease of the muscles which makes them fatigue easily. (D.M.H.)

THYRATRON. **Tube, Electronic.**

THYROID GLAND. This important gland of internal secretion is made up of two flattened lobes lying beneath the superficial muscles of the lower anterior part of the neck on either side of the **trachea**. The two portions of the gland are connected by a small bridge of thyroid tissue lying across part of the trachea. Other masses of accessory thyroid tissue may sometimes be present along the length of the trachea. Dur-

ing pregnancy and menstruation the thyroid may temporarily increase in size. Complete removal and abnormal secretion of the gland causes grave systemic disturbances. The gland is also subject to **tumor** formation, which may be **benign,** causing enlargement only (adenoma), or toxic (toxic adenoma), or **malignant** (**cancer**).

The function of the thyroid is to serve as a storehouse for **iodine** and to secrete into the blood stream thyroid hormone, which has a stimulating effect on growth and metabolism. The thyroid affects other ductless glands and the sympathetic nervous system. In a reverse manner, other endocrine glands in turn influence the thyroid; this is particularly true of the pituitary gland, which has a multiplicity of influences on the endocrine system. The interglandular relationship of the thyroid as well as other endocrine glands is not well understood at present.

Diseases of the thyroid may be classified as those due to:

1. Hypofunction: **cretinism** and myxedema.
2. Hyperfunction: exophthalmic goiter and toxic nodular goiter (toxic adenoma).
3. **Tumors**: simple or colloid goiter; **adenoma**; nodular goiter; **malignant disease, cancer.**
4. Inflammatory disease: acute and chronic thyroiditis.

Diseases due to hypofunction: Cretinism is a condition originating in fetal life, or soon after birth, due to a more or less complete lack of thyroid secretion, and sometimes congenital absence of the gland. It is not incompatible with long life. The condition is rare in the United States. It is most common in iodine-deficient districts, where there is a lack of iodine in the maternal organism.

Large simple goiter in girl seventeen years old. (*Nelson Loose-Leaf Surgery, Thomas Nelson & Sons.*)

Often the disease is not recognized until the child has reached the age of 1 year, when a failure of physical and mental development becomes apparent. The skin is coarse, scaly, the tongue is thickened, and the child is dull and slow, with an intelligence far below normal.

The most important treatment is prophylactic and consists of proper treatment of pregnant women in goiter districts with iodine compounds. Cretins must be treated early in life with thyroid gland substance if relief of symptoms is to be obtained.

Hypothyroidism or **myxedema** is a disease of adults which may occur spontaneously, or as a result of the removal of too much of the gland in surgical treatment of Graves' disease. The disease occurs four to five times more frequently in women than in men. A goiter of simple type may be present although this is not usually the case.

The onset is gradual and occurs most frequently after 25 years of age. There are slowing of mental and bodily activities, an increase in weight, decreased appetite, and loss of a feeling of well-being. The individual complains of feeling cold. Blood pressure is lowered and the pulse is slowed. Mental sluggishness, forgetfulness, and lack of ambition may be marked. There is a tendency to increased sleep and drowsiness. The skin is thinned, coarsened, dry, and scaly, and the nails and hair may be brittle. Pains in the joints are common. **Anemia is a** frequent finding. The **basal metabolism** varies from minus 5 to minus 40.

Brilliant and dramatic results are obtained by administration of thyroid gland substance or thyroxin. The symptoms entirely disappear as long as substitution of thyroid substance is maintained to counteract the deficiency. The basal metabolism rises to normal limits and this test provides a means of estimating the proper maintenance dose of thyroid substance.

Diseases Due to Hyperfunction. Hyperfunction of the thyroid results in exophthalmic goiter (Graves' disease, hyperthyroidism, Basedow's disease, Thyrotoxicosis). The cause of this condition is not known, but constitutional predisposition seems to be a factor. It is a disease of civilized countries and is most common where conditions tend toward mental activity and strain. More women than men are affected; frequently a nervous shock or strain seems to start the process. The clinical manifestations are the result of an increased metabolic rate, increased **metabolism** of cells, and disturbances in the **autonomic nervous system.** Exophthalmus, a protrusion of the eyeballs giving a peculiar staring expression to the eyes, is usually present in marked cases; the cause of this disturbance is not known.

Hyperthyroidism begins insidiously, with early symptoms of fatigue, loss of weight, marked nervousness. The patient's disposition may change, with the development of irritability and inability to get along with people. A fine tremor, seen best when the hands are extended, is characteristic. The basal metabolism is greatly increased and may be 40–75% above normal. Because of this there is an increased appetite although the individual loses weight. The patient complains of feeling warm and of excess perspiration. Gastrointestinal symptoms are common. The heart, sooner or later in the severe forms, shows the effect of increased metabolism. Rapid heart rate, abnormal rhythm, and cardiac enlargement are common. The thyroid is often, but not always, enlarged to form a goiter.

The usual treatment of hyperthyroidism is surgical removal of a large part of the gland after a period of bed rest and iodine therapy. In certain cases x-ray irradiation of the thyroid, or the administration of a newly developed drug, thiouracil, may be used instead of surgery.

Tumors. Simple goiter, or colloid goiter, is a diffuse symmetrical enlargement of the thyroid gland due to the deposition of excessive amounts of colloid containing iodine. It is a compensatory or work **hypertrophy** which is a response to inadequate supplies of **iodine** in food and water. The disease usually appears soon after puberty; it is commoner in females than in males. There are no symptoms other than enlargement of the neck, and, if the tumor reaches very great size, secondary pressure symptoms. The metabolic rate is not disturbed. There are certain districts in the world where colloid goiter is common. These in general are in mountainous regions and the sites of glacial ice fields—that is, districts deficient in iodine. Near the sea coast, where sea-water iodine is present, the disorder is relatively uncommon. In the United States, goiter districts are found around the Great Lakes, Mississippi Valley, and the Northwest. In these areas supplementary iodine added to the water to make up the deficiency is important in order to correct this disorder and prevent cretinism in offspring.

Many colloid goiters gradually decrease after puberty. Others may respond to iodine treatment, and a few require surgery if they reach great size.

Adenoma of the thyroid seldom causes constitutional symptoms unless the **adenoma** becomes toxic and then hyperthyroidism develops. These adenomatous growths develop from fetal rests of thyroid tissue. Surgical removal is the treatment for both the simple and toxic varieties; it gives excellent results.

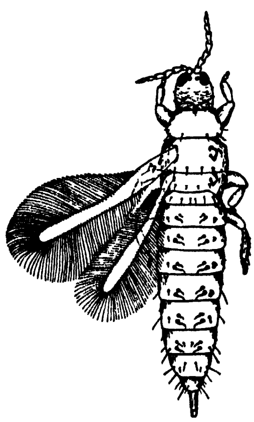
Malignant tumors, **carcinoma** and **sarcoma** are rare and difficult to distinguish from benign adenomas. Surgical and x-ray treatment are used palliatively.

Thyroiditis is infection of the thyroid gland. This condition is very uncommon. (D.M.H.)

THYROIDITIS. Thyroid Gland.

THYSANOPTERA. The thrips, an order of minute **insects,** with or without wings. Their mouths are formed for sucking, the tarsi have an expanded tip, and the metamorphosis is gradual. When wings are present there are two pairs, both formed of slender membranes with very long fringes.

In spite of their minute size a number of species of thrips are serious pests, attacking cultivated plants.



Thrips.

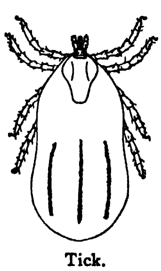
One of these is the onion thrips, introduced from Europe over sixty years ago. It attacks onions, cabbage, melons, and other plants and is sometimes troublesome in greenhouses, although it is not the common greenhouse thrips. Spraying with nicotine sulfate is an effective check, although onions are difficult to spray because the insects cannot easily be reached between the leaves. In greenhouses fumigation is desirable.

Some thrips live on other small insects, eggs, and mites, and so are of some value in checking other pests. (A.W.L.)

THYSANURA. Small to moderately large insects of the primitive wingless group, commonly called bristletails. The more common forms are the **silverfish** and the **fire-brat,** both grayish with silvery luster. The body is about ⅓″ long in both species, bearing long slender antennae and at the opposite end a pair of similar cerci and a slender median filament. The order also includes some species with forceps-like appendages at the tip of the body in place of the slender cerci. (A.W.L.)

TIC. A recurrent, spasmodic, involuntary muscular reaction taking place in a group of muscles. Simple tic is of psychogenic origin and is apt to develop in nervous people; it may accompany psychoneurotic disorders. It is a severe form of the so-called "habit-spasm," and twitching of a part of the face is its most common form. Tic douloureux is a form of neuralgia of the facial nerve which is characterized by sudden severe pain over one side of the face, accompanied by reflex contraction of the muscles in this area. (D.M.H.)

TICK. Arachnida, Acarina. A blood-sucking parasite related to the spiders and mites. Its body is leathery and saclike, with piercing mouth parts forming a small protuberance called the capitulum and a shield or scutum marking the dorsal surface in most species. The ticks are larger than their relatives, the mites, ranging from three to six millimeters in length. When filled with blood the female sometimes reaches a length of ½″.

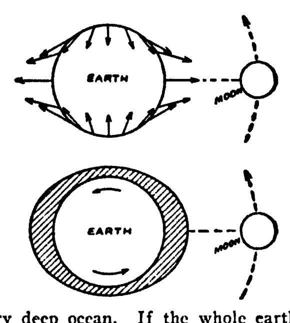


Tick.

The common dog or wood tick of the eastern and central states, *Dermacentor variabilis,* often attaches itself to human beings in the woods and is a common pest of domestic animals, especially dogs, during the warm months. A closely related species in the western states, *D. andersoni,* transmits the dangerous disease, **Rocky Mountain spotted fever.** The Texas cattle tick, *Margaropus annulatus,* transmits Texas fever of cattle, also a destructive disease. (A.W.L.)

TIDES. The periodic rise and fall of the oceans, or other large bodies of water, relative to the surrounding land is commonly known as the tides. Since the earth itself is not a perfectly rigid body, there are tides in the earth itself, and observations of the land tides have provided useful information regarding the rigidity of the interior of the earth.

Tides are produced by the combination of a number of external forces, with the principal force being the **gravitational** attraction of the **moon.** Owing to the differences of distance of the moon from various portions of the earth the amount of the attractive force will be different in different places and tend to produce a deformation. The accompanying diagrams indicate (on a very much exaggerated scale) the deformation forces, and



Tides in a very deep ocean. If the whole earth were covered by very deep water, and if the earth's rotation were slower, high tides would occur under and opposite the moon. The upper figure, after Darwin, shows the tide-raising force of the moon at different places.

the resultant tides in a very deep ocean surrounding a rigid earth.

The tidal force due to the gravitational attraction of the sun ranks second in importance to the tide-raising forces from the moon. Twice during each month, at times of full and new moon, the forces from the sun and moon are acting in parallel directions and produce the maximum tide range known as "spring tides." At times of quarter-moon the forces are acting at right angles to each other and the resultant minimum range of tides is known as "neap tides." Other tidal forces due to the rotation of the earth, the revolution of the earth-moon system, and the revolution of the sun-earth system, make the problem of tide prediction one of great complexity. Detailed **harmonic analysis**

of the observed tides have indicated the presence of tidal forces due to the attractions of several of the major **planets**. In the open ocean, from observations taken on isolated islands, the average range of ocean tides relative to the land is about 2½′. Configuration of shore line and contour of the ocean floor greatly increase this range for most stations along the coasts of the continents. The maximum range of tides in the land is about 9″.

If no other forces than lunar attraction were effective in producing the tides, the time of high water (the crest of the tidal bulge) would occur at a given point when the moon is on the local **meridian** (either at upper or lower culmination). Due to the other effective tidal forces the actual time of high tide differs from the instant of meridian passage of the moon by an amount known as the "lunar interval." The effect of lunar interval will average zero in the course of a long period of time, and the average interval between successive high tides is found to be 12 hours 25.5 minutes, which is ½ the average interval between successive upper culminations of the moon.

The difference between the actually observed time of high tide and the time calculated from the instant of transit of the moon across the meridian, combined with the lunar interval, is known as the "establishment of the port." The values of the "establishment" are obtained observationally for various ports and are tabulated in tide tables. The values obtained for two ports, which may be separated by only a few miles, may be very different owing to the configuration of the coast line between the ports.

The tides represent expenditure of energy, and a large part of this must come from the **kinetic energy** of rotation of the earth. This should tend to check the earth's rotation and thus increase the length of the day, but the effect is too small to have been observed. Considerable effort has been directed towards utilizing tidal energy for useful purposes to man, but so far the success has been very limited. Tidal forces also play an important part in the evolutionary processes of the various astronomical bodies. (W.K.G.)

TIE. The rails of a **railway** are supported by cross ties, which maintain the gauge between rails and transmit the wheel load to the **ballast** in which the ties are embedded. Some limited use has been made of concrete and steel substitutes for wooden ties, but the wooden tie is standard practice in the United States. The low cost, combined with certain advantages that wooden ties possess, such as the method of fastening rails by spikes, ease of disposal, freedom from corrosion, electrical insulating property, give the wood tie a very pronounced advantage over substitutes. In countries where suitable timber is scarce and expensive, the substitute tie will be more economical. Most cross ties in this country are made of oak or Southern pine. Locust, hickory, and beech are also accepted. The size of a class A tie is 7″ × 9″ × 8′ 6″. The ties must be made from sound live timbers, free from soft or decayed spots, shakes, worm holes, or other imperfections which would impair the usefulness. Ties may be made from a log by sawing or hewing slabs from the surface, or by sawing or splitting larger logs. The ties are barked before use. Ties are spaced about 21″ on centers, and are embedded nearly to their upper surface, with rock or gravel thoroughly tamped around them.

At the present time, practically all wooden ties are creosoted before use, as it has been amply proved that creosote extends the life of the tie sufficiently to more than pay for the cost of creosoting. This fact is not likely to be altered with time, because of the increasing cost of ties, and the improvements of creosoting processes. In a treating plant, the tie is first seasoned and steamed. A vacuum is maintained for a sufficient time to draw out the sappy moisture content of the timber, and then after this is drained off the cylindrical retort is filled with hot creosote oil. A pressure is then applied, and this drives the oil into the pores of the wood. Then the pressure is released, and the excess oil is drained from the retort, after which a quick vacuum is applied to complete the extraction of the excess creosote. (F.T.M.)

TIE PLATE. Compression Member; Railway Track.

TIE ROD. A tie rod is a slender structural rod capable of carrying tensile loads only. Since the ratio of its length to the **radius of gyration** of its cross-section is usually very large, it would buckle (bend) under the action of compressive forces. Tie rods are used for airplane structures and in steel structures such as bridges, industrial buildings, tanks, towers, and cranes. Tie rods known as sag rods are sometimes used in connection with purlins (see **Bent**) to take the component of the loads which is parallel to the **roof**. The strength of a tie rod is the product of the allowable working stress and the minimum cross-sectional area. In a rod which is threaded at the end and not **upset** to allow for the reduction of area caused by the thread, the minimum area will be that which occurs at the root of the thread. Tie rods are connected at the ends in various ways, but the strength of the connection should be, at least, equal to the strength of the rod. The ends may be threaded and passed through drilled holes or shackles and retained by nuts screwed on the ends. If the ends are threaded right- and left-hand the length between points of loading may be altered. This furnishes a method for pre-stressing the rod at will by turning it in the nuts so that the length will be changed. A turnbuckle will accomplish the same purpose. The ends may also be swaged to receive a fitting which is connected to the supports. Another way of making end connections is to forge an eye or hook on the rod. (C.W.C.)

TIED ARCH. Arch.

TIEDEMANN'S VESICLES. Water Vascular System.

TIGER. Mammalia, Carnivora. One of the largest of the **cats**, *Felis tigris*, ranking with the lion in size and strength. The fur normally varies from reddish to brownish yellow, with transverse black stripes and a black-ringed tail. The total length of adult males, including the tail, is 9–10′. The tiger is an Asiatic animal, found chiefly in the warm southern countries, but also northward into Turkestan and southern Siberia. It is by no means a tropical species.

Tigers have been hunted extensively for sport, but they have also had to be destroyed in India, Java, and Sumatra because of their destruction of domestic animals. Occasionally also tigers have become man-eaters. Tales of the killing of these great beasts are numerous in the records of big game hunting. (A.W.L.)

TIGER BEETLE. Insecta, Coleoptera. A small long-legged **beetle** of predacious habits. They are usually found on exposed earth or sand in the glare of the sun, where they both run and fly very rapidly. The numerous species are blue or green, reddish, or white, with or without a characteristic pattern of spots and dashes on the elytra. The **larvae** live in burrows in the ground, lying with the head at the entrance to the burrow ready to seize any victim that comes near. (A.W.L.)

TIGER-CAT. Ocelot.

TILE FISH. Pisces, Teleostei. A marine fish (**Pisces**), *Lopholatilus chamaeleonticeps*, found in the warmer seas.

These fishes are covered with small scales and are brightly colored. They are chiefly remarkable for the discovery of a new species off the Massachusetts coast in the seventies which promised to be a valuable food fish. The fishes were taken for a time in the same way as cod, but they disappeared abruptly. (A.W.L.)

TILL. A general term for coarsely graded and extremely heterogeneous sediments of glacial origin. Till is generally classified as unstratified drift which may vary from clays to mixtures of clay, sand, and boulders. A particularly sticky form of clay till is called gumbo. (R.M.F.)

TILLERING. Grass Family.

TILLITE. Conglomerate.

TIMARAU. Tamarao.

TIMBER. Wood.

TIME. In the purely physical sense of the term, time is defined as measured duration. In accordance with this definition we say that two intervals of time are equal if a body, moving in **equilibrium,** moves over equal distances in the two intervals. The moving object is frequently referred to as the clock.

From the earliest recorded history the apparently moving sun has been adopted as the clock for regulating human affairs, and the apparent solar day is the interval of time between successive passages of the true sun across a local **meridian.** For many centuries upper culmination, or apparent noon, marked the beginning of an apparent day and local apparent time was the **hour angle** of the true sun. In 1925, to bring the apparent day into synchronism with that used in civil life, the beginning of the apparent day was transferred to lower culmination, or midnight, and the local apparent time defined as the hour angle of the true sun plus 12 hours.

The various hour angles, or local apparent times, were formerly recorded by the position of the shadow of a rod on a graduated dial known as a **sun dial.** Such an instrument is useful only when the sun is shining, and the need for mechanical clocks arose. As the development of these timekeepers progressed, with ever increasing accuracy, from burning candles, water clocks, sand glasses, and other such contrivances, down to the modern mechanical and electric clocks, it became evident that the apparent solar day is not constant in length throughout the year. These variations in length may be traced to the fact that the earth is not only rotating on an axis, but is also revolving about the sun in an **orbit.** The plane of the orbit is not perpendicular to the axis of rotation of the earth, and the angular motion of the earth in its orbit is not constant but in accordance with the elliptical motion described by **Kepler's Law of Areas.**

To assist in the development of mechanical clocks, the mean solar day was introduced. This is a day which is the average, in length, of all apparent solar days in a given year. A purely fictitious object, known as the **mean sun,** was defined and a mean solar day is the interval between successive passages of this fictitious object across any local meridian. The mean solar day begins at lower culmination of the mean sun and local mean time is the hour angle of the mean sun plus 12 hours. The difference between local apparent time and local mean time, taken in the algebraic sense of apparent minus mean, is known as the **equation of time.**

The term local civil time is sometimes used as synonymous with local mean time. Prior to 1925 the mean solar day began at upper culmination (mean noon) and the civil day began at midnight.

All three of the different kinds of time thus far discussed are measured from the local meridian. Accordingly, only those people living in the same terrestrial **longitude** would have synchronous clock readings. To avoid this confusion the surface of the earth has been divided into a series of **standard time** zones. The different sorts of standard time will be discussed elsewhere, but standard time is defined as the civil time of some standard meridian.

While the sun provides the most convenient reference point for measuring time for everyday life, nevertheless it is not convenient for stellar astronomy because of the fact that the sun is continually moving eastward through the stars. Sidereal time is defined as the hour angle of the **vernal equinox.** Since the sun is apparently moving to the eastward through the stars, due to the revolution of the earth about the sun, there is one more sidereal day than solar day in the course of a **year.** A clock keeping sidereal time gains approximately 4 minutes each day on a mean solar clock, the sidereal clock agreeing with the civil time clock on approximately September 21. The **right ascension** of a star is measured from the vernal equinox in a direction contrary to the direction of apparent rotation of the **celestial sphere** and the sidereal time is the hour angle of the vernal equinox, and hence measured in the direction of apparent rotation of the celestial sphere. Therefore, sidereal time minus right ascension is equal to the hour angle of a star.

The standard unit of time for the physical sciences is the mean solar day as defined above. The practical unit is 1/86,400 part of the mean solar day and is known as the mean solar second. This is one of the three basic units of the so-called **c.g.s. system.** It should be carefully noted that the mean solar day is based upon a purely fictitious object known as the mean sun. Hence the unit of time is just as arbitrary in character as are the other two units of the c.g.s. system. (See **Relativity.**) (W.K.G.)

TIME CONSTANT. This is a measure of the time of response of a circuit or device. In electrical circuits containing inductance and resistance it is L/R, L being the inductance in henries and R the resistance in ohms. For a capacitance and resistance circuit is it RC, C being the capacitance in farads and R as before. For both of these it is the time required for the circuit variables (current, charge, voltage) to reach to within $1/e$ of the final value, where e is the base of the natural logarithms (2.72). (L.R.Q.)

TIME QUENCHING. Steel.

TIME-GAMMA CURVE. This curve represents the relationship between gamma and the time of development for a particular sensitive material, developing formula and manner of development (temperature, agitation, etc.). The time-gamma curve is obtained by plotting the value of gamma (as determined from several sensitometric exposures which have been developed for different times) on the vertical axis against the time of development along the base of the chart. (See **Exposure-Density Relationship.**) From the time-gamma curve can be obtained (1) the time of development for a given gamma, (2) the gamma which will be produced by a given time of development under the same conditions, and (3) an indication of the range of gamma to which the particular film or plate should be developed for best results, since it is generally advisable to develop to a gamma which is at least 75% of the maximum gamma obtainable on that particular film or plate. (C.B.N.)

TIMING AXIS OSCILLATOR. Sweep Oscillator.

TIN. Symbol: Sn (stannum). Atomic number: 50. Atomic weight: 118.70. Density: white, 7.31 at 20° C.;

gray, 5.75 at 20° C. Hardness: 1.5–1.8 (white). Melting point: 231.85° C. Boiling point: 2260° C. (**Isotopes**: page 290.)

Tin is a silver-white metal with a bluish tinge, softer than zinc and harder than lead; malleable, ductile at 100° C.; can be powdered at 200° C., and upon exposure to temperatures below 18° C. crumbles to a grayish powder due to the "tin pest," which is caused by the transformation of white to gray tin (the reverse transformation may be brought about by heating gray tin to about 100° C.); when a bar of tin is bent a marked creaking sound is emitted due to the friction of the crystals; not oxidized on exposure to air at ordinary temperatures; burns to stannic oxide when heated to high temperatures in air or oxygen; soluble in **hydrochloric acid** to form stannous chloride; converted by **nitric acid** into insoluble beta-stannic acid; soluble in **aqua regia** to form stannic chloride; soluble in **sodium** hydroxide solution slowly to form sodium stannite and **hydrogen** gas; reacts with **chlorine** to form volatile stannic chloride. Discovery prehistoric.

Tin is used (1) as a protective coating on iron and steel and on copper. Tin coating on steel sheet is largely used for "tin can" containers, the coating being applied by dipping the sheet in molten tin or by electrolysis in acid or alkaline tin salt solution (very thin and continuous layers of tin are thus produced), (2) in **alloys**, such as solder, bronze, pewter, and bearing metals.

Tin occurs as oxide (**cassiterite**, tin stone, stannic oxide, SnO_2), obtained commercially in Federated Malay States, Dutch East Indies, and Bolivia. The ore is concentrated and then roasted to oxide (83–88% stannic oxide). The product is treated in a **blast furnace** and crude tin recovered. Refining is conducted by **electrolysis**, or by fractional fusion.

Chlorides: Stannous chloride ($SnCl_2 \cdot 2H_2O$), white solid, soluble, formed by reaction of tin metal and **hydrochloric acid** and then crystallizing, used as a mordant and reducing agent in dyeing and printing textiles; stannic chloride ($SnCl_4 \cdot 5H_2O$), (1) white crystals, soluble by reaction of stannous chloride with **chlorine** and then crystallizing, (2) colorless liquid, soluble, boiling point 114° C., formed by heating tin metal in chlorine and condensing the distillate.

Hydroxide: Stannous hydroxide ($Sn(OH)_2$), white gelatinous precipitate, by reaction of stannous chloride solution and alkalis, soluble in acids and in **sodium** hydroxide, insoluble in ammonium hydroxide.

Nitrate: Stannous nitrate ($Sn(NO_3)_2$), white solid, by reaction of tin metal and dilute **nitric acid** and crystallization, soluble in water with slight excess of nitric acid.

Oxalate: Stannous oxalate (SnC_2O_4), white precipitate, by reaction of stannous chloride solution and **oxalic acid** or ammonium oxalate solution, upon heating yields stannous oxide.

Oxides: Stannous oxide (SnO), black solid, insoluble, (1) by heating stannous chloride solution and **sodium** carbonate solution several hours, (2) by ignition of stannous oxalate out of contact with air; stannic oxide (SnO_2), white solid, insoluble, (1) by heating tin metal to a high temperature in air or oxygen, (2) by reaction of tin metal and concentrated nitric acid and ignition of the precipitate, (3) by reaction of stannic salt solution with **alkalis**, and ignition of the precipitate.

Stannates: Sodium stannate (Na_2SnO_3) and potassium stannate (K_2SnO_3), colorless solutions, by reaction of stannic salt solutions with excess of **sodium** or **potassium** hydroxide, respectively.

Stannic acids: Stannic acid (H_2SnO_3), white solid, insoluble (1) aipha, by reaction of stannic salt solution and alkalis, or by reaction of stannate solutions with **acids**, (2) beta, by reaction of tin metal and nitric acid.

Stannites: Sodium stannite (Na_2SnO_2) and potassium stannite (K_2SnO_2), colorless solutions, by reaction of stannous salt solutions with excess of sodium or potassium hydroxide, respectively. Powerful reducing agents.

Sulfates: Stannous sulfate ($SnSO_4$), white solid, soluble; stannic sulfate ($Sn(SO_4)_2$), white solid, soluble.

Sulfides: Stannous sulfide (SnS), dark brown precipitate, by reaction of stannous salt solution and hydrogen sulfide, insoluble in sodium sulfide solution but soluble in sodium polysulfide solution, forming sodium thiostannate; stannic sulfide (SnS_2), yellow precipitate, by reaction of stannic salt solution and **hydrogen sulfide**, soluble in sodium sulfide solution, forming sodium thiostannate.

Stannous chloride solution, when treated with **mercuric** chloride solution, yields a precipitate white to gray, depending upon the relative amounts of mercurous chloride (white) and mercury metal (black) formed. (R.K.S.)

TIN STONE. Cassiterite.

TINAMOU, TINAMU. Aves, Crypturiformes. A bird (**Aves**) resembling the partridges superficially. Characterized by the vestigial tail and by details of anatomy resembling the ostriches. The several species live only in South America. They are like game birds in many respects.

Tinamous are remarkable for their courting habits. The females court the males and the males fill the usual role of mother in the care of eggs and young. The nest is a scantily lined depression in the ground and the eggs are unusually smooth and glossy, resembling porcelain of a bluish green or wine red color. Some species have been reported as singers of exceptional ability. (A.W.L.)

TINCTURE. An alcoholic (**ethyl alcohol**), or water and alcohol, extract of a **drug**. The proportion of drug in a tincture varies, but is usually 10%. (R.S.M., D.M.H.)

TINGUAITE. A term proposed by Rosenbusch, in 1887, for a usually **porphyritic dike** rock chemically related to **aegirine-phonolite**. Similar to sölvsbergite but containing **nepheline**. (R.M.F.)

TINPLATE. Thin sheet steel with a protective coating of pure tin applied either by a hot dipping process or by electrodeposition. The principal use is for tin cans and other containers. (R.H.H.)

TISSUE. An aggregation of **cells** of characteristic form, specialized for the performance of some limited function or functions. All cells of the multicellular animal body take part in the formation of tissues, and tissues in turn are to a great extent incorporated in organs. The cells in a tissue may be all alike, or several kinds may be present, and in some tissues the cells are supplemented by a conspicuous bulk of intercellular materials.

Tissues are divided into five classes: **epithelial, muscular, nervous, connective,** and **vascular.** (A.W.L.)

TISSUE CULTURE. A method for the study of the behavior of single **cells** and isolated bits of tissues of the multicellular body independent of their usual surroundings. Minute pieces of tissue are separated from a growing mass, as in an **embryo** or a **tumor,** and are placed under aseptic conditions in a nutrient medium in small glass cells, where they can be observed microscopically. Tissues taken from birds or mammals must be kept at the body temperature of the species from which they are derived. Under proper conditions the cells of these isolated fragments continue to grow and divide, behaving to some degree as in the normal organism. Cells in cultures, however, do not grow old but persist at a uniform level of metabolism, apparently indefinitely.

This method of study has been especially important in cancer research, in studies of the physiology of senility, and in the observation of cellular phenomena in the living units.

Some progress has also been made in the attempt to cultivate, under aseptic conditions, isolated tissues and organs of plants. Very young embryos have been grown in culture media based on the liquid endosperm of the coconut (coconut milk). Excised root-tips and portions of embryos have been grown in culture media based on cane sugar solution to which are added vitamins and salts containing the chemical elements essential for plant metabolism. (A.W.L., P.A.W.)

TIT. Aves, Passeriformes. A small insect-eating bird (**Aves**) of agile habits and friendly nature, exemplified by the **chickadees**, *Penthestes,* and titmice, *Baeolophus,* of North America. They are chiefly birds of the northern hemisphere, but the group is represented in the Australian region. The colors of most species are quiet, ranging from white to black through bluish grays, relieved by a limited amount of buff or chestnut. The blue tit and the azure tit of the Old World, however, are much more brightly colored, as their names imply.

In North America some species of chickadee is to be found in almost every locality, while titmice occur in the far west and in the states east of the Mississippi.

These species are unusually fearless, and although they have no reputation as singers their cheery calls are always welcome. In the winter they visit feed boxes readily and soon become accustomed to close observation if the observer avoids sudden movements. (A.W.L.)

TITANIUM. Symbol: Ti. Atomic number: 22. Atomic weight: 47.90. Density: 4.5. Melting point: 1800° C. (**Isotopes**: page 290.)

Compact titanium is a while metal, when cold it is brittle and may be powdered, but at a red heat may be forged and drawn into wire. At 610° C. titanium reacts with **oxygen** to form titanium dioxide; at 800° C. with **nitrogen** to form titanium nitride; and upon heating with **chlorine** to form titanium tetrachloride. Cold, dilute **sulfuric acid** readily dissolves titanium metal to form titanous sulfate, and the hot, concentrated acid yields titanic sulfate. Discovered by Gregor in 1791.

Ferrotitanium is used as a "scavenger" for the removal of oxygen and nitrogen from molten iron and steel, and copper-titanium and manganese-titanium similarly for brass and bronze.

Titanium is used in some **stainless steels** in order to stabilize the carbon as carbide. Titanium carbide is an important **abrasive.**

Titanium occurs in practically all rocks, estimated by Clarke as ninth in abundance of the elements of the earth's crust (0.58% Ti), and in two important ores, **rutile** (titanium dioxide, TiO_2), and **ilmenite** (ferrous titanate, $FeTiO_3$). Ilmenite is a usual component of monazite sand of India, Brazil, and southeastern United States. The **magnetites** (ferroferric oxide, Fe_3O_4) of New York State contain titanium oxide.

Titanium metal is obtained by reduction of the oxide (1) with **carbon** in the **electric furnace,** or (2) with **aluminum** powder upon ignition.

Chlorides: Titanium dichloride ($TiCl_2$), black, deliquescent crystals; titanium trichloride ($TiCl_3$), violet crystals; titanium tetrachloride ($TiCl_4$), liquid, boiling point 136° C., which fumes in moist air, and used for producing white smoke screens in air.

Hydroxides: Titanous hydroxide ($Ti(OH)_3$), dark color; titanic hydroxide ($Ti(OH)_4$), white precipitate, soluble in acids, soluble in bases to form titanates.

Oxalate: Titanium potassium oxalate ($TiOC_2O_4 \cdot K_2C_2O_4 \cdot 2H_2O$), greenish-white crystals, used as a mordant in textile and leather dyeing.

Oxides: Titanium monoxide (TiO) of slight importance; titanium sesquioxide (Ti_2O_3), black, lustrous crystals by heating the dioxide in hydrogen; titanium dioxide (TiO_2), white powder, used as a paint pigment of high covering power and stability, and in glass and ceramic ware; titanium peroxide (TiO_3), formed in solution as a yellow to red color upon the addition of **hydrogen peroxide** to titanic salt solution and an important test for titanic.

Sulfates: Titanous sulfate ($Ti_2(SO_4)_3$), violet solution by reduction of titanic solutions with **zinc** metal; titanic sulfate ($Ti(SO_4)_2$), colorless solution used as a textile mordant. (R.K.S.)

TITANIUM DIOXIDE, TiO_2. **Octahedrite.**

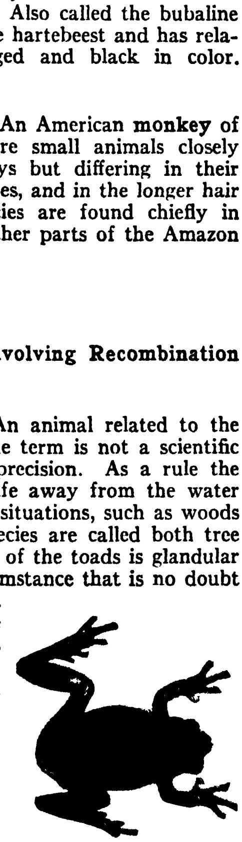
TITEL. Mammalia, Artiodactyla. An African **antelope** related to the hartebeest. Also called the bubaline antelope. It is smaller than the hartebeest and has relatively short thick horns, ringed and black in color. (A.W.L.)

TITI. Mammalia, Primates. An American **monkey** of the genus *Callithrix.* They are small animals closely related to the squirrel monkeys but differing in their more rounded heads, smaller eyes, and in the longer hair of the tail. The several species are found chiefly in Brazil but to some extent in other parts of the Amazon valley. (A.W.L.)

TITMOUSE. Tit.

TITRATION. Reactions Involving Recombination of Ions; Analysis.

TOAD. Amphibia, Anura. An animal related to the frogs and of similar form. The term is not a scientific one and its application lacks precision. As a rule the toads are better adapted for life away from the water and are found in merely moist situations, such as woods and gardens. The arboreal species are called both tree toads and tree frogs. The skin of the toads is glandular and more or less warty, a circumstance that is no doubt responsible for the false idea that handling toads will produce warts. Like the frogs, most toads have an aquatic larval stage.



Anderson's tree toad. (*American Museum of Natural History, Photo by Mary C. Dickerson.*)

The surinam toad, *Pipa pipa,* is probably the most famous member of the group because of the peculiar habits of reproduction. During the breeding season the skin of the female's back becomes thick and soft. The male imbeds each egg, as it is laid, in this soft skin, and development proceeds to completion in a resulting pouch. The young issue as small toads.

The common toads belong to the family Bufonidae. These species contrast strikingly with frogs in their warty skin and shorter and weaker hind legs. They are largely insectivorous and are of some slight value in the garden. Unlike the frogs, they deposit their eggs in long strings of jelly. (A.W.L.)

TOAD BUG. Insecta, Hemiptera. A small broad **bug** found on the muddy shores of ponds and streams. It is peculiarly like a toad in appearance and habits, capturing insects as prey and burrowing at times. Only a few species are known. (A.W.L.)

TOADSTONE. An old English term for **amygdaloidal basalts** interbedded with **carboniferous limestones** of Derbyshire, England. The rock probably takes its name from the resemblance of the amygdales to the warts or spots on the skin of a toad. (R.M.F.)

TOADSTOOLS. **Agarics and Basidiomycetes.**

TOBACCO. **Potato Family.**

TOBACCO WORM. Insecta, Lepidoptera. The caterpillar of a large **sphinx moth,** *Protoparce sexta,* which eats the leaves of tobacco, tomato, and other plants. The moth is gray with a row of six orange spots on each side of the abdomen and the larva is green, about 3″ long, with a stout horn near the caudal end of the body. Its sides are marked with oblique whitish lines.

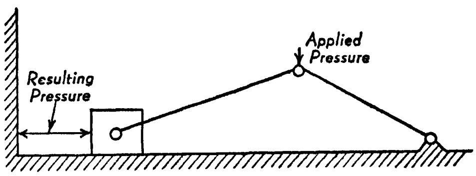
Crop rotation as prescribed for the region involved, and dusting with lead arsenate (see **Lead**), are effective methods of control on large fields. The **larvae** are so easily seen when they become large enough to cause severe damage that hand picking is effective on truck crops of smaller extent.

Tobacco is attacked by other caterpillars, hence the term tobacco worm is not always restricted to this form. (A.W.L.)

TODY. Aves, Coraciiformes. A small green and red insect-eating bird (**Aves**), *Todus viridis,* of the West Indies. The legs are relatively small and the beak is long and flattened. They nest in tunnels along the banks of streams like their relatives, the kingfishers. (A.W.L.)

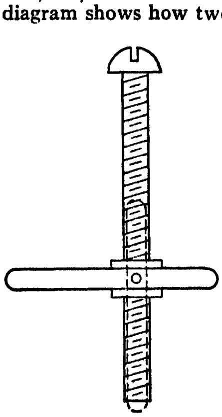
TOEPLER-HOLTZ MACHINE. Static Machines.

TOGGLE. The toggle is the particular class of **mechanism** commonly used to apply heavy pressure. The toggle effect which will be described is incorporated in mechanisms known variously as toggle mechanisms, toggle joints, etc. The principle of the toggle is the straightening out of a flat angle between two joined



Toggle mechanism.

members, one of which is affixed at its outer end, the other connected at its outer end to an anvil, jaw, hammer, die, or whatever is used at the pressure face. The diagram shows how two links, one pivoted and the other connected to a sliding block, have a common joint at which pressure is applied. Due to the flat angle between the two links, a comparatively small force effectively applied in a direction tending to straighten them out still more is capable of overcoming a large resistance at the moving end. The force is applied at the joint by means of a threaded screw, a cam, a crank and connecting rod, or any other suitable means. Examples of the use of the toggle are found in stamping machines, presses, crushers, etc.



Toggle bolt.

A toggle bolt is one having a short bar pivoted to the nut so that the bolt, with nut attached, can be pushed through a hole in a wall, then reversed. The bar, which is laid parallel to the bolt when entering the hole, swings to a perpendicular position, thus retaining the bolt in the hole. (F.T.M.)

TOGGLE JOINT. **Machines; Toggle.**

TOLERANCE. **Interchangeable Manufacturing; Fit.**

TOLLEN'S SOLUTION. **Formaldehyde.**

TOLUENE. Toluene, "toluol," methyl **benzene,** phenyl methane ($C_6H_5 \cdot CH_3$ or ) is a colorless, odorous **hydrocarbon,** boiling point 110.5° C., insoluble in water, miscible in all proportions with alcohols, ether, chloroform, and many organic liquids, dissolves **iodine, sulfur, oils, fats, resins, phosgene,** burns when ignited with a smoky flame. Toluene reacts (1) with **chlorine,** to form substitution products (one-half of the chlorine forms **hydrogen chloride**), such as (a) ortho- and para-chlorotoluenes ($(1)CH_3 \cdot C_6H_4 \cdot Cl(2)$ and $(1)CH_3 \cdot C_6H_4 \cdot Cl(4)$) at ordinary temperatures, moist, and in the presence of a catalyzer (e.g., **iodine, iron**). Both products are colorless, pleasant-smelling liquids, heavier than and insoluble in water, unchanged by sodium hydroxide solution, and (b) benzyl chloride ($C_6H_5CH_2Cl$), benzal chloride ($C_6H_5CHCl_2$), benzotrichloride ($C_6H_5CCl_3$), at boiling temperature, dry, and in the absence of a catalyzer. All three products are colorless, heavy liquids separable by fractional distillation, of pungent and irritating odors, insoluble in water, reactive with sodium hydroxide solution to form benzyl alcohol ($C_6H_5CH_2OH$), benzaldehyde (C_6H_5CHO), sodium benzoate (C_6H_5COONa), respectively, (2) with oxidizing agents, e.g., **sodium** dichromate plus **sulfuric acid,** to form benzoic acid (C_6H_5COOH). Toluene, benzyl chloride, benzotrichloride, benzyl alcohol, benzaldehyde form benzoic acid upon oxidation, (3) with concentrated **nitric acid,** to form ortho- and para-nitrotoluene ($(1)CH_3 \cdot C_6H_4 \cdot NO_2(2)$ and $(1)CH_3 \cdot C_6H_4 \cdot NO_2(4)$), dinitrotoluene ($(1)CH_3 \cdot C_6H_3(NO_2)_2(2,4)$), trinitrotoluene ("T.N.T.") ($(1)CH_3 \cdot C_6H_2(NO_2)_3(2,4,6)$), (4) with concentrated **sulfuric acid,** to form ortho- and para-toluene sulfonic acids ($(1)CH_3 \cdot C_6H_4 \cdot SO_3H(2)$ and $(1)CH_3 \cdot C_6H_4 \cdot SO_3H(4)$). From the former, **saccharin** $\left(C_6H_4\left\langle{}^{CO}_{SO_2}\right\rangle NH\right)$, which is some 500 times sweeter than sucrose and not a sugar, is made, and from the latter, chloramine T ($(1)CH_3 \cdot C_6H_4 \cdot SO_2 \cdot NClNa(4)$), an important antiseptic. Toluene is obtained from coal tar and coal gas, as described under **benzene.**

Toluene is used (1) as a solvent for various substances, (2) in the manufacture of nitrotoluenes for toluidines and explosives such as T.N.T., of sulfonic acids for saccharin and chloramine T, of benzoic acid, and of other organic chemicals, especially dyes and perfumes. (R.K.S.)

TOMATO. **Potato Family.**

TOMATO WORM. Insecta, Lepidoptera. A large **caterpillar,** *Protoparce quinquemaculata,* similar to the tobacco worm in appearance and habits and belonging to a closely related species. The moths of the two species are similar but are easily distinguished by comparison. (A.W.L.)

TOMBOLO. A type of sand bar which connects one island with another, or an island to the mainland. (R.M.F.)

TONALITE. **Diorite.**

TONE CONTROL. This is the control for regulating the **frequency response** of an audio **amplifier.** In its most common form as found in most radio **receivers** it consists of a condenser in series with a variable resistance shunted across the circuit at some point. Since

such a combination passes high frequencies more easily than low values, the highs will be attenuated, the degree being determined by the setting of the variable resistance. Thus by varying the resistance more or less attenuation may be given the high frequencies and the effect is as if the bass response were being varied. In more elaborate tone controls separate bass and treble controls are provided, thus allowing a balanced control of the response. (L.R.Q.)

TONGUE. For the use of this term in geology, see **Apophysis.** In anatomy an organ associated with the floor of the oral cavity, usually projecting or protrusible. The true tongue is a vertebrate structure, occurring in all classes above the fishes. It is made up largely of voluntary muscle fibers, so distributed that it can be protruded and withdrawn and swung in every possible direction. It arises embryonically from the floor of the anterior part of the pharynx, extending forward into the oral cavity.

The tongue is used in man and other species for the manipulation of foods in chewing, and in some of the amphibians, reptiles and birds it aids in capturing food, usually by adhesion. In man it is an important organ of speech, aiding in the modulation of sounds produced by the larynx.

The word is sometimes applied to the **radula** of the snails and to parts of the insect mouth, but only from superficial similarity with the true tongue of the vertebrates. (A.W.L.)

TONGUE SHELL. A common name for animals of the phylum **Brachiopoda,** also called lamp shells. (A.W.L.)

TONKA. Bean.

TONSILLITIS. An acute infection of the **tonsils** and surrounding throat tissues, usually caused by the hemolytic streptococcus. Tonsillitis may be a mild disease of short duration or a severe one with high fever and constitutional symptoms. In follicular tonsillitis both tonsils may be red, tremendously swollen and covered with patches of pus forming a thick exudate. The throat is sore and exceedingly painful, especially on swallowing. Either mild or severe tonsillitis may be followed immediately by **scarlet fever**, or after a latent period by **rheumatic fever** or **nephritis.** Faucial **diphtheria** or diphtheria involving chiefly the tonsillar areas must be distinguished from streptococcus tonsillitis.

Treatment of the severe type of infection consists of irrigation with warm saline or glucose, and in some instances, **sulfonamides** or penicillin. (D.M.H.)

TOOL. An appliance, device, or machine used by a worker in pursuing his art. In the metal-working trades, tools include hand tools such as **hammers, saws, chisels,** etc., tools for gauging and **measurement,** and power and **machine tools.** (H.C.H.)

TOOL STEELS. Steels used in the manufacture of all types of tools are many, diversified in composition and properties and made under strict quality controls to meet rigid specifications and withstand rigorous service conditions. These steels, comprising less than 1% of the tonnage of all steels produced, are now made by the basic electric melting process to the almost complete exclusion of the crucible process formerly used. They are, however, still made in comparatively small lots and orders for one size or one composition are often of only a few hundred lbs. in weight.

Tool steels require, in almost all instances, a potential of high hardness and strength and, therefore, generally possess a carbon content in excess of .50%. The plain carbon tool steels, still in extremely wide use, contain little or no alloying elements as the name implies. All other tool steels contain one or more alloying elements (manganese, silicon, chromium, tungsten, molybdenum, vanadium, nickel) in quantities from less than 1% total alloy content in certain types to over 45% total alloy content in other types. The composition of typical tool steel types is shown in the table on p. 1480.

Carbon tool steels may be used for innumerable purposes covering the entire range of machine and hand tool operations. They are adapted to meet the requirements of certain applications involving repeated shock yet requiring higher than average wear resistance because of their peculiar quality of hardening to a limited depth, readily controllable. Internal stresses remaining in the steel are compressive at the surface in this case and result in greatly increased fatigue strength and service life. Carbon tool steels are manufactured with .50–1.40% carbon, the carbon content selected being high where wear resistance is of prime importance and being low where toughness is a major consideration.

Chromium and chromium-vanadium tool steels containing .75–2.50% chromium have the ability to harden to a greater depth than carbon tool steels and are, therefore, applicable for large size tools and dies (see **Hardenability of Steel**). A large range of applications from shock-resisting tools to cutting tools and dies, small- or intermediate-size rolls, bearings and bearing races is encountered with these steels based on their exceptional strength and toughness, their variable hardness and hardenability. As with the straight carbon tool steels the service requirements dictate the carbon content.

The low alloy chromium-nickel-molybdenum die steels are essentially high-carbon varieties of the Engineering S.A.E. alloy steels. The higher carbon increases the depth of hardening and the maximum hardness obtainable in large sizes. These oil-hardening steels when hardened to 58 to 62 Rockwell "C" combine an excellent degree of toughness, strength and resistance to wear and find use in dies and machine parts which require a good combination of hardness and toughness.

The *manganese oil-hardening steels* are among the most important of the tool steel types because they can be used for many types of tool and die work. This group of steels exhibits low dimensional changes in hardening, a high as-quenched hardness combined with a great depth of hardening, and a freedom from cracking when intricate sections are quenched. These steels do not possess any **red hardness** properties which would enable cutting at high speeds or which would make them applicable for hot-working operations. The low distortion properties enable this group of steels to find considerable application for tools which cannot be ground or machined after heat-treating.

Silicon tool steels originally used for springs are valuable primarily because of their high resistance to shock, very high fatigue-resistance and good wearing ability. They can be treated to a fairly high degree of hardness, making them applicable to many punch and die applications, as well as to shock-resisting tools. They are well adapted for chisels, punches, rivet sets, coal cutters and for shear blade where good wearing qualities and a comparatively low-cost steel are required. They are especially useful as shanks for tipped carbide or high-speed steel tools for which purpose they have largely supplanted many other types in the last several years.

Tungsten-finishing steels are generally used in cases where extreme wear resistance or abrasion resistance is necessary and where the ability to retain a keen cutting edge is desired. The wear resistance of tungsten-finishing steels is 4 to 10 times that of plain carbon steels at maximum hardness. In addition to applications for cutting tools the tungsten-finishing steels are extensively used for small tube and wire drawing dies as well as for sizing plugs and gauges and forming and piercing punches.

A recent addition to the steels used for tools is the group of materials known as *graphitic steels* which contain a relatively high carbon content of which a portion is graphitized during heat treatment. The remaining

ungraphitized carbon is generally in an amount equal to the eutectoid content of the steel. Such a structure results in a hardenable free-machining steel to which can be added various alloy additions to change the hardening characteristics in accordance with the need of different applications.

Tungsten chisel steels are used for much the same purpose as silicon tool steels, namely, shock-resisting tools, but find additional use in tools for hot-working purposes. For the latter purposes they are used when the dies for hot-working are subject to considerable shock, such as in heading dies for square-headed bolts, tools with deep recesses or grooves, and hot shear blades having notched edges. In certain instances the tungsten chisel steels will be carburized to produce a tool having a very high toughness and at the same time a surface near file hardness.

The *air-hardening die steels* containing 1% carbon and 5% chromium and 1% molybdenum compete with both the manganese oil-hardening steels and the high-carbon high-chromium steels as cold-work die materials. Their wear-resistance is midway between these two types of competing steels but their toughness is greater than either. They possess a very high hardenability and can be hardened in air with a distortion amounting to only about ¼ that found in oil-quenched manganese oil-hardening steels. They are, therefore, used where fair abrasion-resistance must be combined with exceptional toughness, such as in dies for blanking, forming, drawing and thread rolling and in rolls and punches. They also have a limited application for certain types of shear blades.

High-carbon high-chromium steels first developed commercially as a substitute for high-speed steel cutting tools during World War I have received very little use for this purpose because of their exceptional brittleness but their high wear-resistance combined with remarkable non-deforming qualities make them extremely useful for cold-working dies. They may be obtained in either the air- or the oil-hardening varieties, the latter having a slightly greater wear-resistance than the former. The wear-resistance of the high-carbon high-chromium steels is approximately 8 times that of carbon tool steels, and by virtue of their high chromium content resist oxidation at high temperatures and have an appreciable resistance to staining when hardened and polished. Properly designed tools made from these steels can punch steel plate up to ¼″ in thickness and they also are used for shear blades, slitting cutters, cold-forming rolls, gauges and drawing dies.

Die steels used for hot-working operations are readily divided into two classes: (1) those containing high chromium contents, and (2) those containing high tungsten contents. These steels must possess a high resistance to deformation at the temperature of working and should resist fire or heat checking. The *1% carbon–4% chromium steels* have excellent wear-resistance and sufficient rigidity for applications where hot-working is performed mainly by compressive action, finding considerable use for gripper dies in bolt and rivet plants. The most widely used of all die steels for general hot-working operations are the *low-carbon 5%-chromium steels* with molybdenum or tungsten additions which were originally developed for the die casting of aluminum alloys. These steels are air-hardening and in addition to their die casting die applications are used for forging dies, punches, piercers and mandrels for hot work, shear blades for hot work and all types of hot-working dies which involve shock. The *tungsten hot-work steels,* sometimes called semi-high-speed steels, containing low percentages of carbon and 9–15% tungsten plus additions of other alloying elements, will withstand the highest working temperatures without failure and also possess better wearing qualities than any of the other hot-work die steels generally in use. Their main disadvantage lies in the fact that they will not withstand shock and cannot generally be rapidly cooled in operation with water without danger of breakage.

High-speed steels, regardless of type, have a striking similarity in their physical make-up. Practically all of the high-speed steels possess a very high alloy content combined with sufficient carbon to permit hardening to file hardness; they are all hardened from temperatures just under their fusion point; they harden so deeply that almost any size encountered commercially will have a uniform hardness throughout the cross-section; and all

Type	C	Si	Mn	W	Cr	V	Mo	Ni	Co

high-speed steels can be hardened to near maximum hardness by cooling in still air. But perhaps the most important property common to all high-speed steels is the ability to retain a considerable hardness at elevated temperatures.

The basic type of high-speed steel which has been developed over a period of many years and the one which has received the most study contains 18% tungsten, 4% chromium, 1% vanadium and .50–.80% carbon. It is used for both cutting and die applications. The war emergency period caused the commercial development of molybdenum high-speed steels, the most popular of which are the 6% tungsten-5% molybdenum type and the 8% molybdenum types with vanadium or tungsten in small amounts. To each of these types cobalt in amounts up to 12% may be added to increase the hot hardness and cutting efficiency in certain instances.

Actually no one composition of high-speed steel can always meet all of the requirements. The standard tungsten and the standard molybdenum types can be more generally applied than any others. These steels have good toughness and cutting ability and the tungsten type can be very readily fabricated and heat treated. The addition of vanadium in amounts over 1.50% to the tungsten and molybdenum types offers an advantage of greater wear-resistance and hot-hardness and these steels are, therefore, more suited for fine and finishing cuts on hard and soft materials. The cobalt types are slightly more brittle than the non-cobalt types but will give better performance on cutting hard materials at high speeds.

High-speed steels of any type have a hardness at 1100° F. of between 450 and 520 Brinell and have a hardness at 1200° F. of between 300 and 400 Brinell. At 1100° F. they are superior in hot-hardness to the cast cutting materials but at or above 1200° F. their hardness is lower than that of the cast cutting materials. (GEORGE A. ROBERTS, VANADIUM ALLOY STEEL CO.)

TOOTH. 1. A hard structure projecting from the wall of the mouth or the anterior part of the alimentary tract (**digestive system**) and used for grasping and breaking up food. Teeth vary from the chitinous projections on the radula of **mollusks** to the complex structures of the vertebrates. Chitinous teeth of **annelid** worms, located on the walls of the **pharynx**, are also known as jaws.

Vertebrate teeth are formed of two layers of hard materials over a living papilla, the pulp, which contains blood vessels and nerves. They form in the **embryo** from ingrowths of the outermost layer of the body, the ectoderm, associated with masses differentiated in the middle layer, the mesoderm. The mesoderm forms the dental papilla and around its outer surface, except at the end that is to remain connected with the body, lays down a layer of dentine. This material is similar to bone in composition but not in minute structure. It is harder, contains less organic matter than bone, and is the ivory of commerce. The ectodermal cap over the dental papilla develops into an enamel organ and deposits a layer of enamel on the dentine. Enamel is made up of minute prisms and is the hardest substance produced by the animal body, containing only 2–4% organic matter. When the tooth takes its place in the jaw in the process of eruption the enamel organ is destroyed, hence no more of this substance can be produced. Dentine may be deposited later in life, however, encroaching on the pulp cavity.

The teeth of sharks are the most primitive vertebrate teeth. They are formed like the placoid scales of the body, with a principal point and sometimes smaller supplementary points, and are superficially attached in rows on the jaws. Both scales and teeth contain dentine covered with enamel.

In other fishes (**Pisces**) and **amphibians** teeth are distributed in various parts of the oral cavity and are associated with the bones of the jaws and skull. In **reptiles** and **mammals** they are limited to the jaws and are seated in sockets (alveoli) in the bones by means of a third hard substance, cementum, deposited between the dentine of the roots and the bone of the jaw.

Primitive teeth are simple conical structures. In mammals this type persists only in the canines. The other teeth are sharp-edged incisors, broad molars with projecting cusps on the apposed surfaces, and premolars of intermediate form. The premolars of man are also called bicuspids. An assemblage of teeth of these kinds, variously specialized for cutting, tearing and holding, and grinding and crushing, is known as a heterodont dentition, and is the fundamental plan of **dentition** in the mammals. The various forms of teeth are the basis of specialization in different groups of mammals for the use of limited types of food Thus species that depend on plant tissues have greater need of crushing teeth while carnivorous forms need cutting teeth for their tougher food. The molars of the former are broad and are so folded that the worn apposed (occlusal) surfaces show alternating bands of dentine, enamel, and cementum in patterns characteristic of the kind of animal. In the elephants these materials form transverse ridges. The incisors of grazing animals are also flattened, forming clipping, rather than cutting, teeth. The canines are reduced or lacking. In carnivores the incisors are greatly reduced, the canines are highly developed, and the molars are sharp-edged. Molars of the two jaws work together like the blades of shears. Some mammals, notably certain **anteaters**, have lost all trace of teeth.

The tusks of various animals are greatly elongated teeth projecting from the jaws for use in fighting and digging. They are usually devoid of enamel. Those of the elephants are upper incisors and in early growth are provided with enamel tips. Those of **walruses** and **swine** are canines. Single tusks of **elephants** weighing almost 200 lbs. have been recorded but the average is less than 100. These tusks provide the finest ivory.

Some teeth grow constantly as they are worn away, while others attain a fixed form within a short period and still others undergo a partial compensation for wear. The incisors of **rodents** are of the first type. These chisel-like teeth wear away in gnawing but are constantly renewed by growth at their bases to preserve a uniform length. The molars and premolars of horses are elevated in the jaws by lengthening of the roots, but the amount available for use during the life of the animal is regulated by the height of the crown at the initial formation of the tooth. Human teeth assume a fixed form. The only compensation for wear is the partial filling in of the pulp cavity by the deposition of dentine.

A compensation for breakage and wear is also found in the replacements that occur in lower vertebrates. Mammals normally have no more than two sets, milk and permanent, and when once the permanent teeth of adult life have assumed their functional positions in the jaws, loss through accident is permanent. Rarely a third set of teeth develops.

The word tooth also denotes:

2. The interlocking projections at the hinged edges of the valves of the bivalve molluscan shell.

3. Tooth-like projections on a hard structure or on the surface of the body of an animal. (A.W.L.)

TOP MINNOW. Pisces, Teleostei. Any small fish (**Pisces**) of several species, belonging to several genera, which live in quiet water of streams and in pools, swamps, and ditches, feeding on mosquito larvae and other small insects. Some are also called mosquito fish and one species is known as the rain-water fish. These fishes vary from less than 1″ to 3″ in length. They are most abundant in the southern states and southward into Central America, living in fresh and brackish water.

For introduction into lily pools to keep down mosquitoes these fishes are the most desirable. (A.W.L.)

TOPAZ. The mineral topaz is a silicate of aluminum and fluorine corresponding to the formula $(AlF)_2SiO_4$. It is orthorhombic and its crystals are mostly prismatic terminated by pyramidal and other faces, the basal pinacoid being often present. Massive varieties are known. It has an easy and perfect basal cleavage hence for this reason gems or fine specimens should be handled with care to avoid developing cleavage flaws. The fracture is conchoidal to uneven; hardness, 8; specific gravity, 3.4–3.6; luster, vitreous; color, of typical topaz, wine or straw-yellow but may be colorless, white, gray, green, blue or reddish-yellow; transparent to translucent. When heated, yellow topaz often becomes a reddish pink. Topaz is found associated with the more acid rocks of the granite and rhyolite type and may occur with fluorite and cassiterite. Topaz comes from many foreign localities, a few of which are: Russia in the Urals and the Ilmen Mountains; Czechoslovakia, Saxony, Norway, Sweden, Japan, Brazil and Mexico. In the United States topaz has been found in Oxford County, Maine; Carroll County, New Hampshire; Fairfield County, Connecticut; El Paso and Chaffee Counties, Colorado; and in Texas, Utah and California. The name topaz is derived from the Greek meaning to seek, which was the name of an island in the Red Sea that was difficult to find from which a yellow stone, now believed to be a yellowish-olivine, was obtained in ancient times. In the Middle Ages any yellow stone was called topaz, but now the name is properly applied only to the species here described. (E.S.C.S.)

TOPAZOLITE. Garnet.

TOPE. Pisces, Elasmobranchii. *Galeus.* A small shark found in all temperate and tropical seas More commonly called the dog shark or dogfish in North America, and sometimes the hound shark. It attains a length of 6′ but is usually much smaller. It is used as food to some extent. (A.W.L.)

TOPIOLITE, $FeTa_2O_6$. Mossite.

TOPOGRAPHIC MAP. Map; Topographical Mapping.

TOPOGRAPHIC SURVEYING. Topographical Mapping.

TOPOGRAPHICAL MAPPING. Topographical mapping consists of representing on a map the physical features of a given section of land, by showing thereon contours or hachures representing the elevation, and noting various other physical features by conventionalized signs. Thus trees, streams, marshes, and roads may be part of a topographic survey. The method of topographic surveying and mapping of large areas consists of establishing points for horizontal and vertical control, and surveying the adjacent area from these points by the use of direct leveling or stadia. (F.T.M.)

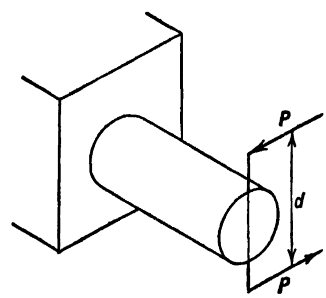
TOPOGRAPHY. Topography is a term used in a broad sense to include all details, both natural and artificial, which are required for a topographic map. The details cover such points as the disposition of the parts of the earth's surface; namely, hills, valleys, plains, plateaus, etc., and the location of waterways, bridges, highways, railroads, cultivated fields, forests, buildings, etc. The delineation of these features is also known as topography. (C.W.C.)

TOPOLOGY. Topology may be described as a study of those properties of a geometrical figure unaffected by any deformation not involving tearing or joining. (L.L.S.)

TOPSOIL. Soil.

TORNADOES. Some thunderstorms, particularly the line-squall type, occasionally develop a violent whirl of air which extends down from the base of the cloud and touches the earth. It often draws up into the cloud again and may strike some distance away or never reappear. Very low pressure prevails inside a tornado because of its great vorticity. When a tornado passes over a building, therefore, the building virtually blows up because of the low pressure surrounding it. Tornadoes in the U. S. are most common to the South and Middle West. (P.E.K.)

TORQUE. A torque, often called a torsional or twisting moment, is a moment which tends to twist a body about an axis of rotation. In the accompanying illustration a shaft of diameter d is connected to a rigid



support. The forces P tend to rotate the shaft in a counter-clockwise direction causing a torque $(T) = Pd$.

For a body in free rotation the torque $= I\alpha$, in which I is the moment of inertia of the mass of the body and α is the angular acceleration. (See Statics.) (C.W.C.)

TORSION. Elasticity.

TORSION BALANCE. The torsion balance is an instrument for measuring very feeble forces of attraction or repulsion. It has played an important rôle in the demonstration of Coulomb's laws and in measuring the gravitation constant and radiation pressure. It consists essentially of a light horizontal rod suspended by a slender elastic wire or fiber and carrying at each end a small ball, vane, or other object upon which the unknown force is to act tangentially. The resulting torsional deflection is measured by an optical lever, the small mirror of which is attached at the base of the suspension. To calculate the corresponding torque (and hence the force), the "torsion coefficient" of the suspension must have been previously determined. This is the torque required to twist the suspension through an angle of 1 radian, and is conveniently obtained by using the same suspension as the support for a torsion pendulum of known moment of inertia, and measuring the period. In the Cavendish method for determining the gravitation constant, small balls of gold or platinum are used and the torque applied by the attractions of much more massive balls or cylinders of lead in the same horizontal plane. The Eötvös balance (see Gravitation and Gravity) is a highly specialized form of the torsion balance, used in gravity measurements. (L.D.W.)

TORSION PENDULUM. The torsion pendulum consists of a body suspended by a fine wire or elastic fiber in such a manner that it will execute rotational oscillations as the suspension twists and untwists. If I is the moment of inertia of the body with respect to the axis of oscillation, and if K is the torsion coefficient of the fiber (torque required to twist it through an angle of one radian), the period of oscillation is given by the simple formula

$$T = 2\pi\sqrt{\frac{I}{K}}. \qquad (1)$$

Both I and K may have to be determined by experiment in actual laboratory practice. This is easily done by measuring the period T and then adding to the suspended body another of known moment of inertia I', giving a new period of oscillation T', which is also measured. From (1),

$$T' = 2\pi\sqrt{\frac{I + I'}{K}}; \qquad (2)$$

and the solution of the two equations now gives $K = 4\pi^2 I'/(T'^2 - T^2)$, $I = T^2 I'/(T'^2 - T^2)$.

The oscillating balance wheel of a watch is, in effect, a torsion pendulum, with the suspending fiber replaced by hairspring and pivots. The watch is regulated, first roughly by adjusting I (for which purpose screws are set radially into the rim of the wheel), then accurately by varying the free length of the hairspring, and hence its torsion coefficient K. (L.D.W.)

TORSIONAL LOAD. Load.

TORSIONAL STRESS. The **shearing stress** which occurs at any point in a body as the result of an applied **torque** or **torsional load** is called a torsional stress. If the body is a circular shaft, the stress is found from the formula:

$$s_s = \frac{Tc}{J}$$

in which s_s = Required **unit stress.**
T = Torque.
c = Radial distance from the center of the shaft to the point.
J = **Polar moment of inertia** of the cross-sectional area.

This formula is based on the assumption that a plane section before twisting remains a plane after the torque is applied; also that the radii remain straight. The theory of **elasticity** shows that these assumptions are true for all sections except those adjacent to the applied torque and the supports.

The cross-section of a non-circular body becomes decidedly warped after twisting, so the stress must be obtained by formulae developed from the theory of elasticity, by experimental means or by approximate formulae which are given in textbooks on advanced strength of materials. (C.W.C.)

TORSK. Pisces, Teleostei. A marine fish (**Pisces**), *Brosme brosme,* found in northern waters. Reported as abundant near the Shetland and Orkney islands. It is related to the cod. (A.W.L.)

TORTOISE. Reptilia, Chelonia. A **turtle.** There is no accurate scientific distinction between the two terms, although some species are called turtles and some tortoises. This is true even of members of the same family.

In North America the term turtle is commonly used, although a few species, including the gopher turtle of the south, belong to the genus of land tortoises. This group is known especially for the giant land tortoises once so abundant on the Galapagos Islands. These animals attain a weight of 500 lbs. and live a century or more.

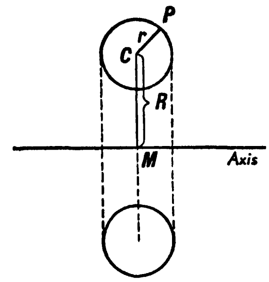
One species of northeastern South America is noteworthy for the angular prominences on the shell and head and for peculiar projections fringing the long neck. It is called the matamata. (A.W.L.)

TORTOISE SHELL. The mottled horny plates of the shell of a marine **turtle,** ***Eretmochelys imbricata.*** This species is found in warm seas, extending as far north as Massachusetts occasionally. It is known as the hawksbill or tortoise-shell turtle.

Tortoise shell was once highly valued for ornamental use, as in toilet articles and the handles of pocket knives, but it has been largely replaced by synthetic materials. (A.W.L.)

TORTOISES. Fossil Reptiles.

TORUS. In mathematics, a torus (or anchor ring) is the figure generated by revolving a circle about an axis in its plane but not intersecting it.



Generation of torus.

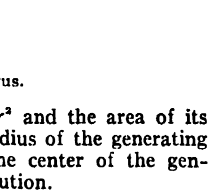
The volume of a torus is $2\pi^2 Rr^2$ and the area of its surface is $4\pi^2 Rr$, where r is the radius of the generating circle and R is the distance of the center of the generating circle from the axis of revolution.

In zoology, a torus is a pad at the tip of a **digit** of the **vertebrates.** These structures form the tough resilient bearing surfaces of the appendages of most vertebrates, and are nicely illustrated by the pads on which the dog and cat walk. (L.L.S., A.W.L.)

TOTAL DERIVATIVE. Partial Derivatives.

TOTAL DIFFERENTIAL. Differentials.

TOTAL REFLECTION. Total reflection occurs when light is reflected in the more refractive of two media from the interface between them, at any angle of incidence exceeding the so-called "critical angle." This is the angle whose sine is equal to the relative **refractive index** for light attempting to pass from the more to the less refractive medium. (See **Refraction.**) Thus, for water against air, for which the index is 0.75, the critical angle is 48° 35′; so that if light is incident in the water at an angle of 50°, it will be totally reflected. This phenomenon may be easily observed by holding a glass of water with the surface slightly above the eye and inserting the finger or a matchstick into the water. The under side of the surface is then seen to reflect this object like a perfect mirror, and gives the impression of a mercury surface inverted. The principle is often utilized in reflecting prisms such as those used in the prism **binocular.** Here the refractive index is about 0.6 and the critical angle, therefore, only 36° 52′, while the angle of incidence is commonly 45° (see figure). **Refractometers** utilize this principle. For some metals whose refractive index for light is less than unity, total reflection occurs on the outside of the surface. The same is true of glass for x-rays. (See **Mirage.**) (L.D.W.)



Total reflection in a right-angled prism.

TOUCAN. Aves, Coraciiformes. A bird (**Aves**) of South and Central America, characterized by the enormous beak. Most species are brilliantly colored and of large size. The beak, several times as large as the head, is of very light structure, with serrated edges used in cutting up fruit. It is covered with a thin horny shell and contains a fine bony reticulum. Toucans are also remarkable for their peculiar habit of tossing bits of

food into the air and catching them in the mouth to be swallowed. (A.W.L.)

TOUCH. A special sense that responds to contacts. The **tactile organs** through which the stimuli of contact are received are sensitive to varying pressures, sometimes of exceedingly slight degree. They are related to other sense organs which respond to pressure, including internal receptors, chordotonal organs of insects, lateral line organs of fishes, and organs of hearing, but differ in responding to simple pressures from the outside of the body, while the other external receptors are stimulated only by vibratory pressures of varying frequency, usually in the surrounding air or water.

The perception of degrees of simple pressure by organs of touch permits the formation of mental images of conformation of objects and characteristics of surfaces through the varied stimuli arising from contact with high and low points, yielding and rigid projections, adhesive materials, and other factors capable of carrying the pressure transmitted by the sensory endings. (A.W.L.)

TOUGHNESS. The property of a material which enables it to absorb energy when stressed beyond the **elastic limit** is called toughness.

The modulus of toughness is the total energy per unit of volume which must be absorbed in order to produce **failure** by fracturing (breaking). It is equal to the area between the **stress-strain curve** and the axis of unit **deformation.**

A ductile (see **Ductility**) material is tougher than a brittle material; therefore the former should be used for members which are subjected to **impact** or **energy loads** since it is impossible to predict an exact value for these loads. (C.W.C.)

TOURACO. Plantain-Eater.

TOURMALINE. The mineral tourmaline is a complex **silicate** of **aluminum** and **boron,** but because of **isomorphous** replacements this mineral varies widely in chemical composition, **iron, magnesium,** and **lithium** entering into combination to a greater or less extent with the aluminum and boron. Tourmaline belongs to the **hexagonal** system, its crystals are usually prismatic, tending to be long and slender, often acicular. The crystals are ordinarily terminated with three faces of a **rhombohedron** and usually **hemimorphic.** The smaller crystals are frequently found in radial arrangement, and columnar masses are common. The prisms are usually three, six, or nine sided with heavy vertical striations producing a rounded effect. Tourmaline is essentially without **cleavage;** fracture, conchoidal to uneven; brittle; hardness, 7–7.5; specific gravity, 2.9–3.2; luster, vitreous inclining to resinous; color, in common tourmaline black, bluish-black, brown, blue, green, red or pink, and in the transparent varieties colorless (rare), various shades of rose and pink, greens, blues and browns. The color arrangement in tourmaline is of considerable interest; bi-colored crystals are common and may be green at one end and pink at the other, or green on the outside, and pink within, which, in the case of transparent or translucent crystals, is very attractive. The opaque black tourmaline is called schorl, which term was applied to all tourmaline until 1703 when tourmaline was introduced, it being a corruption of the Ceylonese word, *turamali.* The origin of the word schorl is not known, but is perhaps Scandinavian. The rose or pink tourmalines are called rubellite (from ruby); the dark blue, indicolite (from Indigo); the lighter, Brazilian sapphire; the green, Brazilian emerald; the brown, dravite (from the Drave district of Carinthia); and the colorless, achroit from the Greek meaning without color. Small tourmalines are found in **granites** and some **gneisses.** Due, no doubt, to the mineralizing action of **magmatic** vapors, tourmaline is found particularly well developed in **pegmatites,** and as a contact **metamorphic mineral.** A few of the important foreign localities are: The Ural Mountains, Bohemia, Saxony, the Island of Elba, Norway; Devonshire and Cornwall, England; Greenland, Madagascar, and Brazil. In the United States in Oxford and Androscoggin Counties, Maine; Grafton and Sullivan Counties, New Hampshire; Hampshire County, Massachusetts; Haddam and Fairfield Counties, Connecticut; St. Lawrence County, New York; Sussex County, New Jersey; Delaware County, Pennsylvania; and San Diego County, California. (E.S.C.S.)

TOWHEE. Aves, Passeriformes. A North American bird (**Aves**) related to the finches and sparrows. The common eastern species, *Pipilo erythrophthalmus,* is a black and white bird with red-brown sides. It is seen chiefly on the ground and nests chiefly beneath tangled thickets. From its call this bird is also known as the chewink. Four other species are found in the west, three congeneric with the eastern towhee and a fourth, the green-tailed towhee, *Oberholseria chlorura,* is placed in a related genus. (A.W.L.)

TOXEMIA. The varying degrees of prostration which result from the presence of specific toxins liberated by the bacteria associated with such diseases as **scarlet fever, diphtheria, tetanus,** etc. The term is also used loosely and incorrectly to describe various vague symptoms in any severe illnesses. (D.M.H.)

TOXEMIAS OF PREGNANCY. A variety of complications occurring during the course of pregnancy. The most important are pernicious vomiting, acute yellow atrophy of the liver, pre-eclampsia, eclampsia, and several forms of nephritis.

Pernicious vomiting occurs during the first trimester, and is an exaggeration of the normal nausea and vomiting, or "morning sickness" of pregnancy. Its cause is unknown. Although it occurs more often in neurotic individuals, it has an organic basis which is little understood. In severe cases, unless the pregnancy is terminated, the patient may die. At autopsy, the liver shows toxic necrotic changes.

Acute yellow atrophy (see **Hepatitis**) is a rare and calamitous disease, which occurs in the last half of pregnancy. It is characterized by sudden and extensive **necrosis** of the liver so that the organ shrinks in a few days to half its normal size. There is deep **jaundice** and prostration. Recovery is unusual and death usually supervenes promptly.

Pre-eclampsia and eclampsia occur in the latter part of pregnancy, or at term. Pre-eclampsia is characterized by elevation of the **blood pressure, albuminuria,** and **edema.** Headache, visual disturbances, diminished urinary output and abdominal pain are the common symptoms. Pre-eclampsia may go on to eclampsia just before or just after delivery. In this case the patient develops convulsive seizures and coma. Unless immediate treatment is given, death is the outcome. **Morphine,** magnesium sulfate and other sedatives are used effectively. The cause of eclampsia is unknown. At autopsy characteristic lesions in the kidney and liver are seen but their pathogenesis is still mysterious.

Glomerulonephritis, pyelonephritis, and nephrosclerosis may first become manifest during pregnancy; it may be difficult to distinguish them from pre-eclampsia if they appear late in the pregnancy. Their persistence after delivery is a characteristic feature.

Pre-natal care is directed toward the prevention of toxemias, or their early recognition and treatment. This is the reason that regular examinations are made by the physician throughout pregnancy. (D.M.H.)

TOXIN. A soluble poison produced and liberated by certain **bacteria,** insects, snakes, and plants. Toxins are usually protein substances which may be destroyed by

heat. They vary in potency, and in their tissue affinities. The toxins produced by **tetanus** and *botulinus bacilli* are extremely potent and affect only nervous tissue; **diphtheria** toxin attacks the nervous system and the heart. Other organisms liberating toxins are hemolytic streptococci (notably in scarlet fever), **dysentery** bacilli, and staphylococci causing food poisoning. (D.M.H.)

TRACHEA. 1. An air tube of the **arthropod** respiratory system. These tubes open at the surface of the body through **spiracles** and lead inward, branching extensively and in some species expanding to form air sacs. At their inner extremities they connect with very fine tubules called tracheoles, of independent origin. Tracheae are ingrowths of the outer layer of the body and are lined with a continuation of the cuticula, which forms spiral rods in their walls. Near the spiracle they are often provided with a muscular closing device by which air can be excluded if it contains harmful materials. The tracheoles form within cells of the lining of tracheae, later breaking out and assuming their connection with the larger tubes. They have no spiral supporting rods (taenidia).

2. The principal air tube of the vertebrate **respiratory system**, also called the wind pipe. It leads from the **pharynx** to the major branches (bronchi) connecting it with the **lungs**, and its wall is supported by rings of cartilage. At the pharyngeal end in **amphibians** and **mammals** it forms an expanded larynx containing vocal cords, and at the point where it forks to form the bronchi in birds the remarkable vocal organ called the syrinx is developed. (See **Vessel.**) (A.W.L.)

TRACHEIDS. A tracheid is an elongate xylem cell (angular in transverse section) with tapering ends; when mature it contains no **protoplasm.** In the thickened, lignified walls of a tracheid there are many bordered **pits.** Functionally a tracheid serves both for conduction of water and for support.

For their development, see **cambium.** (R.M.W.)

TRACHEOPHYTES. All plants with true **vascular** system composed of **xylem** and **phloem** are known as tracheophytes. **Pteridophytes** and **spermatophytes** are the tracheophytes. The alternative group is the atracheata, the **thallophytes** and **bryophytes,** which lack these special modified conducting cells. (R.M.W.)

TRACHOMEDUSAE. Hydrozoa.

TRACHYTE. The name of an **extrusive, igneous,** fine-grained or **porphyritic rock,** the surface equivalent of **syenite.** Trachyte is predominant in alkali **feldspar** and usually contains **biotite** and **augite.** Trachyte is an old name, proposed by Brongiart in 1813, and has never been altered or supplanted. It is derived from the Greek, meaning rough. (R.M.F.)

TRACING. Drawing Reproduction.

TRACK. The term track is used in **navigation** to describe the direction and distance a ship has moved in a given length of time. If a ship is known to be in a definite position at a given time and known to be in another position after the elapse of a definite period of time, then the direction of the **rhumb line** between the two points is the track and the length of the line gives the track distance. Other lines such as **Lambert, great circle,** etc., might be computed between the two points, yielding the Lambert track, etc., but the term track is usually restricted to the rhumb line. It should be carefully noted that the positions at the extremes of the track must be accurately known. These may be determined by any reliable **fix** or, in the case of airplanes, by landmarks beneath the ship. (See **Course** and **Heading.**) (W.K.C.)

TRACKING. In radio circuits this term is used to designate the following of two or more circuits tuned from the same shaft. Thus in the superheterodyne **receiver** the **oscillator** tuning must track with the **tuned radio frequency** circuits so the difference in frequency will always be the constant intermediate frequency.

In gunnery the term is used to designate the following of the target by the director or gun. (L.R.Q.)

TRACTION. In a narrow sense, traction refers to the **friction** developed between a powered surface and one in contact with it. The most common example of traction is the resistance to slipping developed at the point of contact of a driven wheel with the surface on which it rolls. The locomotive driver on its rail, the pneumatic tire on the highway, or the traction engine wheel on earth, illustrate this case. But traction is not confined to wheels, as may be proved by citing another example. The traction sheave of an elevator is a grooved pulley, power-driven, over which passes a rope which is driven by the sheave. The friction between the rope and pulley constitutes the traction.

In a larger sense, traction includes the act of pulling a load over a surface by overcoming the resistance to motion, and the word may also be used descriptively of any vehicle which by its excess of power over its own tractive needs is able to pull other vehicles. In the case of an automobile rolling on a highway, traction is applied through the rear wheels by means of a live axle which delivers a torque to the wheel. The load on the wheel presses it against the road surface enough to develop sufficient friction so that the resistance to motion will be overcome before the wheel slips on the road. If the roadbed be covered with a surface of low frictional power, for example, wet clay, there will be little traction developed because of the low coefficient of friction. The traction of an automobile must overcome wind resistance, wheel bearing friction, rolling resistance, and grade.

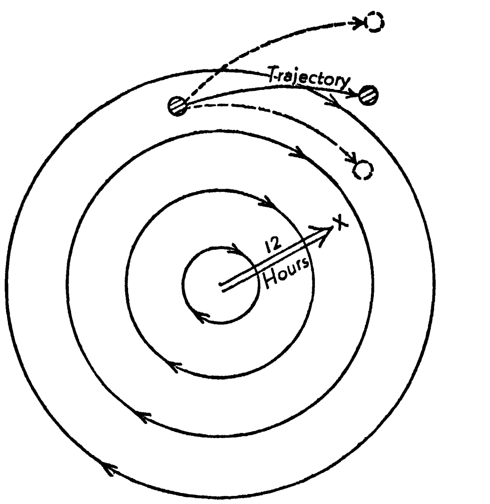
The railway train is drawn by the locomotive by means of traction developed between the drivers and the rail. The weight on the drivers, multiplied by the coefficient of friction of steel on steel is equal to the traction. In winter sand is sprinkled on icy rails in order to increase the coefficient of friction and so get more tractive power. The train resistance which traction must overcome is composed of the rolling resistance of wheels on rails, journal friction (static), air resistance, grade, and friction of wheel flanges on rails. The tractive efforts needed for starting a train are much higher than those required to keep it moving. While standing, oil is squeezed out of the bearing surfaces at the wheels, and metal to metal contact exists for the first few revolutions when the train has started. After the journal has revolved, oil is drawn into the surface between the journal and bearing, and a lower coefficient of friction results. Rolling resistance would be zero if the rail and wheels were perfectly inelastic, but rails deform slightly ahead of the wheels, making the reaction of the rail on the wheel inclined somewhat from the vertical in the direction of increased drag. (F.T.M.)

TRACTION STRESS. Stress.

TRADE WINDS. Air Circulation of the Atmosphere; Winds.

TRAGOPAN. Aves, Galliformes. A large game bird **(Aves)** found in wooded country at high altitudes in **China** and northern India. These birds are related to the pheasants and are known as horned pheasants and, improperly, as Argus pheasants. The last name belongs to a different group. The head bears a pair of fleshy projections, the horns, and the plumage of all of the several species **is** beautifully colored. (A.W.L.)

TRAJECTORY OF AIR PARCELS. A parcel of air located in a given pressure field will move with the gradient wind of the field (assuming steady flow). At the end of a few hours, the parcel will locate in some new region where it has been carried by the wind. If, however, the pressure field and therefore the wind is changing, the parcel will not move into a position indicated by the existing gradient flow. It will follow a



Trajectoıy of air parcels about anticyclone.

trajectory or path dictated by successive gradient directions and velocities as indicated by **synoptic charts.** An approximation to its trajectory can be had by extrapolating the parcel's indicated movement for as small a time interval as practicable (usually 3 or 6 hours between synoptic charts) using successive synoptic charts. The average of the velocity vectors at the beginning and the end of a given time interval would be taken as the true velocity and direction of the parcel over that time interval. Obviously, the smaller the time interval, the more accurate the trajectory. One of the charts may be a prognostic chart for computing future trajectories. Air trajectories are valuable in estimating the influence the earth will have on air as it flows over varied earth surfaces. (P.E.K.)

TRANSCENDENTAL EQUATIONS. A transcendental equation is an equation which is not an **algebraic equation**; it contains one or more **transcendental functions.**

Transcendental equations include as special types: **trigonometric equations, exponential equations, logarithmic equations,** etc. (L.L.S.)

TRANSCENDENTAL EQUATIONS, SOLUTION OF. **Transcendental equations** may be solved approximately by graphical methods, by successive interpolation, or by **Newton's method.**

One graphical method is to write the equation in the form of a single **function** equated to zero, plot the **graph** of this function and find the **abscissas** of the point or points of intersection of this graph with the X-axis; this gives only the real roots of the equation.

Another graphical method is to write the equation in the form of an equality of two appropriately chosen functions, construct the graphs of the two functions on the same diagram, and find the abscissas of their intersection points. (L.L.S.)

TRANSCENDENTAL FUNCTION. **A transcendental function is a function which is not an algebraic function.**

Among the transcendental functions are the following types: **trigonometric functions, inverse trigonometric functions, exponential functions, hyperbolic functions, logarithmic functions, gamma functions, beta functions, elliptic functions, Bessel functions,** etc. (L.L.S.)

TRANSCENDENTAL NUMBERS. A transcendental number is a **number** which is not an **algebraic number,** i.e., is not a root of a **polynomial equation** in one unknown with integral coefficients.

Two well-known transcendental numbers are $e \approx 2.71828$ and $\pi \approx 3.14159$. (L.L.S.)

TRANSFER OF SKILLS. **Measurement.**

TRANSFORMATION OF COORDINATES. In **rectangular coordinates in the plane,** the transformations of coordinates are: translation of axes and rotation of axes.

If a set of rectangular axes are moved from a first position OX, OY to a new position $O'X'$ and $O'Y'$ such that $O'X'$ and $O'Y'$ are respectively parallel to OX and OY, the axes are said to be translated from the first to the second position.

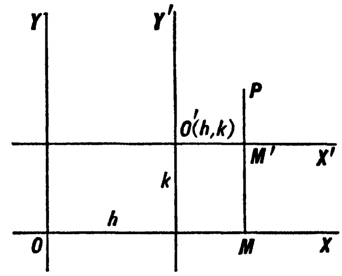


Fig. 1.

If the axes are translated to a new origin $O'(h,k)$, then (Fig. 1) the old coordinates are given in terms of the new by the formulae:

$$x = x' + h, \quad y = y' + k.$$

If a set of rectangular axes are rotated about the origin through an angle θ, the old coordinates in terms of the new are given by (Fig. 2)

$$\begin{cases} x = x' \cos\theta - y' \sin\theta, \\ y = x' \sin\theta + y' \cos\theta. \end{cases}$$

In **rectangular coordinates in space,** we have also translation of axes and rotation of axes.

If the origin is translated to a new origin $O'(h, k, l)$, the equations for the old coordinates in terms of the new are:

$$x = x' + h, \quad y = y' + k, \quad z = z' + l.$$

If $(\alpha_1, \beta_1, \gamma_1)$, $(\alpha_2, \beta_2, \gamma_2)$, $(\alpha_3, \beta_3, \gamma_3)$ are respectively the **direction angles** of three mutually perpendicular axes OX', OY', OZ' with respect to a given set of per-

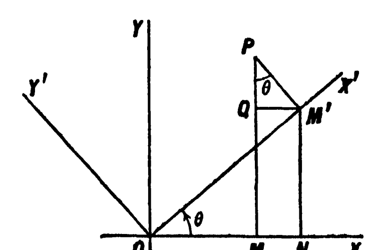

Fig. 2.

pendicular axes OX, OY, OZ, then the equations for rotating the old axes into the new position $O - X'Y'Z'$ are:

$$x = x' \cos \alpha_1 + y' \cos \alpha_2 + z' \cos \alpha_3,$$
$$y = x' \cos \beta_1 + y' \cos \beta_2 + z' \cos \beta_3,$$
$$z = x' \cos \gamma_1 + y' \cos \gamma_2 + z' \cos \gamma_3.$$

These nine **direction cosines** satisfy the following six equations:

$$\cos^2 \alpha_1 + \cos^2 \beta_1 + \cos^2 \gamma_1 = 1,$$
$$\cos \alpha_1 \cos \alpha_2 + \cos \beta_1 \cos \beta_2 + \cos \gamma_1 \cos \gamma_2 = 0,$$
$$\cos^2 \alpha_2 + \cos^2 \beta_2 + \cos^2 \gamma_2 = 1,$$
$$\cos \alpha_2 \cos \alpha_3 + \cos \beta_2 \cos \beta_3 + \cos \gamma_2 \cos \gamma_3 = 0,$$
$$\cos^2 \alpha_3 + \cos^2 \beta_3 + \cos^2 \gamma_3 = 1,$$
$$\cos \alpha_3 \cos \alpha_1 + \cos \beta_3 \cos \beta_1 + \cos \gamma_3 \cos \gamma_1 = 0.$$

(L.L.S.)

TRANSFORMATIONS OF POLYNOMIAL EQUATIONS. To transform a **polynomial equation** of the n^{th} degree into an equation each of whose **roots** is m times the corresponding root of the original equation, we multiply the successive coefficients of the equation, beginning with that of the next to the highest degree term, by $m, m^2, \cdots, m^n$. If the given equation is

$$a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n = 0,$$

the new equation will be

$$a_0x^n + ma_1x^{n-1} + m^2a_2x^{n-2} + \cdots + m^{n-1}a_{n-1}x + m^na_n = 0.$$

If any power of the variable below the highest is missing, it must be written with a zero coefficient.

To transform a polynomial equation into one whose roots are changed in sign from those of the original, we change the signs of the coefficients of the odd powers of the variable in the equation.

To transform a polynomial equation of the n^{th} degree

$$P(x) \equiv a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n = 0$$

into an equation each of whose roots is less by h than a corresponding root of the given equation, we proceed as follows: Divide the polynomial $P(x)$ by $x - h$ synthetically and denote the remainder by R_n; divide the quotient by $x - h$ and denote the remainder by R_{n-1}; etc.; continuing this process n times, obtaining a_0 as the last quotient and R_1 as the last remainder. Then the coefficient a_0 and the remainders $R_1, R_2, \cdots, R_n$, in order, are the coefficients of the transformed equation, which is therefore

$$a_0x^n + R_1x^{n-1} + R_2x^{n-2} + \cdots + R_{n-1}x + R_n = 0.$$

The divisions should be performed synthetically. (L.L.S.)

TRANSFORMER. Without doubt, adoption of a.c. in favor of d.c. by the growing electric industry was due as much to the ease and efficiency with which power could be transferred from low to high potential, and vice versa, as to the advantages of **alternators** over d-c **generators.** The power transformer is used to increase alternator voltage to economical transmission voltage or to decrease alternator or line voltage for station power service. It can be defined as a device for transferring electric energy from a circuit to another by magnetic induction, usually with a change of voltage. There are no moving parts, nor is there any electrical connection of the two circuits (except in the case of the auto-transformer); the energy is transferred through magnetic linkage. Regardless of the voltage, the energy supply circuit is termed the primary, and the energy receiving circuit the secondary.

Transformers may be classed as follows:

1. According to purpose.
   a. Constant voltage ratio.
   b. Constant current.
   c. Feeder voltage regulation.
2. According to use.
   a. Heavy duty. Power type as used in substations.
   b. Distribution. At customer end of the distribution system.
   c. Instrument. Potential and current transformers of small capacity and light weight, but having accurate ratios.
3. According to arrangement of magnetic circuit.
   a. Shell type. Large, low-voltage units.
   b. Core type. Small, high-voltage units.
4. According to arrangement of electric circuit.
   a. Single- or three-phase. Small transformers are often three-phase, but large capacity is met by the three-phase connection of three single-phase transformers.
   b. Connection of three-phase windings. Δ to Δ, Δ to Y, Y to Y, open Δ.
5. According to cooling.
   a. Air-cooled.
   b. Oil-filled. Oil-cooled by direct radiation or by heat transfer to separate water-cooling system.
   c. Pyranol-filled.

The ordinary single-phase transformer consists of the magnetic circuit, the windings, the leads, the insulating bushings (solid dielectric, condenser, or oil-filled types),

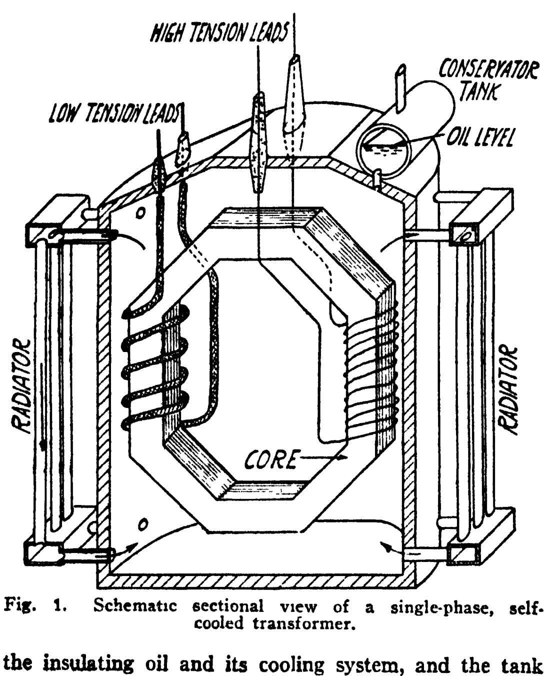

Fig. 1. Schematic sectional view of a single-phase, self-cooled transformer.

the insulating oil and its cooling system, and the tank to contain the oil and provide support for the other components. The auto-transformer is a modification of this, having only one winding which is tapped to give a low voltage. Reference to Fig. 2 will indicate that power can flow from primary to secondary by conduction. However, the two parts are also linked by the magnetic flux, thus allowing transformer action also. The use of part of the winding for both primary and secondary, and the fact that all of the power is not transformed makes the auto-transformer more efficient and cheaper than the conventional type. It is, however, not suitable for many applications because of the

direct connection between the high- and low-voltage sides. This, together with the fact that its advantage decreases with increased voltage ratio, gives it a very limited use.

In an ideal transformer the voltage ratio is the same as the turn ratio. Except for transformer losses, $N_1I_1 = N_2I_2$, in which N is number of turns and I is effective current. Due to the excellent efficiency of transformers, especially in the larger sizes (where the efficiency is 99% or better), the ratio E_1/E_2 of voltage is very nearly N_1/N_2. The losses which occur in a transformer are iron losses and copper losses. The iron losses are nearly constant and are present as long as the transformer is connected to the supply circuit. Transformer regulation is much superior to alternator, rarely exceeding 5%. A transformer is rated at its maximum continuous kva., on the secondary side, as limited by heating.

When single-phase transformers are operated alone there is no obstacle to correct connections. When single-phase or polyphase operate in parallel, or when three single-phase transformers are connected into a three-phase bank, the terminals must be joined correctly on the basis of polarity. The standard marking for polarity is an H_1 on the primary lead and an X_1 on the secondary. When the current is flowing towards the transformer in the H_1 lead it will be flowing away from it in X_1. A few typical connections for transformers are shown in Fig. 2. Transformers which are operated in parallel should have equal ratios of transformation, equal impedances, and have their terminals connected in accordance with the polarity markings. (See **Parallel Operation.**)

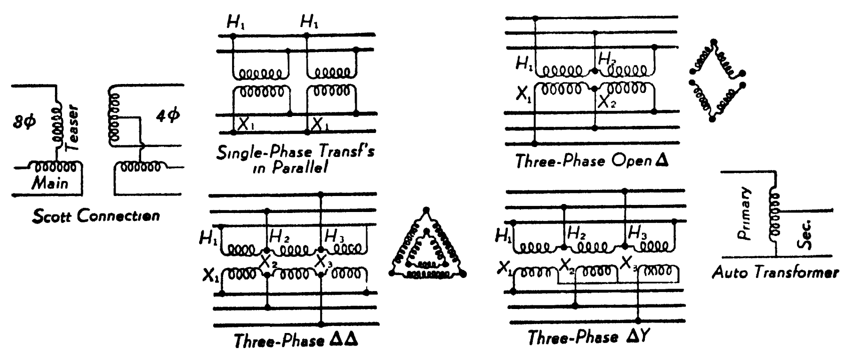

Fig. 2. Typical transformer connections.

The losses in a transformer appear as heat which should be carried away from the windings as soon as possible. At present transformer windings are cooled either by oil, by air, or special non-inflammable insulating liquids such as pyranol.

Most power transformers (instrument transformers excepted) are oil-insulated and of the self-cooled type. If the oil is kept in good condition the solid insulation of the windings will usually remain likewise. In addition to its insulating qualities, the oil should have low viscosity and high coefficient of expansion for good circulation. The expansion of the oil, while essential to good circulation, has a disadvantage in that air is exhaled or inhaled due to the total increase or decrease of oil volume in the tank. This phenomenon, called "breathing," is the principal source of water and sludge in the oil. Water comes from the condensation of atmospheric moisture "breathed" into the tank; sludge, from the oxidation of the surface of the oil. A conservator tank is used on some transformers to expose the minimum of oil surface to the air.

Small current and potential transformers may be divided into two classes, i.e., tripping transformers and instrument transformers. The former are used primarily with relays and trip coils of switching equipment; the latter with measuring instruments. Small transformers are of importance because their applications in the central station are exceedingly numerous. They are used for two very good reasons: to protect station operators from contact with high voltage and to permit the use of trip coils, instruments, etc., of moderate current and voltage capacity. Through the use of small transformers low-voltage circuits can be obtained which reflect the characteristics of high-voltage ones to a practical degree of accuracy. (F.T.M., L.R.Q.)

TRANSFUSION. Transfer of blood or plasma from one person to another, usually by intravenous drip through a sterile rubber tube connected with a needle placed in a vein. The person from whom the blood is taken is known as the donor. The patient receiving the blood is the recipient. Both the donor and recipient must be of the same **blood group** and, furthermore, must be tested to make sure that the two bloods will be compatible. In emergencies when there is no time for grouping, a donor of the universal type (Group I, Jansky. Group IV, Moss. Group O, International) may be used, although this is not desirable. If plasma is used, no typing or cross matching is necessary since the antigens have been removed with the red cells.

At present, transfusions are used in many conditions while formerly they were used only as a measure of last resort. After any severe hemorrhage, transfusion may be life-saving. In **anemia**, in the course of severe infections, preoperatively to prepare a patient for operation, post-operatively if blood loss has been great, and in many other conditions transfusions are a very important therapeutic measure.

There are many methods of transfusion. Since blood banks have become a part of most hospitals, the so-called indirect method has come to be used almost exclusively. With this technique, the total amount of blood to be given is withdrawn from the donor at one time into a suitable container containing sodium **citrate** which prevents clotting. The blood is then typed, cultured, Wassermann tested, and stored at 0° C. It may be kept so for as long as one week before being strained and given to a recipient of the same type. Great care is necessary in the handling and typing of blood, for serious and even fatal transfusion reactions can occur due to contaminated or incompatible blood. (See **Blood Groups.**) (D.M.H., R.S.M.)

TRANSIENT CURRENTS. Transients.

TRANSIENTS. Everyone has noticed that when an electric heater is turned on or off, the light from lamps on the same or closely connected circuits gives a slight flicker, and, if a radio receiver is operating at the time, it produces an audible click. A lightning flash or the sudden readjustment of connections in a transmission line may produce a similar "surge" of current. This is due to the fact that when the current in any part of a net-

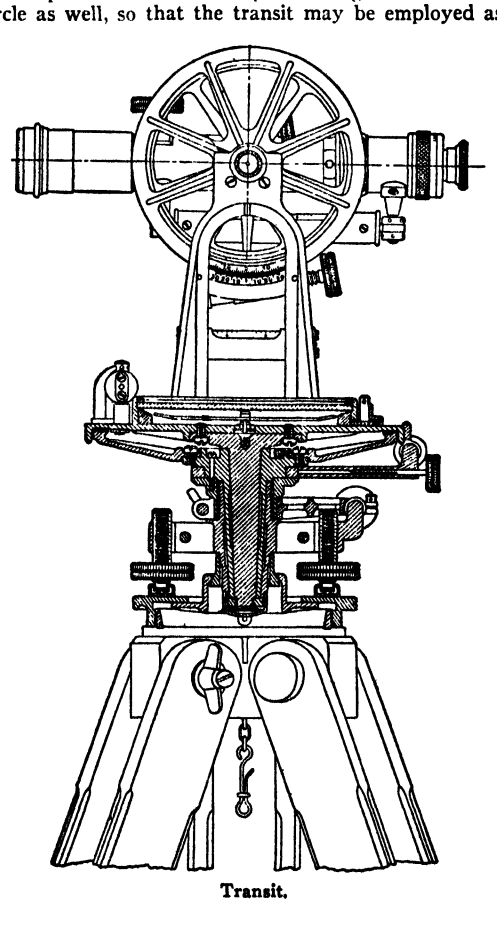
work changes, because of a change in the resistance of that part or the electromotive force operative in it, there is a readjustment of the potential differences and currents in the other parts. (See **Kirchhoff's Laws of Networks.**) Such readjustments take place very quickly, and the corresponding momentary fluctuations of current are called transients.

Mathematically, the general expression for the current in any circuit as a function of the time contains terms which rapidly become negligible; these are the transient terms. A very common and comparatively simple example is found in the case of an unbranched circuit having resistance R, inductance L, and series capacitance C, to which is suddenly applied an alternating electromotive force of low frequency n and maximum voltage E_0. If the switch is closed at a voltage maximum, the voltage at any time t (sec.) thereafter is $E_0 \cos 2\pi nt$, and the current is given by the equation

$$I = \frac{E_0}{\sqrt{R^2 + \left(2\pi nL - \frac{1}{2\pi nC}\right)^2}} \cos (2\pi nt + \Delta) + k_1 e^{m_1 t} + k_2 e^{m_2 t}$$

where Δ is the phase difference between electromotive force and current. (See **Alternating Currents.**) In the last two terms, k_1, k_2, m_1, and m_2 are constants depending upon the circuit characteristics R, L, and C. The quantities m_1 and m_2 are both negative; as a result, these exponential terms "decay" or fade away after a few cycles. Only the first term is therefore usually written. (L.D.W.)

TRANSIT. The transit is an instrument used by engineers and surveyors for measuring horizontal angles. Modern transits are usually equipped with a level attached parallel to the telescope, and a graduated vertical circle as well, so that the transit may be employed as a level, and may also be used to read vertical angles. It may also be equipped with **stadia** wires. An exceptionally accurate transit of the type used for precise surveying is known as a theodolite. A transit is constructed largely of metal, and is mounted upon a wooden tripod. A tripod plate (foot plate) is screwed to a tripod head provided on the tripod. This tripod plate contains the socket of a ball and socket joint, and has a smooth surface upon which leveling screws may rest. The base of the instrument is carried on a vertical conical shaft which turns in a socket, on the lower end of which is a ball which is a part of the ball and socket joint just mentioned. The conical socket carries also projections into which the leveling screws are threaded. By operating these leveling screws, the shaft may be accurately aligned in vertical position. The shaft carries at its top a horizontal plate on which are mounted at right angles two levels which are used by the instrument man to guide and operate the leveling screws, so that the plate may be horizontal, and the shaft vertical. A compass is also mounted on this plate. The telescope is mounted on horizontal trunnions which are supported on standards attached to the above mentioned plate (limb). The telescopes are usually erecting, although many favor the inverting telescope. The motion of the telescope around the vertical axis can be accomplished by loosening clamping screws and swinging it at will until it is brought to sight on the desired object. It can then be clamped, and small additional motions obtained by the use of a **vernier** adjustment. The horizontal plate is usually graduated to ½° and the vernier permits readings to single minutes of arc. (F.T.M.)



Transit.

TRANSIT LINE. Station.

TRANSIT OF VENUS OR MERCURY. Both **Venus** and **Mercury** revolve about the **sun** in **orbits** which lie inside of the orbit of the **earth** about the sun. Accordingly, if the planes of the planetary orbits coincided with the plane of the ecliptic, once during the **synodic** period of each planet the object should pass between the earth and the sun. Because of the small angular diameter of the planets relative to that of the sun, at the time they pass between the earth and sun they appear as small black spots moving across the brilliant disk of the sun. Such a phenomenon is known as a transit of Venus or a transit of Mercury.

The orbits of both Mercury and Venus are inclined to the plane of the ecliptic with the result that transits do not occur during each synodic period, but only when the planet happens to come to inferior conjunction close to the passage through a **node.** Transits of Mercury can occur only in May and November, when the earth crosses Mercury's line of nodes; those of Venus occur only in June and December. Since Mercury is closer to the sun than Venus, transits of Mercury are more common than those of Venus. The last transit of Venus came in 1882 and the next will take place in 2004.

The first recorded observation of a transit of Venus was made in England in 1639 by Horrocks. Four transits have been observed since that time. Since observations of the duration of transit of the planet across the disk of the sun made from widely separated positions on the earth provide a method for determination of the important astronomical constant known as **solar parallax,** expeditions were always dispatched to observe the phenomena. Within recent years more accurate methods for determination of solar parallax have been devised, and henceforth, transits of planets across the sun will be of value only for the purpose of obtaining accurate positions of the objects and thus improving the orbital elements. (W.K.G.)

TRANSIT STATION. Station.

TRANSIT SURVEY. Surveying.

TRANSLOCATION. This is the term most commonly used to designate the movement of solutes from one part of a plant to another. The principal conductive tissues in plants are the xylem and the phloem (see **Stems**) which constitute continuous tissue systems from just back of the tip of every root into all parts of every leaf and other lateral organs. One of the most important types of translocation in plants is the downward movement of the carbohydrates made in the leaves into the other parts of the plant. This movement occurs in the phloem and, in woody plants, only in the youngest layers of phloem. In tall trees and some vines the carbohydrates which reach the root tips may have moved hundreds of feet through the continuous phloem from the leaves in which they were made. Most of the translocation of solutes through the phloem occurs in the sieve tubes. The exact mechanism of downward movement of solutes is not known. The rate of movement is in some cases so great that it appears likely that the metabolic activity of the cells operates in some manner to speed up movements of the solute molecules.

Under some conditions considerable upward movement of carbohydrates and other soluble foods occurs in plants. This type of translocation also occurs in the phloem. The new shoots formed on woody plants when the buds resume growth in the spring are largely made at first from foods which move in an upward direction through the stems from the older existing stems. A similar upward translocation of foods occurs in the phloem towards the aerial portions of young seedlings from the seeds, towards fruits or flowers which are located at a terminal position on stems, and during the early stages of the development of leaves or shoots from bulbs, corms, tubers, or other underground organs. It is not known with certainty whether solutes can move simultaneously in both directions through the phloem, or whether they can only move in an upward direction under certain conditions, and in a downward direction under other conditions.

The mineral salts absorbed by the roots are moved mostly, and perhaps entirely, in an upward direction through the xylem. A large proportion of the mineral salts are translocated to the leaves and hence may be moved in some plants for distances of several hundreds of feet. The dissolved mineral salts are present in relatively low concentration in the water in the xylem conduits and appear to be passively carried through the plant in an upward direction in the ascending columns of water (see **Ascent of Sap**). Once translocated into a leaf the mineral salts do not necessarily remain there permanently. Some of them may subsequently be translocated out of the leaf in essentially the same form in which they enter it. Others may be used in the synthesis of complex compounds and subsequently be re-translocated out of the leaf in the form of such compounds. Shortly before the abscission of leaves or floral parts, for example, a considerable proportion of the nitrogen, phosphorus, potassium, sulfur, and magnesium are translocated back into the stems in one form or another. On the other hand there seems to be little or no such reverse translocation from the leaves of such elements as calcium, iron, boron, or manganese. All movement of minerals out of the leaves into other parts of the plant appears to occur in the phloem. It is possible that there may be a periodic daily circulation of at least some of the mineral elements in plants. There are indications, for example, that mobile phosphorus compounds can move from the root to the leaf through the xylem and return from the leaf to the root in the phloem within a 24-hour period. (B.S.M.)

TRANSMISSION LINE. Electric Power Transmission.

TRANSMITTER. In telephony the transmitter is the microphone, universally a single-button carbon type. The radio transmitter is the complete group of equipment utilized in converting the incoming audio-frequency signal from the studio into the modulated radio frequency signal fed to the antenna. The usage varies somewhat and may mean just the modulators and radio frequency stages or it may mean all the audio as well as radio-frequency stages. For **radio telegraphy** the transmitter consists of the **oscillator,** various radio frequency **amplifiers** and the **power supply** with necessary operating auxiliaries such as **keying** circuits. For radio telephony the transmitter consists of the same essential components as for telegraphy plus the necessary audio equipment and modulators. (See **Radio Communication** and **Radio Telegraphy.**) (L.R.Q.)

TRANSPIRATION. All plants require water for their continued existence and most kinds of plants require it in considerable quantities. In spite of the absolute indispensability of water for their growth and metabolism plants in general are very inefficient in their use of water. An overwhelmingly large proportion of the water absorbed by most kinds of terrestrial plants escapes from them as water vapor. This process of the loss of water vapor from plants is called *transpiration.* Although some water vapor loss may occur from any organ of a plant which is exposed to the atmosphere, in the vast majority of plants most transpirational water loss occurs from the leaves. There are two kinds of foliar transpiration: 1. Stomatal transpiration in which water vapor loss occurs through the **stomates.** 2. Cuticular transpiration, in which evaporation of water takes place directly through the surface of the epidermal cells through the cuticular layer into the atmosphere. In most species stomatal transpiration represents 90% or more of the total foliar transpiration.

Stomatal transpiration involves the two physical processes of evaporation and diffusion. Evaporation of water takes place from the moist cell wall surfaces into the air-filled intercellular spaces between the mesophyll cells. If the stomates are closed this soon results in the saturation of the intercellular spaces with water vapor. If, however, the stomates are open, diffusion of water vapor takes place through them into the outside atmosphere except when the vapor pressure of the surrounding atmosphere is equal to that of the intercellular spaces. This latter condition rarely prevails, however, during the daylight hours of clear days when the stomates are most likely to be open. The rate of transpiration of a given plant varies greatly according to the environmental conditions to which it is subjected. The rate of transpiration of most plants is relatively low during the night hours because the stomates are usually closed during that period. During daylight periods when the stomates are open the rate increases, in general, with rise of air temperature or with decrease in atmospheric vapor pressure. Transpiration rates are usually greater in a breeze than in quiet air, but a gentle breeze is almost as effective as a strong wind in its influence on this process. Soil conditions are often even more important in influencing the rate of transpiration than atmospheric conditions. Whenever soil conditions are such that the rate of absorption of water is retarded the rate of transpiration is correspondingly reduced. During droughts, for example, transpiration rates are low or negligible no matter how favorable the atmospheric and light conditions may be to high transpiration rates.

Because of the occurrence of transpiration certain precautions must be taken when plants are transplanted. When plants are dug many of the roots are usually damaged or broken off. This results in a reduced rate of absorption of water. Hence it is always desirable and often imperative to reduce the transpiration rate

of the plant by removing leaves, pruning, or covering the plant in some suitable manner. Newly transplanted plants should also be copiously watered. Gradual development of new roots on the transplanted plants sooner or later permits sufficient absorption of water to compensate for normal transpirational water loss.

Transpiration is not an essential plant process but a necessary consequence of the structure of plants. The structure of green terrestrial plants must be such that carbon dioxide gas will have access to moist cell wall surfaces in which it can dissolve (see **Photosynthesis**). The principal carbon dioxide absorbing surfaces of vascular land plants are the mesophyll cell walls bounding the intercellular spaces of the leaves. Most carbon dioxide diffuses into the leaves through the open stomates. When the stomates are open, outward diffusion of water vapor is unavoidable and most of the water lost from plants escapes in this way. Some of the incidental effects of transpiration upon the plant are beneficial but none is indispensable. Likewise some of the incidental effects of the process are detrimental to plants but plants have existed through countless centuries in spite of transpiration.

Rates of transpiration rarely, if ever, exceed 5 grams per sq. decimeter of leaf surface per hour and are usually considerably less. Under drought conditions the rate of transpiration may fall to an almost zero value. Only approximate computations can be made of the loss of water from vegetation covered areas but considerable interest from the standpoint of water conservation and meteorology attaches to such figures. It has been calculated, for example, that an acre of corn in central Illinois transpires water equivalent to 15 acre-inches in the course of a growing season. The corresponding figure for an acre of young apple orchard in central New York is 9 acre-inches. (See also **Guttation**.) (B.S.M.)

TRANSPOSITION. Inductive Interference.

TRANSVERSE LOAD. Load.

TRAP. A general term for fine-grained, **basic** and therefore dark-colored **igneous** rocks, having a relatively high specific gravity. The term is derived from an old Scandinavian word meaning a stair, because these rocks, as particularly well displayed in the 3000-ft. cliffs of the Faroe Islands, develop architectural forms simulating colossal stairways. The term is also used as a synonym for **basalt**, especially by contractors who use it for road metal. (Compare with **Whinstone**.) (R.M.F.)

TRAUMA. Any injury to the body caused by an outside physical force such as a fall, blow, or weapon, etc. Traumatic surgery is surgery that deals with injuries, and is usually of an emergency nature. (R.S.M.)

TRAVERSE. A traverse is a series of connected straight lines, forming the outline of a plot of land or the center line of a roadway or railway. A traverse which forms a closed figure is a closed traverse. A traverse which is not closed is an open traverse. The traverse is obtained by means of a survey. Ordinarily, the **transit** and tape are used, the transit being successively set up over each point constituting the junction of two adjacent lines. The distances between transit stations (the length of the straight lines) are measured by taping with a graduated tape or **chain**. The **bearings** of the lines or the angles between the lines, as well as the length of the lines, are noted by the instrument man at the time of the survey in a field book. These field notes are later employed to map the traverse by one of the several methods available, such as **tangent offsets, latitudes and departures**, coordinates, etc.

A traverse which follows the shore line of a body of water is a meander line. The general outline of the shore is found by taking offsets from the transit lines at regular intervals and also at points where there is an abrupt change of shape.

In navigation, the term traverse or traverse sailing is sometimes used to determine, by **dead-reckoning** methods, the course and distance made good by a ship, when the ship has been on several different headings in the time interval involved. Cases of this sort commonly arise in determining the day's run from noon to noon. An example of traverse sailing is discussed in detail in the article on dead reckoning. (F.T.M., C.W.C., W.K.G.)

TRAVERSE TABLES. In many problems in surveying and navigation (e.g., the important navigational problem of **dead reckoning**) the solution of a plane right-triangle becomes necessary. In traverse tables the plane right-triangle is solved without the necessity of using tables of **trigonometric functions**. The tables are constructed by tabulating for successive values of one apex angle the two sides of the triangle as functions of the hypotenuse. The traverse tables as published for navigational purposes solve the dead-reckoning problem by tabulating difference of **latitude** and **departure** as functions of the distance for each course either in quarter points of the compass or every degree. Since the tables must contain pages for each value of the apex angle they are more bulky than ordinary trigonometric tables. However, the rapidity with which the plane triangle may be completely solved more than compensates for the time lost in turning pages, particularly when extreme accuracy is not required in the solution. (W.K.G.)

TRAVERTINE. Carbonated waters dissolve large amounts of **calcium** carbonate, especially under high temperature. Such waters reaching the earth's surface as hot springs often deposit the calcium carbonate, in great quantities. This material is called travertine from the ancient name for Tivoli, Italy, where a very thick deposit occurs. Travertine may be compact, crystalline, fibrous or, if rapidly deposited, spongy and porous. The less compact varieties are known as tufa. Travertine is being formed at the Mammoth Hot Springs, Yellowstone National Park and at many other localities. A banded travertine used as an ornamental stone is called **onyx marble** or Mexican onyx. (R.M.F.)

TREE HOPPER. Insecta, Homoptera. An **insect** of moderate size with a peculiarly formed **thorax**, prolonged over the hinder part of the body and in many species with other projections of bizarre form. These insects make up the family Membracidae, related to the **leaf hoppers** and spittle bugs.

The buffalo tree hopper, *Ceresa bubalus*, sometimes damages twigs of fruit trees by laying eggs in the bark and is occasionally troublesome in the garden through sucking the juices of young seedlings. Clean cultivation is an effective control. (A.W.L.)

TREE OF HEAVEN. Ailanthus.

TREE OF LIFE. Phylogenetic tree. A diagrammatic scheme for showing the probable evolutionary relationship of the various kinds of organisms. Arising from primordial living matter and now found at their simplest in the 1-celled forms, all forms of plants and animals may be traced through graded relations to their present condition. (A.W.L.)

TREE SHREW. Mammalia, Insectivora. *Tupaia*. Small arboreal animals of the Oriental region. They resemble squirrels closely in general form and in the long tail but the muzzle is long and sharp as in other **shrews**. One species is remarkable for the feather-like form of the tip of the tail, which is elsewhere clothed with short hair. The group is interesting chiefly because it has been

regarded by one school of thought as probably ancestral to the primate stock. (A.W.L.)

TREE TOAD, TREE FROG. Amphibia, Anura. Small animals like the other **frogs** and **toads** in form but largely of arboreal habits. The toes are provided with adhesive disks at the tips. The spring peeper and the cricket frog, each about an inch in length, are well known North American species. Our tree frogs deposit their eggs in the water but in some species the larval stage is passed in the egg, which is attached to a leaf. The extensive family Hylidae includes tree frogs of every continent. Species of another family occur in Madagascar and South America. (A.W.L.)

TREE-CREEPER. Aves, Passeriformes. A small dull-colored bird (**Aves**) with a long curved beak. It seeks its prey, consisting of insects and other small creatures, in the crevices of bark, moving about the trunks and branches of trees in any position. The group is represented in North America by the brown creeper, *Certhia familiaris,* and its several subspecies. (A.W.L.)

TREE-FERNS. Paleobotany.

TREE-PIE. Aves, Passeriformes. A bird (**Aves**) of the Oriental region related to the magpies. The colors of these birds are shades of brown, black, and gray and their beaks are relatively short, but in habits they resemble the magpies. (A.W.L.)

TRELLIS DRAINAGE. The type of drainage pattern which is similar to a trellis or fireman's ladder. Trellis drainage is characteristic of the canoe-shaped valleys of the Appalachians. (R.M.F.)

TREMATASPIS. Fossil Fishes.

TREMATODA. The flukes, a class of flatworms (Phylum **Platyhelminthes**). They are very variable in size, are flattened or rounded in cross-section, and are exclusively parasitic. Flukes resemble the free-living flatworms (Turbellaria) more closely than tapeworms, but in addition to their parasitic habits they differ in having the mouth usually near the anterior end of the body and the intestine usually forked and sometimes provided with anal openings. The body is covered with a **cuticle** and bears suckers and in some species hooks or spines by which the worm attaches itself to the host.

Many flukes hatch from the egg as free-swimming **larvae** and pass through a life cycle in two or more hosts before attaining maturity. The passage from host to host is made with the changes in the metamorphic cycle.

Some flukes attach themselves to the gills or skin of fishes while others live in the internal organs of various animals. Man is affected by four types, the liver, lung, blood, and intestinal flukes, found chiefly in tropical and Oriental countries. Since some of these parasites pass some stages of their **metamorphosis** in fishes, the eating of uncooked or imperfectly cooked fish is dangerous in regions where they occur.

The class is divided into two subclasses and five orders:

Subclass Monogena. External parasites with a single host.
- Order Monopisthodiscinea. Small species on the skin and gills of fishes. Body without suckers but with a posterior disk bearing hooks.
- Order Monopisthocotylinea. With or without anterior suckers. No oral sucker. Posterior end with a sucking disk, usually bearing hooks. Parasitic on marine fishes.
- Order Polyopisthocotylinea. Posterior lobe with at least two suckers. On gills and in mouths of fishes, and on skin or in bladder of amphibians and reptiles.

Subclass Digena. Internal parasites with two or more hosts. With one or two suckers.
- Order Gasterostomata. Mouth at the middle of the body. Parasitic in fishes and marine mollusks.
- Order Prosostomata. Mouth at the anterior end. A large order. Many species, attacking many invertebrate and vertebrate hosts. (A.W.L.)

TREMOLITE. The mineral tremolite is a **calcium-magnesium silicate** corresponding to the formula $H_2Ca_2Mg_5(SiO_3)_8$ belonging to the **amphibole** group. The replacement of magnesium by ferrous **iron** causes tremolite to approach **actinolite** in composition. Tremolite is **monoclinic**, developing bladed prismatic crystals, but it is frequently found in compact columnar, granular, or fibrous masses. The perfect prismatic cleavage at angles of 56° and 124° typical of this group is to be noted; hardness, 5–6; specific gravity, 2.9–3.1; luster, vitreous to silky; color, varies from white or whitish-gray through shades of green or greenish-yellow; transparent to opaque. Tremolite is formed as a result of contact **metamorphism** and occurs in **marbles, dolomites,** and **schists.** It may alter to **talc.** Tremolite is found in Switzerland, in the St. Gotthard region, being named for the Tremola Valley, and is common elsewhere in Europe. In the United States it occurs in Maine, Pennsylvania, and New York. In Canada tremolite has been found in Quebec and Ontario.

Hexagonite is a pinkish-purple variety of tremolite which contains a small amount of manganese. So called because it was at first believed to be **hexagonal.** It has been since shown to be monoclinic, and is found in St. Lawrence County, New York. Some nephrite and asbestos is tremolite. (E.S.C.S.)

TRENCH MOUTH. Stomatitis.

TREPAN. Trephine.

TREPANG. Holothuroidea.

TREPANNING. Originating a hole by removing an annular ring of material, instead of reducing to chip form the entire volume of the material originally within the hole. Contrast **boring, drilling.** (H.C.H.)

TREPHINE. 1. A hollow, circular, saw-tooth, drill-like instrument that is used for removing a disk of bone from the skull. This opening may then be enlarged or several of these drill holes may be made or connected so as to raise a piece of bone to expose a portion of the brain. 2. To open the skull with a trephine. The skull is usually operated upon for removal of an intracranial **tumor,** to relieve intracranial pressure, or to drain a brain abscess. (R.S.M., D.M.H.)

TRF. TUNED RADIO FREQUENCY. Receivers.

TRIANGLES. It is shown in **geometry** that the three sides and three angles of a plane triangle are so related that when any three parts, excluding the case of three angles, are given, the other three parts are determined, so that the triangle is fixed in shape and size. Geometry also gives methods for constructing the triangle by geometrical constructions with straightedge and compasses when three appropriate parts are given.

The process of finding the unknown parts of a triangle from a set of given parts is called the solution of the triangle.

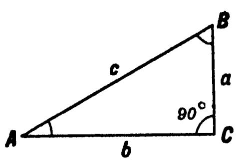
If the known parts of a triangle are given by their numerical values, we may draw the triangle to scale, carrying out the geometric constructions and measurements with a graduated ruler, compasses, and protractor, and then on the completed figure we may measure off the required parts with ruler and protractor, and obtain the numerical measures of these parts. This is called

the graphic solution of triangles. This method is limited in accuracy; however, many important practical problems in which only a moderate degree of accuracy is required can be readily solved by the graphic method; it is also of use as a check on the trigonometric solution of triangles.

The trigonometric solution of triangles is based on calculations with the use of formulae. This method is capable of any desired degree of accuracy.

To solve a right triangle, ABC:

Choose one of the formulae expressing the definition of one of the trigonometric functions of one of the acute angles of the triangle which involves an unknown part (side or angle) and two known parts, and solve for the unknown part.



We also use the geometric relations $A + B = 90°$, and the Pythagorean theorem $a^2 + b^2 = c^2$.

Every oblique triangle can be solved by means of the methods for solving right triangles, by division into two right triangles by drawing a perpendicular from one vertex to the opposite side or opposite side extended. Special formulae are also available for the solution of oblique triangles.

The law of sines is: Any two sides of a plane triangle are proportional to the sines of the opposite angles:

$$\frac{a}{b} = \frac{\sin A}{\sin B}, \quad \frac{b}{c} = \frac{\sin B}{\sin C}, \quad \frac{c}{a} = \frac{\sin C}{\sin A};$$

also

$$\frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C} = D,$$

where D is the diameter of the circumscribed circle of the given triangle.

The law of cosines is: The square of any side of a plane triangle is equal to the sum of the squares of the other two sides minus twice the product of these two sides and the cosine of their included angle:

$$a^2 = b^2 + c^2 - 2bc\cos A,$$

$$b^2 = c^2 + a^2 - 2ca\cos B,$$

$$c^2 = a^2 + b^2 - 2ab\cos C.$$

The law of tangents is: The tangent of half the difference of any two angles of a plane triangle is equal to the difference of the two opposite sides divided by their sum, multiplied by the cotangent of half their included angle:

$$\tan\frac{1}{2}(A - B) = \frac{a - b}{a + b}\cot\frac{1}{2}C,$$

$$\tan\frac{1}{2}(B - C) = \frac{b - c}{b + c}\cot\frac{1}{2}A,$$

$$\tan\frac{1}{2}(C - A) = \frac{c - a}{c + a}\cot\frac{1}{2}B.$$

The half-angle formulae for a plane triangle are:

$$\tan\frac{1}{2}A = \frac{r}{s - a}, \quad \tan\frac{1}{2}B = \frac{r}{s - b}, \quad \tan\frac{1}{2}C = \frac{r}{s - c},$$

where $s = \frac{1}{2}(a + b + c)$, and

$$r = \sqrt{\frac{(s - a)(s - b)(s - c)}{s}}.$$

The best formulae for use in checking the solution of an oblique triangle are the Mollweide's formulae:

$$\frac{a + b}{c} = \frac{\cos\frac{1}{2}(A - B)}{\sin\frac{1}{2}C},$$

$$\frac{a - b}{c} = \frac{\sin\frac{1}{2}(A - B)}{\cos\frac{1}{2}C},$$

and four others obtained by cyclic interchange of letters.

The fundamental formula for the area of a triangle is:

$$\text{area} = \tfrac{1}{2}\text{ base} \times \text{altitude}.$$

If the angles of the triangle are denoted by A, B, C and the opposite sides by a, b, c, then:

$$\text{area} = \sqrt{s(s - a)(s - b)(s - c)}, \text{ where } s = \tfrac{1}{2}(a + b + c);$$

$$\text{area} = \tfrac{1}{2}ab\sin C = \tfrac{1}{2}bc\sin A = \tfrac{1}{2}ca\sin B;$$

$$\text{area} = \frac{1}{2}a^2\frac{\sin B\sin C}{\sin(B + C)} = \frac{1}{2}b^2\frac{\sin A\sin C}{\sin(A + C)} = \frac{1}{2}c^2\frac{\sin A\sin B}{\sin(A + B)}.$$

In the solution of oblique triangles, four cases need to be distinguished:

I. Given one side and two angles, a, A, B.
II. Given two sides and an angle opposite one of them, as a, b, A.
III. Given two sides and the included angle, as a, b, C.
IV. Given the three sides, a, b, c.

All oblique triangles can be solved, by use of natural functions (i.e., the actual values of the trigonometric functions), by use of the law of sines, the law of cosines, and the angle formula $A + B + C = 180°$, as follows:

Case I, given a, A, B: Angle C may be found by the angle formula, then b and c may be found by use of the law of sines used twice.

Case II, given a, b, A: Angle B may be found by use of the law of sines, angle C from the angle formula, and c by the law of sines again.

Case III, given a, b, C: Side may be found by the law of cosines, and angles A and B from the law of sines used twice, or angle A by the law of sines and angle B from the angle formula.

Case IV, given a, b, c: The angles may all be found by the law of cosines, or angle A from the law of cosines and angles B and C from the law of sines, or angle A from the law of cosines, angle B from the law of sines, and angle C from the angle formula.

In all cases, the solution may be checked by Mollweide's formulae.

Case II is called the ambiguous case, as there may be one solution, or two solutions, or no solution. Given a, b, A:

1. If $A < 90°$ and $a < b\sin A$, no solution.
2. If $A < 90°$ and $a = b\sin A$, one solution, a right triangle.
3. If $A < 90°$ and $b > a > b\sin A$, two solutions, oblique triangles.
4. If $A < 90°$ and $a \geqq b$, one solution, an oblique triangle.
5. If $A < 90°$ and $a \leqq b$, no solution.
6. If $A > 90°$ and $a > b$, one solution, an oblique triangle.

All oblique triangles can be solved, by the use of logarithms, with the law of sines, the law of tangents, the half-angle formulae, and the angle formula, as follows:

Case I, given a, A, B: Angle C is found from the angle formula, then the law of sines is used to find b, c.

Case II, given a, b, A: Use the law of sines to find angle B, the angle formula to find angle C, then the law of sines to find c.

Case III, given a, b, C: Use the law of tangents to find $\frac{1}{2}(A - B)$, from this and the angle formula find A and B, then use the law of sines to find c.

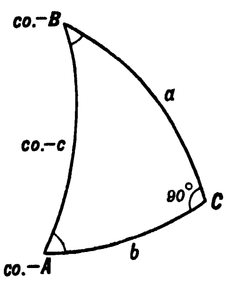
Case IV, given a, b, c: Use the half-angle formulae to find $\frac{1}{2}A$, $\frac{1}{2}B$, and $\frac{1}{2}C$.

Mollweide's check formulae are adapted to logarithmic calculation.

The solution of right spherical triangles is based on the following formulae (where C is the right angle):

$$\sin a = \sin A \cdot \sin c,$$
$$\sin a = \tan b \cdot \cot B,$$
$$\cos A = \cos a \cdot \sin B,$$
$$\cos A = \tan b \cdot \cot c,$$
$$\cos c = \cot A \cot B,$$
$$\sin b = \sin B \sin c,$$
$$\sin b = \tan a \cot A,$$
$$\cos B = \cos b \cdot \sin A,$$
$$\cos B = \tan a \cdot \cot c,$$
$$\cos c = \cos a \cdot \cos b.$$

Let the five values a, b, *co-A*, *co-B*, *co-c* (where *co-* means complement of) be arranged in order as indicated in the accompanying figure. Denote any one of these as a middle part, then two of the other parts are adjacent to it and the other two parts are opposite to it. The above ten formulae are summarized in the following rules, known as Napier's rules of circular parts:



Spherical triangle. (Napier's rules.)

1. The sine of a middle part is equal to the product of the tangents of the adjacent parts.
2. The sine of a middle part is equal to the product of the cosines of the opposite parts.

The solution of oblique spherical triangles is based on the following formulae:

$$\text{Law of sines: } \frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c}.$$

Law of cosines: $\cos a = \cos b \cos c + \sin b \sin c \cos A,$

$$\cos A = -\cos B \cos C + \sin B \sin C \cos a.$$

Half-angle and half-side formulae:

$$\tan \frac{1}{2} A = \sqrt{\frac{\sin (s - b) \sin (s - c)}{\sin s \sin (s - a)}}$$

where $s = \frac{1}{2}(a + b + c)$,

$$\tan \frac{1}{2} a = \sqrt{\frac{-\cos \sigma \cdot \cos (\sigma - A)}{\cos (\sigma - B) \cos (\sigma - C)}}$$

where $\sigma = \frac{1}{2}(A + B + C)$.

Napier's Analogies (Formulae):

$$\frac{\tan \frac{1}{2}(a - b)}{\tan \frac{1}{2}c} = \frac{\sin \frac{1}{2}(A - B)}{\sin \frac{1}{2}(A + B)},$$

$$\frac{\tan \frac{1}{2}(a + b)}{\tan \frac{1}{2}c} = \frac{\cos \frac{1}{2}(A - B)}{\cos \frac{1}{2}(A + B)},$$

$$\frac{\tan \frac{1}{2}(A - B)}{\cot \frac{1}{2}C} = \frac{\sin \frac{1}{2}(a - b)}{\sin \frac{1}{2}(a + b)},$$

$$\frac{\tan \frac{1}{2}(A + B)}{\cot \frac{1}{2}C} = \frac{\cos \frac{1}{2}(a - b)}{\cos \frac{1}{2}(a + b)}.$$

Delambre's Analogies:

$$\frac{\sin \frac{1}{2}(A - B)}{\cos \frac{1}{2}C} = \frac{\sin \frac{1}{2}(a - b)}{\sin \frac{1}{2}c},$$

$$\frac{\sin \frac{1}{2}(A + B)}{\cos \frac{1}{2}C} = \frac{\cos \frac{1}{2}(a - b)}{\cos \frac{1}{2}c},$$

$$\frac{\cos \frac{1}{2}(A - B)}{\sin \frac{1}{2}C} = \frac{\sin \frac{1}{2}(a + b)}{\sin \frac{1}{2}c},$$

$$\frac{\cos \frac{1}{2}(A + B)}{\sin \frac{1}{2}C} = \frac{\cos \frac{1}{2}(a + b)}{\cos \frac{1}{2}c}.$$

The area of a spherical triangle is given by the formula

$$\Delta = \frac{\pi R^2 E}{180},$$

where $E = A + B + C - 180°$ is the spherical excess of the triangle and R is the radius of the sphere, and E is also given by L'Huillier's formula:

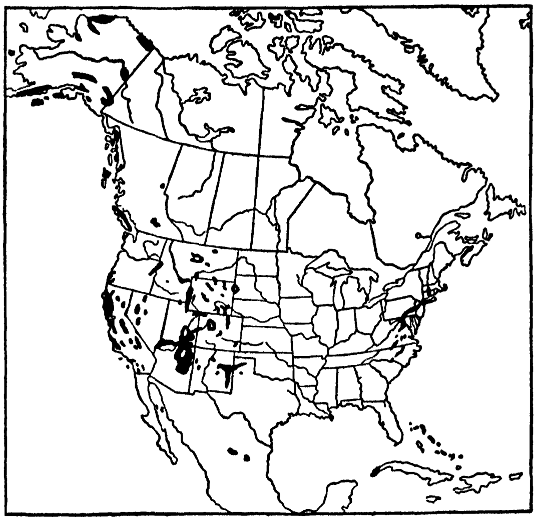
$$\tan \tfrac{1}{4}E = \sqrt{\tan \tfrac{1}{2}s \cdot \tan \tfrac{1}{2}(s - a) \cdot \tan \tfrac{1}{2}(s - b) \cdot \tan \tfrac{1}{2}(s - c)},$$

where $s = \frac{1}{2}(a + b + c)$. (L.L.S.)

TRIANGULATION. In surveying, the field work necessary to obtain the angular measurements between the sides of a series of connected triangles, and the length of one or more of the sides, is known as triangulation. The system of connected triangles is called a triangulation system. The topographic surveying of land requires the establishment of control points of known position and elevation. This control usually takes the form of a series of surveyed triangles, with the apices located on prominent points in the area, such as peaks, mounds, cliffs. In laying down a network of triangles, a fairly level region is selected on which to measure a straight **base line.** The transit is then set over one end of this base line, and the angles between pairs of selected control points taken. The transit is then taken to the other end of the base line, and the angles are again taken to the same points. By occupying, progressively, advancing triangulation points the network may be extended over as large an area as necessary. These angles are read to a high degree of precision by very accurate instruments, using the method of repetition. Even then the angular data as taken in the field will not be consistent, one triangle with another or with the whole. Such small errors or inconsistencies as exist must be adjusted, or balanced, by distributing the error. This is a fairly specialized and intricate process but must be executed to obtain a consistent system of triangles of highest probable accuracy. Upon the completion of this process the position of any triangulation point with respect to any other or with respect to the base line may be very accurately computed. The United States Coast and Geodetic Survey has covered the country with a triangulation system, the sides of the triangles often being many miles in length. The accuracy of triangulation depends upon the accuracy with which the instrument is constructed and read, and the precision with which the base line is measured. The precision of triangulation is classified as first order, second order, third order, etc., first order triangulation being that in which the base line is required to be measured to an accuracy of 1 part in 25,000, and the average triangle closure being only one second. The geodetic surveying calls for first and second order triangulation, but ordinary intermediate work is satisfactory with third or fourth order triangulation. (F.T.M., E.W.S.)

TRIASSIC PERIOD. The earliest, major subdivision of the **Mesozoic Era** of the geologic time-scale. One of the oldest **systemic** terms and denoting a three-fold division of the German formations into the lower or Bunter sandstones, the middle or Muschelkalk limestones, and the upper or Keuper copper-bearing shales. The term Triassic was proposed by Alberti in 1834. The period began about 200 million years ago and lasted for about 50 million years. The maximum thickness of formations, 25,000′, occurs in the Alps. In

eastern North America, especially in Massachusetts, Connecticut, and New Jersey, occur a thick series of red sandstones, arkoses, shales, and argillites of fresh water origin, containing the footprints of the earliest known



Map showing the surface distribution (areas of outcrops) of Triassic and Jurassic strata in North America Some areas of doubtful age and extent not shown in British Columbia. All Atlantic Coast Areas are Triassic. In much of the western United States the Triassic and Jurassic have not yet been satisfactorily separated.

dinosaurs. Interbedded with the sedimentary formations are numerous **basalt** lava flows and **sills.** This eastern facies of the Triassic is called the Newark Series after the type locality in New Jersey. In Arizona and New Mexico occur fresh-water **clastic sediments** containing the prostrate fossil trunks of ancestral Sequoias in which the original body structures have been perfectly replaced by silica. Some of the tree trunks are over 150′ long and 3–6′ in diameter. In the Cordilleran region the Triassic formations are marine. Triassic rocks also occur in South America, British Isles, western Europe, Asia, Africa, and Australia. During this period there were great changes in the plants and animals, as disclosed by the fossils. **Ferns, cycads,** and **conifers** predominated among the plants. The modern corals, **hexacoralla,** predominate over the earlier **tetracoralla** of the **Paleozoic. Cystoids** and **Blastoids** have become extinct. The **brachiopods** are less abundant, their place being taken by the pelecypods. Modern insects begin their development in this period, and the modern (bony) fishes are ascendant. Among the terrestrial animals, the **Paleozoic amphibia** (Stegocephalia) are replaced by the dinosaurs. The highest types of marine invertebrates are **ammonites.** Marine reptiles, called **Ichthyosaurs,** and flying reptiles called **Pterosaurs,** first appeared in Europe. Small reptilian-like mammals also made their first appearance. The economic products of this period are chiefly salt, gypsum, and copper. In eastern North America the period closed with relatively slight uplift and block-faulting of the Newark Series, called the Palisades Disturbance. In the Pacific Coast region there was a withdrawal of the marine waters to mark the close of the period. (R.M.F.)

TRIBO-ELECTRIFICATION. Frictional Electricity.

TRIBOLUMINESCENCE. Luminescence.

TRICERATOPS. Fossil Reptiles.

TRICHINA. Nemathelminthes, Nematoda. A small roundworm parasitic in the intestine and muscles of mammals. The species is now classified as *Trichinella spiralis* but it commonly retains the name trichina from that of an older genus.

Adult worms develop in the intestine and bear living young which migrate through the intervening tissues and encyst in voluntary muscle fibers, where they perish unless the flesh is eaten by another animal and the cysts are dissolved in the process of digestion. (A.W.L.)

TRICHINIASIS. An infection caused by a worm of the class called **nematodes.** The larvae of the worms are found in pigs and man acquires the disease by eating infected pork. After ingestion, the larvae develop to the adult stage in the small intestine. Countless **embryos** are then given off which penetrate the walls of the intestine, enter the circulation, and finally lodge in muscle tissue, where they become encysted. (See **Trichina.**)

The symptoms depend on the number of larvae ingested and the number of worms that mature and discharge embryos into the intestine. The first symptoms accompany the period of invasion. These consist of abdominal pain, cramps, vomiting, and diarrhea. On the ninth or tenth day after eating the infected pork, the period of dissemination, corresponding to the migration of embryos to the muscles of the body begins. This is marked by high fever, tenderness, swelling, and pains in the body muscles. A characteristic feature is edema about the face, particularly around the eyes. Mild cases last for 2 weeks, more severe may last for 6 weeks, and are followed by many months of weakness. Convalescence lasts as long as worms are invading muscles and becoming encysted there.

The mortality varies in different outbreaks from 1–25%. The average mortality is about 6%.

The treatment is mainly directed to relief of symptoms and general supportive measures. Once present, the encysted forms remain in the muscle for life. Prophylaxis is important. Thorough cooking of pork destroys all the infecting parasites. In many countries pork is examined in the slaughter house for their presence. (D.M.H.)

TRICHINOSIS. Trichiniasis.

TRICHOCYST. A slender structure found in the outer layer of the body in many species of 1-celled animals (ciliates). They are discharged from the body under stimulation, forming a fine thread with a cap at the base. Although they have been interpreted as defensive structures they have also been regarded as organelles of attachment. They are varied and are not yet wholly understood. (A.W.L.)

TRICHOGYNE. A trichogyne is a beak-like or thread-like projection from an **oögonium** which functions to receive the **sperm** cells and to convey the sperm nucleus to the egg. (R.M.W.)

TRICHOPTERA. Caddis fly. An order of insects closely related to the more primitive moths. Many species are moth-like but all differ from the great majority of moths in their rudimentary biting mouth parts. (A.W.L.)

TRICKLE CHARGER. This is a rectifier-type battery charger which is kept connected across the storage **battery** at all times, charging it at a slow rate and thus keeping it in a well charged condition. (L.R.Q.)

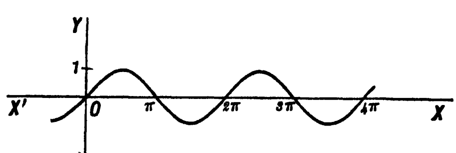
TRICLADIDA. Turbellaria.

TRICLINIC SYSTEM. Crystallography.

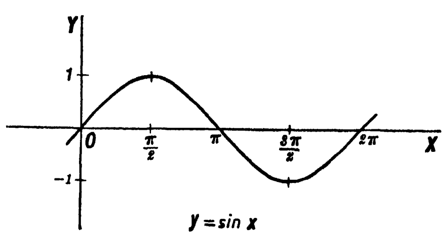
TRIDYMITE. The mineral tridymite is, like quartz, silicon dioxide, SiO_2, but is a high-temperature variety, probably stable above 870° C. It has a conchoidal fracture; is brittle; hardness, 7; specific gravity, 2.28–2.33; vitreous luster; usually colorless and transparent. It is found chiefly in volcanic rocks of the more acidic types like **rhyolite, trachyte,** and **andesite.** It is not a particularly uncommon mineral, occurring in Germany, France, Italy, Japan, the Island of Martinique, Mexico, and in the United States in Wyoming and Washington. Tridymite is **hexagonal** but when heated to about 1470° C. passes into an **isometric** form, cristobalite, which was first noted in the andesitic lavas of the Cerro San Cristobal, Pachuca, Mexico, together with tridymite. Cristobalite has been found also in California and in Germany. (E.S.C.S.)

TRIGGER CIRCUIT. Many of the recent developments in the application of electron **tubes** have utilized various types of triggering action. By this is meant a circuit which suddenly changes its electrical condition, just as if a trigger had tripped it. While there are many varieties of such circuits, they represent some form of unstable electrical equilibrium so the triggering disturbance, whatever it may be, causes it to break over into a new condition. These circuits range from very simple **thyratron** devices to elaborate vacuum-tube circuits which give some special type of output. Many of the modern developments would be impossible without these devices. (L.R.Q.)

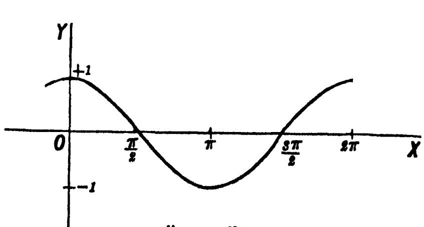
TRIGONOMETRIC CURVES. The graphs of the **trigonometric functions** are shown in Figs. 1–7.



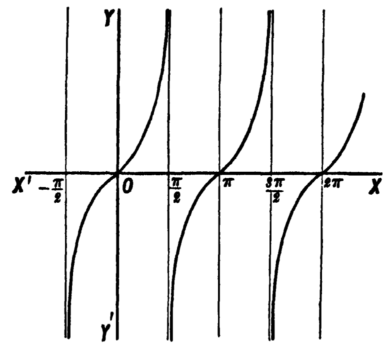
$y = \sin x$
Fig. 1.



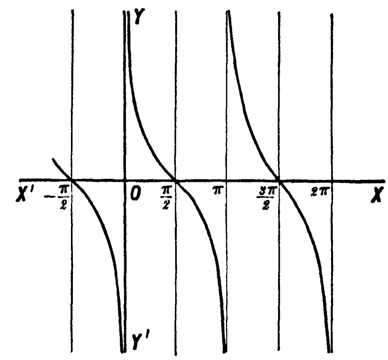
$y = \sin x$
Fig. 2.



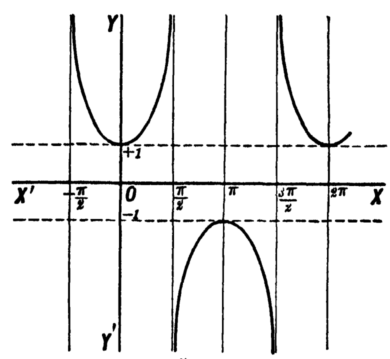
$y = \cos x$
Fig. 3.



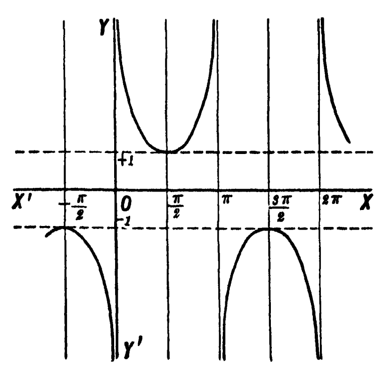
$y = \tan x$
Fig. 4.



$y = \cot x$
Fig. 5.



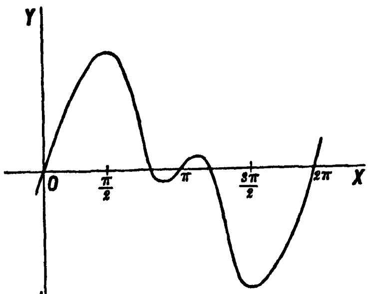
$y = \sec x$
Fig. 6.



$y = \csc x$
Fig. 7.

The graph of $y = \sin x$ is a wave-curve. Its amplitude is its greatest height 1, its wavelength is 2π. The graph of $y = a \sin x$ has amplitude a and wavelength 2π. The graph of $y = \sin bx$ has amplitude 1 but wavelength $2\pi/b$. The graph of $y = a \sin bx$ has amplitude a and wavelength $2\pi/b$. The graph of $y = a \sin (bx + c)$ has phase difference of c from that of $y = \sin x$. The cosine graph differs from the sine graph in phase by $90°$ or $\frac{\pi}{2}$.

By adding corresponding **ordinates** of several simple sine wave-curves, we obtain new types of wave-curves, as for example that in Fig. 8.



$y = \sin x + \sin 2x$

Fig. 8.

The graph of the equation $y = ae^{-kt} \cos(at + \beta)$ is shown in Fig. 9. It represents a damped vibration curve. (L.L.S.)

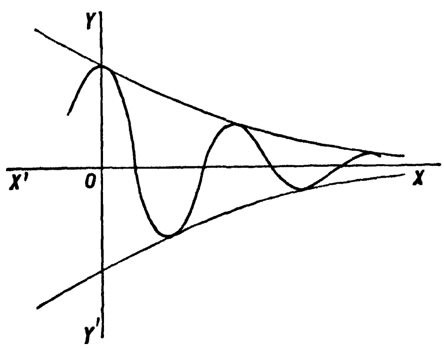


Fig. 9. Damped vibration wave.

TRIGONOMETRIC DIFFERENTIALS. Integration, Technique of.

TRIGONOMETRIC EQUATIONS. A trigonometric equation is a conditional **equation** which involves one or more **trigonometric functions** of an unknown angle.

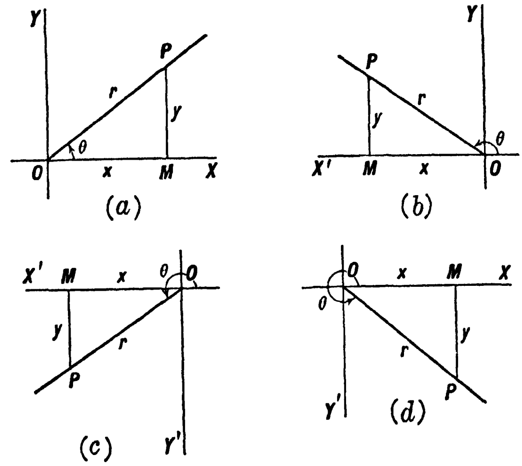
Trigonometric equations have an endless number of solutions, due to the fact that trigonometric functions are **periodic functions.**

In solving trigonometric equations there are many methods which can be used, but one useful method in simple cases is to express all functions occurring in the equation in terms of one function, and then solve this equation algebraically for that function; from this the value of the unknown angle can then be found at once. The fundamental trigonometric identities will often be needed in transforming equations to simpler forms. (L.L.S.)

TRIGONOMETRIC FUNCTIONS. Let θ be any **angle placed in standard position, with initial side along** OX, and let P be any point on its terminal side; drop a **perpendicular** PM from P to the X-axis. Let x,y,r be the **abscissa, ordinate, and radius vector** of P. The **ratios** of these three directed distances are called the trigonometric ratios for angle θ; they are:

$$y/r,\ x/r,\ y/x;\ r/y,\ r/x,\ x/y.$$

Each of these six trigonometric ratios for an angle depends only on the angle and not on the position of the point chosen on the terminal side of the angle and each



ratio changes when the angle changes. In other words, each trigonometric ratio is a **function** of the angle. The trigonometric ratios are therefore called the trigonometric functions.

The trigonometric ratios or trigonometric functions are named as follows:

y/r = sine of θ, written $\sin\theta$,
x/r = cosine of θ, written $\cos\theta$,
y/x = tangent of θ, written $\tan\theta$,

and the reciprocals of these:

r/y = cosecant of θ, written $\csc\theta$ (or $\operatorname{cosec}\theta$),
r/x = secant of θ, written $\sec\theta$,
x/y = cotangent of θ, written $\cot\theta$ (or $\operatorname{ctn}\theta$).

The functions are undefined when θ is such that a zero denominator occurs in these definitions

$(\sin\theta)^2$ is written $\sin^2\theta$, $(\cos\theta)^3$ is written $\cos^3\theta$, $(\tan\theta)^n$ is written $\tan^n\theta$, etc.

Other functions sometimes used are:

versed sine of θ:	$\operatorname{vers}\theta = 1 - \cos\theta$,
coversed sine of θ:	$\operatorname{covers}\theta = 1 - \sin\theta$,
haversine of θ:	$\operatorname{hav}\theta = \frac{1}{2}(1 - \cos\theta) = \frac{1}{2}\operatorname{vers}\theta$,
exsecant of θ:	$\operatorname{exsec}\theta = \sec\theta - 1$.

The algebraic signs of the trigonometric functions in the various quadrants are:

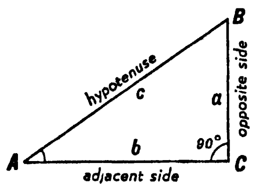
Quadrant	sin	cos	tan	csc	sec	cot
I	+	+	+	+	+	+
II	+	−	−	+	−	−
III	−	−	+	−	−	+
IV	−	+	−	−	+	−

When any one of the trigonometric functions is given the others are determined and may be found by use of the fundamental relations between the functions, or by a geometric method.

The trigonometric functions of quadrantal angles are given by the table:

	0°	90°	180°	270°	360°
sin	0	1	0	-1	0
cos	1	0	-1	0	1
tan	0	∞	0	∞	0

As $\theta \to 90°$ through smaller values, $\tan\theta \to +\infty$, and as $\theta \to 90°$ through larger values, $\tan\theta \to -\infty$, etc.



As a special case of the general definitions, we may formulate the definitions of the trigonometric functions of an acute angle in a form adapted to right triangle applications as follows:

Let A be any given acute angle and construct a right triangle by drawing BC perpendicular to AC. Then the definitions of the trigonometric functions of angle A may be written thus:

$$\sin A = \frac{\text{opposite side}}{\text{hypotenuse}} = \frac{a}{c},$$

$$\cos A = \frac{\text{adjacent side}}{\text{hypotenuse}} = \frac{b}{c},$$

$$\tan A = \frac{\text{opposite side}}{\text{adjacent side}} = \frac{a}{b},$$

$$\csc A = \frac{\text{hypotenuse}}{\text{opposite side}} = \frac{c}{a},$$

$$\sec A = \frac{\text{hypotenuse}}{\text{adjacent side}} = \frac{c}{b}$$

$$\cot A = \frac{\text{adjacent side}}{\text{opposite side}} = \frac{b}{a}$$

Each trigonometric function of the complement of an acute angle is equal to the co-function of the angle:

$$\sin(90° - A) = \cos A, \qquad \cos(90° - A) = \sin A,$$

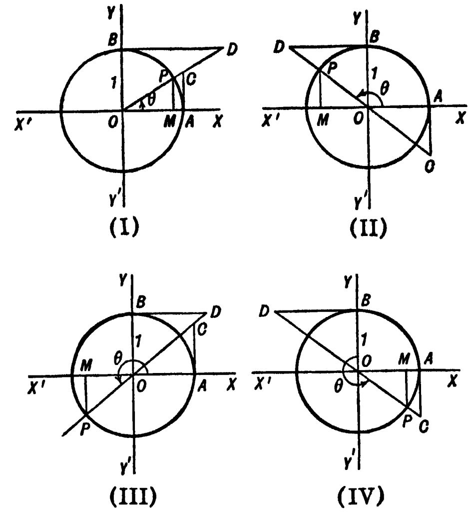
$$\tan(90° - A) = \cot A, \qquad \cot(90° - A) = \tan A,$$

$$\sec(90° - A) = \csc A, \qquad \csc(90° - A) = \sec A.$$

The trigonometric functions of 30°, 45°, 60° are given in the following table:

Angle	sin	cos	tan
30°	$\frac{1}{2}$	$\frac{1}{2}\sqrt{3}$	$\frac{1}{3}\sqrt{3}$
45°	$\frac{1}{2}\sqrt{2}$	$\frac{1}{2}\sqrt{2}$	1
60°	$\frac{1}{2}\sqrt{3}$	$\frac{1}{2}$	$\sqrt{3}$

The trigonometric functions may be represented graphically, both in magnitude and sign, by certain geometric line segments. Draw a unit circle (of radius 1) with the vertex of the given angle at the center of the circle. Let P be the point where the terminal side of angle θ cuts the circle, and draw PM perpendicular to $X'X$, AC perpendicular to $X'X$, BD perpendicular to $Y'Y$. Then for each quadrant, the trigonometric functions are represented, in numerical value and in sign, by the following directed line segments:



Line representation of trigonometric functions.

$\sin\theta$ is represented by MP,
$\cos\theta$ is represented by OM,
$\tan\theta$ is represented by AC,
$\cot\theta$ is represented by BD,
$\sec\theta$ is represented by OC,
$\csc\theta$ is represented by OD.

The variations of the trigonometric functions in the different quadrants are shown in the following table:

Quadrant	Sine	Cosine	Tangent
I	0 to +1	+1 to 0	0 to +∞
II	+1 to 0	0 to −1	−∞ to 0
III	0 to −1	−1 to 0	0 to +∞
IV	−1 to 0	0 to +1	−∞ to 0

The range of values of the trigonometric functions is the following: sine and cosine never can be greater than +1 nor less than −1, the secant and cosecant never can be between +1 and −1, while the tangent and cotangent may take all positive and negative values.

Reduction to the first quadrant may be made as follows:

To find any trigonometric function of any angle θ, take the same function of the acute angle A between the terminal side of θ and the X-axis, and prefix the algebraic sign given by the rule of signs for the quadrants.

For the trigonometric functions of supplementary angles: The sine of an obtuse angle is equal to the sine of the supplementary acute angle; the cosine of an obtuse angle is equal to minus the cosine of the supplementary acute angle; and the tangent of an obtuse angle is equal to minus the tangent of the supplementary acute angle.

The trigonometric functions of a negative angle are given by the formulae:

$$\sin(-\theta) = -\sin\theta,$$
$$\cos(-\theta) = \cos\theta,$$
$$\tan(-\theta) = -\tan\theta.$$

An odd function $f(x)$ is one for which $f(-x) = -f(x)$, and an even function is one for which $f(-x) = f(x)$, for all values of x. The sine, tangent, cosecant, and cotangent

are odd functions, and the cosine and secant are even functions.

Reduction formulae for the trigonometric functions:

$$\begin{cases}\sin(90^\circ-\theta)=\cos\theta\\ \cos(90^\circ-\theta)=\sin\theta\\ \tan(90^\circ-\theta)=\cot\theta\end{cases}\qquad\begin{cases}\sin(180^\circ-\theta)=\sin\theta\\ \cos(180^\circ-\theta)=-\cos\theta\\ \tan(180^\circ-\theta)=-\tan\theta\end{cases}$$

$$\begin{cases}\sin(90^\circ+\theta)=\cos\theta\\ \cos(90^\circ+\theta)=-\sin\theta\\ \tan(90^\circ+\theta)=-\cot\theta\end{cases}\qquad\begin{cases}\sin(180^\circ+\theta)=-\sin\theta\\ \cos(180^\circ+\theta)=-\cos\theta\\ \tan(180^\circ+\theta)=\tan\theta\end{cases}$$

$$\begin{cases}\sin(270^\circ-\theta)=-\cos\theta\\ \cos(270^\circ-\theta)=-\sin\theta\\ \tan(270^\circ-\theta)=+\cot\theta\end{cases}\qquad\begin{cases}\sin(270^\circ+\theta)=-\cos\theta\\ \cos(270^\circ+\theta)=\sin\theta\\ \tan(270^\circ+\theta)=-\cot\theta\end{cases}$$

$$\begin{cases}\sin(360^\circ-\theta)=-\sin\theta\\ \cos(360^\circ-\theta)=\cos\theta\\ \tan(360^\circ-\theta)=-\tan\theta\end{cases}\qquad\begin{cases}\sin(360^\circ+\theta)=\sin\theta\\ \cos(360^\circ+\theta)=\cos\theta\\ \tan(360^\circ+\theta)=\tan\theta\end{cases}$$

When n is an even integer, any trigonometric function of $n\cdot 90^\circ \pm \theta$ is numerically equal to the same function of θ; when n is an odd integer, any trigonometric function of $n\cdot 90^\circ \pm \theta$ is numerically equal to the co-function of θ; the algebraic sign of the result is that of the given function of $n\cdot 90^\circ \pm$ an acute angle.

The six trigonometric functions are related to each other by various relations. The fundamental relations are:

1. The reciprocal relations:

$$\csc\theta = 1/\sin\theta,\quad \sin\theta = 1/\csc\theta,$$
$$\sec\theta = 1/\cos\theta,\quad \cos\theta = 1/\sec\theta,$$
$$\cot\theta = 1/\tan\theta,\quad \tan\theta = 1/\cot\theta.$$

2. The square relations.

$$\sin^2\theta + \cos^2\theta = 1,$$
$$1 + \tan^2\theta = \sec^2\theta,$$
$$\cot^2\theta + 1 = \csc^2\theta.$$

3. The quotient relations:

$$\tan\theta = \frac{\sin\theta}{\cos\theta},\quad \cot\theta = \frac{\cos\theta}{\sin\theta}.$$

Formulae for the trigonometric functions of the sum and difference of two angles are:

$$\sin(x \pm y) = \sin x\cos y \pm \cos x \sin y,$$
$$\cos(x \pm y) = \cos x \cos y \mp \sin x \sin y,$$
$$\tan(x \pm y) = \frac{\tan x \pm \tan y}{1 \mp \tan x \tan y}.$$

These are often called the addition theorems for the trigonometric functions.

From these are obtained the following formulae for transforming sums and differences of trigonometric functions into products, and products into sums and differences:

$$\sin x + \sin y = 2\sin \tfrac{1}{2}(x+y)\cos\tfrac{1}{2}(x-y),$$
$$\sin x - \sin y = 2\cos \tfrac{1}{2}(x+y)\sin\tfrac{1}{2}(x-y),$$
$$\cos x + \cos y = 2\cos \tfrac{1}{2}(x+y)\cos\tfrac{1}{2}(x-y),$$
$$\cos x - \cos y = -2\sin \tfrac{1}{2}(x+y)\sin\tfrac{1}{2}(x-y);$$

and

$$2\sin x\cos y = \sin(x+y) + \sin(x-y),$$
$$2\cos x\sin y = \sin(x+y) - \sin(x-y),$$
$$2\cos x\cos y = \cos(x+y) + \cos(x-y),$$
$$-2\sin x\sin y = \cos(x+y) - \cos(x-y).$$

Formulae for the trigonometric functions of a double angle are:

$$\sin 2x = 2\sin x\cos x,$$
$$\cos 2x = \cos^2 x - \sin^2 x,$$
$$= 1 - 2\sin^2 x,$$
$$= 2\cos^2 x - 1,$$
$$\tan 2x = \frac{2\tan x}{1-\tan^2 x}.$$

Half-angle formulae for the trigonometric functions are:

$$\sin\frac{1}{2}x = \pm\sqrt{\frac{1-\cos x}{2}},$$
$$\cos\frac{1}{2}x = \pm\sqrt{\frac{1+\cos x}{2}},$$
$$\tan\frac{1}{2}x = \pm\sqrt{\frac{1-\cos x}{1+\cos x}},$$
$$\tan\frac{1}{2}x = \frac{1-\cos x}{\sin x} = \frac{\sin x}{1+\cos x}.$$

Transformation of $a\cos x + b\sin x$ is given by:

$$a\cos x + b\sin x = c\cos(x-\alpha),$$

where $c = \sqrt{a^2+b^2}$, $\tan\alpha = b/a$;

$$a\cos x + b\sin x = c\sin(x+\beta),$$

where $c = \sqrt{a^2+b^2}$, $\tan\beta = a/b$.

All co-terminal angles have the same values for their trigonometric functions:

$$f(\alpha \pm n\cdot 360^\circ) = f(\alpha),$$

or

$$f(\alpha \pm 2n\pi) = f(\alpha),$$

where f denotes one of the trigonometric functions.

Hence, all six trigonometric functions are **periodic functions** with the period 2π (radians), or 360°. This is the least period for sine, cosine, secant and cosecant, but tangent and cotangent have also a smaller period π (or 180°) since

$$\tan(x+\pi) = \tan x,\quad \cot(x+\pi) = \cot x$$

and

$$\tan(x+k\pi) = \tan x,\quad k \text{ any integer, etc.}$$

The trigonometric functions all repeat their values in cycles of 360°.

When the angle is small and expressed in **radian measure**, the sine, tangent and the angle have important relations, expressed by:

$$\lim_{\theta\to 0}\frac{\sin\theta}{\theta} = 1 \quad\text{or}\quad \sin\theta \approx \theta,$$
$$\lim_{\theta\to 0}\frac{\tan\theta}{\theta} = 1 \quad\text{or}\quad \tan\theta \approx \theta,$$

when θ is small and is expressed in radians.

A function expressible in the form $y = c\sin(kx+\phi)$, where c, k, ϕ are constants, is a simple harmonic function; c is the amplitude, ϕ is the phase angle and k determines the period: $k/2\pi$ is the frequency and $2\pi/k$ is the period. It may also be written in the form $y = a\cos kx + b\sin kx$. (L.L.S.)

TRIGONOMETRIC IDENTITIES. Trigonometric Functions.

TRIGONOMETRIC INTEGRALS. Integration, Technique of.

TRIGONOMETRIC RATIOS. Trigonometric Functions.

TRIGONOMETRIC TRANSFORMATIONS. Trigonometric Functions.

TRIGONOMETRY. The name "trigonometry" is derived from two Greek words meaning measurement or solution of triangles.

While the solution of triangles forms an important

part of modern trigonometry, it is by no means the only part or even the most important part. In the development of methods for the solution of triangles by computation, certain **functions of angles** occur, and the study of the properties of these functions and their applications to various mathematical problems, including the solution of triangles, constitutes the subject matter of trigonometry.

In plane trigonometry, the solution of plane triangles is considered; spherical trigonometry treats of the solution of spherical triangles.

An idea of the subject matter usually assigned to trigonometry may be gained by consulting the following topics: **Angles, Degree Measures of Angles, Radian Measure of Angles, Trigonometric Functions, Trigonometric Curves, Trigonometric Equations, Inverse Trigonometric Functions, DeMoivre's Theorem, Logarithms, Triangles.** (L.L.S.)

TRILOBITES. **Invertebrate Paleontology.**

TRIM, AIRPLANE. The trim of an airplane denotes the balance of aerodynamic forces around a lateral axis through the center of gravity. An airplane is symmetrical about the other two axes of motion, and consequently would normally always be in trim with respect to those axes. An airplane would be in trim if it had no tendency to nose up or down in steady unaccelerated flight with the elevator control neutralized. Although an airplane which is not thus trimmed can be held in a steady attitude by the use of elevator controls, it is convenient for the pilot on cross-country journeys to be relieved of the steady balancing pressure, which he might otherwise have to maintain, by being able to make trimming adjustments. The two methods commonly employed to make the trim adjustment are: 1. Adjustment of the leading edge of the stabilizer up or down so as to change the tail angle. 2. An adjustment of a **tab** located in the trailing edge of the elevator. In stabilizer adjustment the angle of attack of the tail is altered until the air reaction required for balance is obtained. Tab adjustment produces a change in the effective camber of part of the elevator surface, which causes the elevator to ride in a displaced position, thus changing the effective camber of the whole tail surface, and achieving a desired balancing load.

When perfectly trimmed, the airplane should maintain steady flight at a constant angle of attack with hands off the controls. In this condition the moment of the air reaction on the horizontal tail surfaces is equal in magnitude and opposite in nature to the sum of the moments of the thrust, wing lift and drag, and parasitic drag, all moments being taken with reference to the center of gravity of the complete airplane. Due to the change of center of pressure on a wing at different angles of attack, the magnitude of tail moment necessary for balance varies with the speed of the airplane. Consequently, when the forward speed is changed a new position of stabilizer or tab is required for trim.

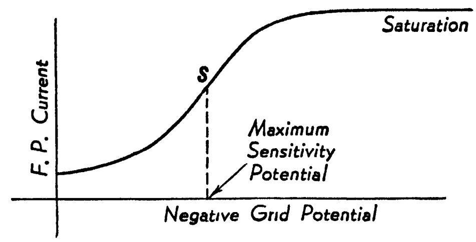
The trimming control on an airplane is usually a small crank or hand wheel located accessible to the pilot, but placed in a subordinate position, as it is one of the less frequently operated and less essential controls. (F.T.M.)

TRIMMING MOMENT. **Trim, Airplane.**

TRIODE. A 3-electrode, thermionic **vacuum tube.** The thermionic current in a hot-cathode tube is unidirectional; that is, reversal of the voltage stops the current, so that the tube acts as a "valve" or **rectifier.** If between the hot cathode and the anode or "plate" of such a tube there is interposed a wire mesh or grid, and if this third electrode is given a slight negative potential or bias, the effect is to reduce the flow of electrons somewhat, by an amount dependent upon this potential. For a suitable adjustment of the voltages and the filament temperature, the thermionic current may prove very sensitive to changes in the grid potential. Very feeble electric oscillations communicated to the grid may then appear as large fluctuations in the main thermionic current, and the triode becomes an **amplifier.** This device, originated by DeForest, is now a most important factor in **radio** reception and in many other types of apparatus requiring high amplification of electric impulses.

By so connecting the circuits that the current fluctuations are made to "feed back," that is, to affect the grid voltage, the amplifier becomes regenerative, tending to build up the fluctuations to a maximum. Large tubes so operating are used to produce the electric oscillations necessary for the emission of the carrier wave in radio broadcasting, sometimes radiating energy at the rate of many kilowatts. The details of the circuits used for these purposes often involve highly complicated radio technique.

To secure the greatest sensitivity, the potential of the grid is adjusted to a value dependent upon the par-



Characteristic curve for typical triode, which is most sensitive at S.

ticular triode. This value is indicated on the "characteristic curve" of the triode as the point S of maximum slope (see figure), where the filament-to-plate current varies most rapidly with the grid potential. (See **Tube, Electron.**) (L.D.W.)

TRIP HAMMER. **Forging.**

TRIPACK. **Bipacks and Tripacks.**

TRIPLE INTEGRAL. Let $f(x, y, z)$ be a **continuous function** in a region V of space. Let this region be divided up into n sub-regions ΔV_k, and let (x_k, y_k, z_k) be any point in ΔV_k. Then form the sum $\sum_{k=1}^{n} f(x_k, y_k, z_k)\Delta V_k$. Let $n \to \infty$ and let the greatest diameter of each $\Delta V_k \to 0$. The **limit** of this sum is then called the triple integral of $f(x, y, z)$ extended over the region V, and we write

$$\lim_{\Delta V_k \to 0} \sum_{k=1}^{n} f(x_k, y_k, z_k)\Delta V_k = \iiint_V f(x, y, z)dV.$$

An iterated triple integral

$$\int_{x_1}^{x_2}\left[\int_{y_1}^{y_2}\left(\int_{z_1}^{z_2} f(x, y, z)dz\right) dy\right] dx$$

means a series of successive integrations; z_1 and z_2 will in general be functions of x and y, and y_1 and y_2 will in general be functions of x, and x_1 and x_2 will be constants. Such an iterated (or repeated) triple integral is sometimes written

$$\int_{x_1}^{x_2}\int_{y_1}^{y_2}\int_{z_1}^{z_2} f(x, y, z)dz\, dy\, dx,$$

or

$$\int_{x_1}^{x_2} dx \int_{y_1}^{y_2} dy \int_{z_1}^{z_2} f(x, y, z)dz.$$

A triple integral may be interpreted geometrically as a **volume.**

The fundamental theorem for triple integrals may be stated: A triple integral $\iiint_V f(x, y, z)dV$ extended over a region V is equal to an iterated triple integral of the form

$$\int_{x_1}^{x_2}\left[\int_{y_1}^{y_2}\left(\int_{z_1}^{z_2} f(x, y, z)dz\right)dy\right] dx,$$

where the limits z_1, z_2, y_1, y_2, x_1, x_2 depend on the boundary of the region V.

In **spherical coordinates**, the element of volume $dx\, dy\, dz$ in a triple integral becomes $r^2 \sin\phi\, d\phi\, d\theta\, dr$.

In **cylindrical coordinates**, the element of volume $dx\, dy\, dz$ becomes $r\, d\theta\, dr\, dz$. (L.L.S.)

TRIPLE POINT. Three-Phase Equilibrium.

TRIPLE PRODUCTS OF VECTORS. The triple scalar product of three **vectors** $(\mathbf{a} \times \mathbf{b})\cdot\mathbf{c}$ is a **scalar**, which may be represented by the volume of the parallelopiped on **a**, **b**, **c** as adjacent edges.

An important formula for the triple scalar product is:

$$(\mathbf{a} \times \mathbf{b})\cdot\mathbf{c} = \begin{vmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix}.$$

This triple scalar product $(\mathbf{a} \times \mathbf{b})\cdot\mathbf{c}$ is sometimes denoted by $[\mathbf{a\ b\ c}]$.

The condition that three vectors **a**, **b**, **c** lie in one plane is $(\mathbf{a} \times \mathbf{b})\cdot\mathbf{c} = 0$, or $[\mathbf{a\ b\ c}] = 0$.

The triple vector product $(\mathbf{a} \times \mathbf{b}) \times \mathbf{c}$ is represented by the important formula

$$(\mathbf{a} \times \mathbf{b}) \times \mathbf{c} = (\mathbf{c}\cdot\mathbf{a})\mathbf{b} - (\mathbf{c}\cdot\mathbf{b})\mathbf{a}.$$

(L.L.S.)

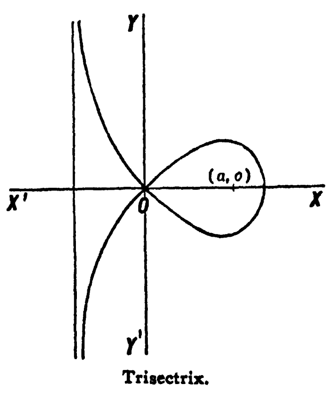
TRIPLOBLASTIC ORGANIZATION. A form of organization based on three embryonic **germ layers.** With the exception of the phyla **Protozoa, Porifera, Coelenterata,** and possibly **Ctenophora,** all animals begin their development with the formation of these three layers, ectoderm, mesoderm, and endoderm. The ectoderm and endoderm develop first as outer and inner layers of the body wall, and the development of **diploblastic** animals proceeds by the differentiation of adult structures from these layers. In triploblastic groups a third layer forms between the two; from this mesodermal layer other parts of the adult are formed. (A.W.L.)

TRIPOLI. Abrasives.

TRISECTRIX OF MACLAURIN. This curve is the locus of the equation in rectangular coordinates

$$x^3 + xy^2 + ay^2 - 3ax^2 = 0.$$

It can be used for the trisection of an angle. (L.L.S.)



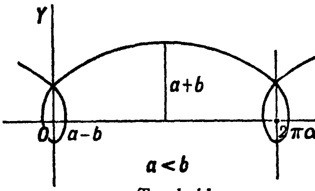
Trisectrix.

TRITOCEREBRUM. The third (posterior) division of the brain of **arthropods.** It is derived from the pair of ganglia of one segment of the head. (A.W.L.)

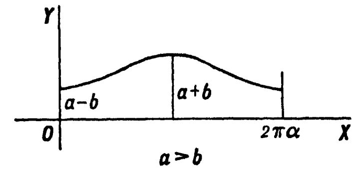
TROCHELMINTHES. Rotatoria.

TROCHOID. A trochoid is a mathematical curve which may be regarded as a generalization of the cycloid.

If a circle of radius a rolls along a straight line, the locus of a point P on a radius of the circle at a distance



Trochoid.



Trochoid.

b from the center is called a trochoid. If $b > a$ (point outside the circle), the curve is frequently called a prolate cycloid, and if $b < a$ (point inside the circle), the curve is called a curtate cycloid.

Parametric equations of the trochoid are:

$$x = a\theta - b\sin\theta, \quad y = a - b\cos\theta.$$

(L.L.S.)

TROCHOPHORE. An invertebrate **larva** with a bent or curved tubular alimentary tract (**Digestive System**) lined with ciliated (**Cilia**) tissue. The surface of the body bears an encircling band of cilia and a tuft at the apex of the body. These larvae develop from the fertilized egg and after drifting and swimming for a time undergo a transformation to become adults.

Trochophore larvae are found in the phyla **Bryozoa, Brachiopoda, Phoronidea, Annelida,** and **Mollusca.** They are also called trochospheres. (A.W.L.)

TROCHUS. The ciliated (**cilia**) disk at the end of the body of a **rotifer.** In many species the end of the body is flattened and is surrounded by two rows of cilia, with the mouth opening between. The outer part is called the cingulum and the disk surrounded by the inner row of cilia the trochus. (A.W.L.)

TROCTOLITE. Gabbro.

TROGON. Aves, Cuculiformes. A brilliantly colored and beautifully feathered bird (**Aves**) of the Oriental region, tropical Africa, and Central and South America. A single species, the Coppery-tailed trogon, *Trogon ambiguus,* enters southern Texas and Arizona. These birds have a moderately large beak, strong and curved. Crests and plumes are highly developed in some of the males, and in this sex the tail is sometimes very long.

The **quezal** of Central America is one of the most widely known of the trogons, probably because it has been pictured frequently on postage stamps of Guatemala and partly because its brilliant colors persist in museum specimens. The male is brilliant green with blood-red under parts below the breast. It has a very long tail, drooping plumes over the wings, and the head bears a rounded crest. (A.W.L.)

TROJAN GROUP. This is the name applied to a group of 11 asteroids which carry the names of the various heroes of the Trojan wars. This group of asteroids all have their periods and mean distances nearly identical with the planet **Jupiter.** The group is of great theoretical interest because of the fact that they represent examples of the solution of the **three-body problem** proposed by Lagrange. Lagrange proved theoretically that an object so located that it is equidistant from both Jupiter and the sun would be in a stable position, i.e., would remain there and continue to go about the sun with the same period as Jupiter. The members of the Trojan group all behave in approximately this manner, each of them being within 20° of the vertex of an equilateral triangle with the sun and Jupiter at the other vertices. They move about this vertex in a complex curve and will remain in this vicinity unless they are perturbed out by the attraction of **Saturn.** (W.K.G.)

TROPACOCAINE. **Alkaloids.**

TROPHALLAXIS. An interchange of nourishment between the various members of colonies of insects. The older idea that instinctive parental care is the basis of the concern manifested by **ants** and **termites** for the welfare of other individuals of the colony has been substituted by recognition of this interchange. The insects exude secretions at the surface of the body which are licked off by others. This reward is apparently responsible for much of the solicitude. Even the insects of other species living within such colonies are welcome guests in some cases because of a similar contribution to their hosts. The relationship has complex ramification which explain other aspects of colonial organization, such as cannibalism, that are difficult to reconcile with the older interpretations of mutual aid within the colony. (A.W.L.)

TROPHI. **Mastax.**

TROPHOSOME. One of several terms used to designate individuals that take in and digest food in colonies of primitive animals, or the stage of development of an individual during which it eats and grows. Trophosome is applied to the **polyp** stage of **hydrozoa,** also called gasterozooids. The term trophozooid is applied to an early stage in the development of the **coral** polyps of the family Fungidae, known as mushroom corals, and the term autozooid to individuals that take food in **alcyonarian** colonies. The root appears again in trophozoite, applied to the growing stage of some parasitic Protozoa (**Sporozoa**). (A.W.L.)

TROPHOZOITE. **Trophosome.**

TROPHOZOOID. **Trophosome.**

TROPICAL AIR MASS. **Air Masses.**

TROPICAL CYCLONE. **Hurricanes.**

TROPINE. **Alkaloids.**

TROPINONE. **Alkaloids.**

TROPISM. For the use of this term in botany, see **Movement in Plants.** In zoology, a tropism is an unavoidable response of an animal to some environmental stimulus involving the orientation of the body in relation to the causative factor. In very simple animals this type of reaction is common. **Protozoans,** for example, may always move toward or away from light, and even animals with organized nervous systems may have some nerve paths associated in such a way that a given condition always evokes the same reaction. This type of response is also called a taxis, a term applied to the responses made without a nervous system and at the other extreme to simple reflexes, which may be nervously intricate although they are automatic.

Both tropism and taxis are combined with various prefixes for special cases. Thus a topotropism or topotaxis is a reaction toward the inciting stimulus and a phobotropism is a withdrawal from the stimulus. These reactions are also designated as positive and negative. Reactions to chemical stimuli are sometimes called chemotropisms. Light evokes phototaxis. By such terms any special orientation of this nature may be concisely expressed. (A.W.L.)

TROPOPAUSE. The discontinuity surface separating the **stratosphere** from the **trophosphere.** It varies in height from about 55,000′ at the equator to 25,000′ over the poles. (P.E.K.)

TROPOSPHERE. The air below the tropopause in which the temperature, on the average, decreases with altitude. All storms occur in the troposphere. (P.E.K.)

TROUGH LINE. A line drawn in a pressure field along which the isobars are symmetrical and curved cyclonically. A V-shaped trough normally contains a front; a U-shaped trough generally contains no front or a very weak one. Usually there is considerable weather associated with a trough line of the V variety. Trough line movements can be computed and a forecast made of future positions. (P.E.K.)

TROUPIAL. Aves, Passeriformes. A name derived from the French and applied variously to members of the family Icteridae, including the **orioles, blackbirds,** and New World **grackles.** The name has been used by various writers for the grackles, for the orioles, and for all members of the family. Also spelled troopial. (A.W.L.)

TROUT. Pisces, Teleostei. A leading game fish (**Pisces**) found in cold waters, including lakes and streams and, some species, in salt water. The various species commonly called trout have been classified with the **salmons** in the genus *Salmo,* and separately in the genera *Trutta, Salvelinus,* and others. They vary greatly in size and to a slight extent in game qualities. The scales are minute to small and the flesh is superior.

Trout are common in streams of the northern hemisphere and have been widely transported for stocking other than their native waters. The brook or speckled trout, *Salvelinus fontinalis,* is the most widely distributed species, ranging from Maine to the Dakotas and northward throughout the continent. Rainbow trout, *Trutta iridea,* from the west coast, are now widely stocked in other waters, and, in places where trout fishing is important, imported species, including the European brown trout, *T. trutta,* and the Lochleven trout, are to be expected. The group includes almost two score of species in North America alone, many without other common names than trout while others are called redfish, greenback, steel-head, blue-back, saibling, and yellow-fin. The lake trouts live in deep water and attain great weight. The mackinaw or common lake trout has been recorded up to 90 lbs.

In North America the relative merits of the trout and bass as game fishes will probably always remain a matter of opinion. Trout fishing with the fly rod has long been regarded as the aristocrat of piscatorial sports, next to salmon fishing, which is less widely available, but the small-mouth bass has many devotees as a fish for the fly rod and his superiority to the trout is often loyally maintained. Probably also anglers will continue to catch the fish that their waters offer, and to be sure that it is the best of all fishes! (A.W.L.)

TROUTON-NOBLE EXPERIMENT. **Ether.**

TROUTON'S LAW. **Heat of Vaporization.**

TROUT-PERCH. Pisces, Teleostei. A common fish (**Pisces**) of the Great Lakes and the rivers of the eastern half of the United States, rare in the south. It attains a maximum length of about 10", with scales like the perches and otherwise similar to the trout. It is one of two species of the family Percopsidae. (A.W.L.)

TRUE BEARING. **Bearing.**

TRUEING. **Grinding.**

TRUFFLE. **Ascomycetes.**

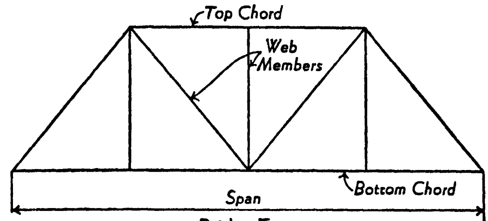
TRUMPETER. Aves, Gruiformes. *Psophia.* A long-legged and long-necked bird (**Aves**) of South America. The few species are characteristically terrestrial in habits, living in the forests and flying poorly. They live in flocks and are said to be tamed in Brazil for the protection of domestic fowls, with which they live contentedly. The word also appears in the names of the trumpeter-hornbills of Africa and the trumpeter swan of North America, both species of other orders. (A.W.L.)

TRUNCUS ARTERIOSUS. The great arterial vessel leading from the **heart** of **vertebrates** in the primitive unpaired condition and in the **embryo.** All blood leaving the heart passes through this vessel, which is differentiated to form the conus arteriosus and the ventral aorta in the fishes and persists as a short trunk in the **amphibians.** In the **reptiles** its subdivision to form the aorta and the pulmonary artery is begun and in the birds and mammals this splitting is complete. The truncus is divided by the growth of a pair of ridges in a spiral course along opposite walls. These ridges unite to form a partition. (A.W.L.)

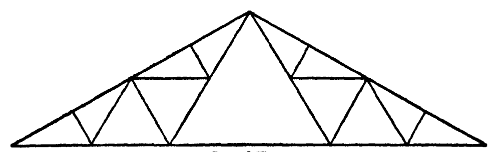
TRUNK. 1. The body of a **vertebrate,** bearing the neck and head at one end and the tail at the other, with the two pairs of appendages attached laterally or ventrolaterally near the two ends. The trunk contains the body cavity in which the viscera lie, and is supported by the vertebral column and the ribs. It is divisible into an anterior thorax and a posterior abdomen. 2. The proboscis of the elephant. This is a muscular organ formed of the elongated nose and upper lip. It contains the greatly elongated nasal passages, which are used for raising water and small particles of food, such as grain, to the mouth by inhaling them into the terminal parts of the tubes. The appendage is also used for grasping by prehension and by the opposition of two finger-like processes at its tip. (A.W.L.)

TRUNK, TELEPHONE. This is the name of a **line** connecting two or more telephone switching points. Thus trunks connect the various central offices within an exchange area. They also connect private exchanges with the telephone company's office. It takes relatively few trunk lines since many calls passing through a switchboard will be for other phones connected to the same board and hence will require no trunk. (See **Telephony.**) (L.R.Q.)

TRUSS. A truss is a framed structure composed of a series of adjoining triangles which are formed by straight members, all lying in one plane. The members are connected at their points of intersection by **pins** or **gusset** plates or by welding. The point of intersection is called a panel point or joint. Since rigidity of the truss is secured by triangles which cannot deform without changing the length of the sides, it is generally assumed that loads applied at the panel points will produce direct **stress** only. This will be true if the gravity axes of the members meet at the panel points and the effect of secondary bending stresses, caused by the **deflection** of the truss, is disregarded. If a load is applied to a member between the panel points it must distribute the load by beam action to the adjacent panel points. The top line of members of a truss is called the top **chord** and the lower line is known as the lower or bottom chord. The members connecting the top and bottom chords are



Bridge Truss



Roof Truss

called web members. The span of the truss is the horizontal distance center to center of end **bearings.**

Framed bridges consist of two or more parallel vertical trusses which support the floor system. The **lateral** bracing in the plane of the top and bottom chords of bridges form the web members of horizontal trusses. A roof truss is one which supports the roof of a building. Trusses are also used over auditoriums to carry the loads from the floors above. The members of a truss are usually made of steel or wood, although concrete trusses have been used for bridges. Steel has the advantage over wood in that it has far greater strength and is less subject to deterioration, but the latter is frequently used for temporary structures and is becoming increasingly popular for reasonably permanent structures. (See **Fuselage; Wing Truss.**) (C.W.C.)

TRYPANOSOME. Protozoa, Mastigophora. A one-celled parasitic animal found in the **blood** plasma of **vertebrates.** The body is characteristically long and slender, with a single **nucleus** and one **flagellum** arising from a small basal body and running along the edge of an undulating membrane, sometimes through the greater part of the length of the body, forming a short free portion at the end. These parasites constitute the genus *Trypanosoma.*

Some species of trypanosomes cause serious diseases of man and domestic animals. Among them *Trypansoma gambiense,* the cause of African sleeping sickness, has been widely publicized. This species is transmitted by the **tsetse fly,** a blood-sucking insect related to the stable fly of our own continent. In South America Chagas' disease is caused by a trypanosome transmitted by a bug. Still another species causes the very destructive disease, nagana, which affects both wild and domestic animals in Africa. (A.W.L.)

TRYPANOSOMIASIS (SLEEPING SICKNESS). A chronic parasitic disease of African and South American regions characterized by wasting, fever, lassitude, and profound lethargy. The parasites responsible for the disease are known as *Trypanosoma gambiense* and *Trypanosoma rhodesiense* (African forms) and *Trypanosoma cruzi* (South American form). The parasites are transmitted by the **tsetse fly,** in which they undergo various changes.

The incubation period in man varies from 10 to 20 days. The acute stage is characterized by irregular fever, enlargement of the **lymph nodes**, and skin rashes. Later, after a latent period of months or years, brain symptoms occur (sleeping sickness). This chronic stage is characterized by headache, mental dullness, paralysis, coma, and convulsions, usually with eventual slow death. A form of this disease occurs which is acute throughout its course, resulting in death. Treatment of all types is difficult. Various combinations of drugs are used, especially compounds of **arsenic**. (R.S.M., D.M.H.)

TRYPSIN. **Enzymes.**

TSETSE FLY. Insecta, Diptera. *Glossina.* A bloodsucking fly found in Africa from the southern borders of Arabia and the Sahara Desert to northern South Africa. About 15 species of these flies have been recognized, varying considerably in habits and distribution. Several of these species are definitely linked with the transmission of **trypanosomes** which cause diseases of man and animals, and none of them are immune from suspicion as carriers.

These flies are related to the stable fly of North America (Family Muscidae). Their chief characteristics are the projection of the proboscis forward from the head and the position of the wings, which are folded over the body so that they overlap completely when at rest.

Tsetse flies suck plant juices as well as blood, and are known to attack animals of many species, both warm- and cold-blooded. They show many interesting reactions. Moving objects attract them more readily than others, and they see dark colors more readily than light. White persons are said to be bothered very little by them when in the company of Negroes. Some species frequent watercourses while others are found in dry areas.

The problem of controlling tsetses in Africa has been important because of the great virulence of the diseases that they transmit. (A.W.L.)

TSUNAMI (SUNAMI). **Earthquakes.**

TUATARA, TUATERA. Reptilia, Prosauria. A primitive reptile, *Sphenodon punctatus,* of New Zealand, superficially like the lizards but different in several anatomical details. It is chiefly noteworthy for the high development of the pineal or median eye. (A.W.L.)

TUBE. The tube is a hollow cylindrical body having a length much greater than its diameter. Generally the tube is used to conduct a fluid, though it may also be used as a container or structural member. Tubes are made of many and varied materials; in fact, almost anything that may be worked into tubular shape has a use somewhere as a tube: steel, iron, copper, brass, glass, cardboard. Metal tubes may be made by rolling a piece of skelp to tubular shape and welding or soldering the joint. This type of tubing has been superseded by seamless tubing, by virtue of the development of processes for producing seamless tubes from a billet. A billet is heated to a plastic state, then pierced by forcing it over the point of a mandrel with revolving rolls which work the metal from the center towards the outside, so that a short thick tube is produced. This intermediate product is then passed between several other mandrels and rolls, each one of which effects a thinning of the tube wall and an elongation. After passing through finishing rolls, the tubes are discharged to cooling and straightening tables. Seamless tubes may also be produced by cupping a circular plate. The plates are first pressed into bowl-shape and then drawn through several dies, each succeeding one being of smaller diameter. The dies eventually bring the tube down to the final shape. A steel tube is differentiated from a steel pipe by the seamless character, and by the nominal size. The tube is sized by its external diameter, the pipe by its nominal internal diameter. (F.T.M.)

TUBE, ELECTRON. The electron tubes form the heart of many of the modern developments in communication and industry. It is safe to say that without them we would have no **radio, television,** satisfactory long-distance telephone service, and many of our common every-day necessities could not be produced as cheaply and as well without the tubes. The electron tube is a device in which **electrons** are freed from the restraints of a solid conductor, pass across a free space (vacuum or gas at low pressure) and are again collected by a solid conductor, but during this passage in free space are controlled in manners which would be impossible if they had not been temporarily freed. Thus we may control the flow of current magnitude in a wire by controlling the voltage across its terminals, but when the electrons are passing between the electrodes of a tube we can superimpose many kinds of complicated controls if desired.

Tubes may be classified in various ways and no one way gives a complete picture. As a first general classification we might use vacuum and gas-filled, the first being a tube which has been as highly evacuated as possible and the latter being one which has been evacuated and then partially refilled with a gas at low pressure. The characteristics of the two groups are usually quite different. Then they may be classified according to the number of elements, two-electrode tubes being diodes (the simplest electron tube must have at least two electrodes), three-electrode tubes being tri**odes,** four being tetrodes, five being pentodes and so on. To give anything approaching a satisfactory picture of the tube it is necessary to use both types of classification and this is usually done.

Let us examine the vacuum-tube family first, starting with the simple diode. This has a thermionic cathode which may be directly (filament type) or indirectly heated to produce electron emission. The other electrode is the anode which collects the electrons. Since electrons are negative charges they are attracted by positive-charged electrodes and repelled by negatively charged ones. Thus if the anode is made positive with respect to the cathode the emitted electrons will be attracted to it, the current usually varying as the $3/2$ power of the applied voltage. If the anode is negative it repels the electrons and no current flows from one electrode to the other since the electrons are the carriers of the charge. It should be noted that the direction of the electron flow is opposite the conventional current direction, the result of an unfortunate error in understanding the nature of electricity in the early days of the science. We can see, then, that if an alternating voltage is impressed across a diode current will flow only during the part of the cycle in which the anode is positive, thus giving rectifier action. This is the major use of this tube.

If a third electrode is inserted in the form of a grid between the **cathode** and **anode** its potential will also affect the electron flow across the tube. As this new electrode, the grid, is much closer to the cathode than the anode is, a given voltage on it will have much more effect on the electrons than the same voltage would if impressed on the plate. This is the basis of the amplifying action of all the grid-controlled tubes and the amplification factor of the tube is a measure of this relative effectiveness, varying from two or three to approximately a hundred in triodes and much higher for tetrodes and pentodes. The electrons which are controlled by the voltage on the grid pass on through the open grid structure and go to the plate (when it is positive as it normally is), thus giving the grid control over the plate current. Another advantage of this control is that the grid takes little or no power from the

controlling circuit, yet the controlled power in the plate circuit may be quite large (there is no creation of energy involved since the additional power comes from the direct current operating source).

The triode has undesirably high capacity between the anode and grid so a second grid may be put between these two electrodes to shield them electrostatically from one another. This gives the screen grid or tetrode tube. The screen grid is operated at a positive potential and ordinarily serves no purpose except shielding although in certain applications it is used for other effects. This tube is characterized by a high **amplification factor**, often many hundred, and a high dynamic **plate resistance**, running well over a megohm in some cases. Its big disadvantage is a **secondary emission** effect when the plate potential is lower than that of the screen. This is overcome in the pentode by inserting a third grid, the suppressor, between the screen grid and the plate, the suppressor being connected to the cathode. This new grid effectively suppresses secondary emission and at the same time the tube retains the desirable characteristics of the tetrode. Another method of accomplishing the same result is the beam tube which is often used for power **amplifiers**. In this tube the electron stream across the tube is focused in such a way that it serves as its own suppressor.

Certain special-purpose vacuum tubes have still other electrodes, the pentagrid converter tube, for example, has five grids which are utilized to make the tube serve both as the **oscillator** and mixer tube of a superheterodyne **receiver**. Other multigrid tubes are used for mixing two or more signals to give a combined effect in the output. Other tubes have effectively two distinct tubes within the same envelope, e.g., a diode or duodiode and triode or pentode are often in the same envelope to serve as **detector** and first audio **amplifier** of a receiver.

The vacuum-tube family ranges from extremely small tubes used for **ultra high frequency** work to the giants of many kilowatt capacity used in radio **transmitters** and large industrial applications. Many of these larger sizes are water-cooled to dissipate the large amount of heat generated by the losses in the tube. The diodes are often called kenotrons and the grid-controlled tubes pliotrons, particularly in industrial applications.

The second group of tubes, the gas-filled, have in general quite different characteristics due to the ionization of the gas during operation. The diode is used primarily as a rectifier and is similar in general construction to the vacuum diode. It is possible to have a cold cathode in a gas-filled tube and in some low power applications such a cathode is often used. Besides the passage of electrons as in the kenotrons, the ionized gas gives positive ions as additional current carriers. The passage of the original electrons across the tube will produce ionization by colliding with the gas molecules if the voltage applied across the tube is sufficient to give the electrons the necessary velocity. This ionization gives rise to more electrons and the positive ions, the latter being attracted to the negative cathode where they neutralize the space charge sheath around the cathode. The result of this is a greatly lowered tube voltage drop with the tube current going up tremendously and no longer following the $3/2$ power law. In fact, if the current is not limited by external **resistance** it reaches destructive values in a small fraction of a second. Hence gas-filled tubes must always be used in circuits with enough resistance to limit the current to safe values. Gas-filled diodes are widely used for rectifiers where large currents are desired since the drop across the tube is low and consequently the efficiency is high. The usual hot cathode tube has a drop between 8 and 15 volts. The **mercury pool tube** is a special type of gas-filled diode. The hot cathode tubes are often called phanotrons.

If the grid is inserted between the cathode and anode of a gas-filled tube the effect is decidedly different from the vacuum tube. At low grid voltages the tube behaves as a vacuum tube, but as the grid voltage is raised, the gas suddenly breaks into a discharge, the voltage drop falling to a low value and the current increasing to a high value. Thus a voltage on the grid can trigger a large current in the plate circuit. This grid-controlled, hot cathode, gas-filled tube is the thyratron. The behavior of the thyratron can be forecast from its grid control characteristic curve, which shows the relation between the grid voltage and the anode voltage for breakdown of the gas. Thus for any given anode voltage the critical grid voltage to cause the tube to trigger may be obtained. Once that tube has broken down the grid no longer has control. For the grid to regain control it is necessary for the plate voltage to fall below the tube drop value and remain below this long enough for the gas ions to recombine. This deionization time puts a definite limit to the frequency with which the tube can be triggered and controlled. On a.c. the anode voltage falls every cycle and if the cycle lasts long enough the tube will not start on the next positive half-cycle unless the grid voltage exceeds the critical value. Thus while the control is not continuous as it is in vacuum tubes, it is possible to control within one cycle which is sufficient for many applications. While it has limited use in communication work it is very valuable for industrial control where a minute actuating power may control, through the thyratron, kilowatts of power in the plate circuit. For many industrial applications the triggering effect is exactly what is desired, the operation being equivalent to a switch without any arcing contacts, mechanical time lag, etc. By using special circuits, such as the **phase shift control**, various special effects may be obtained with the thyratron. Many of these tubes have other grids for producing the desired characteristics. The **ignitron** is another type of controlled gas-filled tube. The grid-glow tube is a cold cathode tube similar to the thyratron.

Besides the tubes discussed here the **phototube** is also an electron tube. (L.R.Q.)

TUBE FOOT. A characteristic appendage of **echinoderms**, associated with the **water vascular system**. In the starfishes (**Asteroidea**) the tube feet are rounded protuberances in the ambulacral grooves along the under surface of the rays. They are cupped at the tips and grip surfaces by adhesion and suction. The tube feet of brittle stars are without suckers. Those of sea urchins (**Echinoidea**) form respiratory organs, and a group of ten around the mouth are sensory. Tube feet of **sea cucumbers** are suctorial with the exception of a group around the mouth that form the **tentacles.** (A.W.L.)

TUBER. Stem.

TUBERCULIN TEST. A skin test which indicates whether or not an individual is sensitive to the **protein** of the *tubercle bacillus*. The test is performed by injecting a small amount of the protein as tuberculin into the skin and observing the injection site for redness and swelling. In a positive test, the reaction is characteristic and persists for several days.

A positive tuberculin test means that the individual has at some time been infected with *tubercle bacilli* and has become sensitized or allergic to the organism. It does not necessarily mean active infection at the time of the test (see **tuberculosis**). Approximately 40% of young adults have positive tuberculin tests. (D.M.H.)

TUBERCULOSIS. A chronic or acute infectious disease caused by an invasion of the body by the *Bacillus tuberculosis*. It may exist without causing symptoms (inactive tuberculosis) or with symptoms (active tuberculosis). The symptoms of tuberculosis depend on the organ involved, the virulence of the strain of tubercle

bacilli and the resistance of the individual infected. Almost any organ or tissue of the body may be attacked by the tuberculous process, although the commonest site is the lungs.

Tuberculosis was known to the Greeks and excellent descriptions of the disease date from the time of Hippocrates. Galen regarded it as infectious. Robert Koch in 1882 demonstrated the causative organism.

The disease is exceedingly widespread and is found in animals as well as in man. It is common in bovine animals, and there is also an avian form. Man is subject to disease from both human and bovine types of organisms. It is estimated that tuberculosis causes about 1/8 of all deaths. In civilized portions of the world there has been a progressive reduction in the morbidity and mortality from this disease. This is due to (1) better economic and social conditions, (2) the present campaign against tuberculosis with its educational aspect toward hygiene and opportunity for diagnosis, (3) earlier diagnosis of the disease both by clinical and x-ray examination, (4) protection of the healthy from active cases, (5) better forms of treatment, especially artificial **pneumothorax** and surgical collapse therapy.

All ages are susceptible, but tuberculosis is most likely to occur in young adult life. Certain races, particularly those who have never before been exposed, are more subject to the disease than others. This was true of the American Indians, who died in great numbers from the new disease which the white race brought to them. The Negro and Irish people also seem to suffer more from the disease than others. Certain occupations have a predisposing effect in that unsanitary surroundings, and particularly exposure to dust, increase its incidence. Also malnutrition, debility from overwork, mental and physical strain, the stresses of puberty and particularly pregnancy seem to increase the susceptibility to tuberculosis.

Tubercle bacilli (*Mycobacterium tuberculosis*) are slender, non-motile rods which are extremely resistant to heat and chemicals. Human, bovine and avian types are distinguishable by cultural characteristics. All can withstand drying for long periods, and the human type may remain alive in dried sputum for as long as 10 months. The human and bovine organisms enter the bodv through several portals. Ingestion of contaminated milk is the route for the entrance of bovine tuberculosis, while pulmonary infection with the human type of organism usually occurs through inhalation. Occasionally, infection enters through the skin.

Once in the body, the reaction set up around the invading organisms is similar, no matter what tissue is attacked. It consists of an accumulation of inflammatory cells including "giant cells" around the tubercle bacilli, forming a tiny, at first microscopic nodule or tubercle. As the tubercle grows, its center breaks down, becomes necrotic, and caseates (i.e., becomes "cheesv"). Several small tubercles may coalesce to form gradually larger ones. The lesion may reach several inches in diameter, and show up as a shadow on an x-ray film. When the center of such a large tubercle caseates, a cavity is formed. The necrotic contents of the cavity may be coughed up in copious amounts. Such sputum is highly infectious and menaces all the individuals exposed to it. As time goes on, the healing stage of tuberculosis begins, with gradual fibrosis and sometimes calcification of the healed tubercles.

Bovine tuberculosis occurs primarily in children. It is a disease of the **lymphatic system** caused by drinking milk from infected cows. Since the advent of pasteurization of milk and inspection of cattle herds, this form of the disease has decreased strikingly. The lymph nodes serve as filters for all foreign material and in this capacity they collect tubercle bacilli as these enter the body through the mouth and gastrointestinal tract. Lymph-node tuberculosis has long been known as **scrofula**. The nodes most commonly involved are the cervical in the neck, and the mesenteric nodes, which drain the intestinal tract. These nodes may also be involved in tuberculosis due to the human type of bacillus. Cervical-node tuberculosis is characterized by swelling, and often suppuration or the discharge of pus from the node. Mesenteric-node tuberculosis is usually without symptoms, although in some children general debility, weight loss, fever, and diarrhea occur. Occasionally acute, abdominal pain causes the disease to be mistaken for appendicitis. Rupture of a node may be followed by tuberculous **peritonitis**.

The treatment of tuberculosis of the lymph nodes is conservative. Surgical removal of infected neck nodes is avoided if possible, because of the tendency of such an infection to ulcerate and form a chronic draining **sinus** to the outside. X-ray treatment and ultra-violet light, in addition to attention to diet and general supportive measures, are employed successfully.

Pulmonary tuberculosis, due to the human strain of tubercle bacilli, is by far the commonest type of the disease. It occurs as a childhood primary complex, consisting of a localized, usually single tubercle in the lung with simultaneous involvement of the regional lymph nodes at the root of the lung, and as a secondary or adult type of infection. The ordinary opportunities for infection are such that approximately 50% of young adults give evidence of having had at some time a primary tuberculous infection. This evidence includes a positive skin test (**tuberculin test**) and the minute shadow of a healed calcified tubercle on an x-ray film of the lungs. The primary infection is usually symptom-free and passes unnoticed. In early childhood, however, it may be a severe disease, spreading rapidly from the original tubercle throughout the lungs, and resulting fatally. Usually the primary complex heals and the individual never has a recurrence of the disease.

Secondary, or the adult type of, pulmonary tuberculosis occurs only in the presence of an old primary lesion. The two theories of its pathogenesis are: (1) it represents a breaking down of the primary tubercle with dissemination in the lung; (2) it is a re-infection following exposure to a large dose of organisms. In either case, it is thought that the primary infection is responsible for an altered reaction in the host's tissues. He has been sensitized and is allergic to the protein of the tubercle bacillus. At the same time, he has developed a certain amount of **immunity**. As the result of the interaction of these two factors, the secondary, or adult, disease tends to be a chronic, low-grade process, with gradual development of thick-walled cavities, and eventually fibrosis and healing.

The symptoms of pulmonary tuberculosis depend on the stage of the disease. If the infection is near the **pleura**, and the latter is involved, the onset may be with acute **pleurisy** and effusion of inflammatory fluid into the pleural cavity. Most commonly in an early active case, the patient notices malaise, weight loss, loss of appetite, easy fatigability, afternoon fever, and slight cough. The sputum usually contains tubercle bacilli by the time such symptoms have developed, and x-ray will reveal an area of infiltration in the lung, most often in the apex of the right lung. As the disease goes on, fever, night sweats, cough, and sputum may increase. Hemorrhage from the lungs and **hemoptysis** occur in about 50% of cases. Sometimes an acute pneumonic episode or tuberculous **pneumonia** develops. Gradually, with proper rest and treatment, the symptoms subside, and the disease settles down to a chronic and slow-healing stage. At this time, there may be extensive involvement of both lungs with cavitation and large amounts of sputum, yet the patient may have little or no fever and feel relatively well. The clinical picture is extremely variable, depending on the natural resistance of the patient to the organism and his degree of acquired immunity. Some individuals are unable to handle the infection, and in spite of good treatment

early in the disease they go on to develop severe symptoms and widespread, often fatal, tuberculosis. Others are able to keep a small lesion localized, and in the course of a year of treatment complete healing may be accomplished.

The complications of pulmonary tuberculosis are associated with spread of the disease to near and distant organs. In some instances the pulmonary disease may be quite minor, and the first manifestation may occur when urinary tract, or abdominal, tuberculosis begins to cause symptoms.

Miliary tuberculosis occurs when the organisms gain access to the blood stream and are suddenly spread throughout the body to all the organs and tissues. The lungs, brain, meninges, liver and spleen usually show great numbers of small miliary tubercles. This form of tuberculosis is universally fatal, usually within a few weeks.

Tuberculosis of the larynx is common in advanced pulmonary disease. It results from direct contact with the organisms as the infectious sputum is coughed up and spat out. Tuberculous **bronchitis** and **bronchiectasis** also occur by direct extension of the infection within the lung. Tuberculous meningitis, which is usually fatal, may be a part of the picture of miliary disease, or may occur from the breakdown of a single tubercle which formed when a few organisms reached the brain through the blood. Intestinal tuberculosis is most often a complication of tuberculosis of the lungs. Spread of the tubercle bacilli to bones, genito-urinary tract, or any other organ or tissue through the blood may occur. Blood-stream invasion is the common way for the disease to reach these organs, although primary disease does occasionally occur in them. Serous-cavity tuberculosis involving the **pleura** and the **pericardium** usually is the result of extension from the lungs, or in the case of the pericardium, lungs or tracheobronchial lymph nodes. Tuberculous peritonitis is a complication of intestinal or mesenteric node tuberculosis by extension, or of pulmonary disease. In the latter case, the peritoneal infection is blood borne.

The treatment of pulmonary tuberculosis always involves a period of several years at least. For best results certain fundamentals must be adhered to: a strict regime of bed rest, good food, and fresh air, in cheerful surroundings, are all essential. High, dry, sunny climates have long been thought to be desirable. Although these may be the most pleasant, they have no special curative value. Early treatment is one of the most important features in achieving a cure.

In recent years, collapse therapy in tuberculosis has been developed and carried out with considerable success. It is based on the fact that healing of a diseased lung is more rapid if the organ can be put at rest. Several types of collapse therapy are used. **Pneumothorax** is employed in unilateral lung disease which has not responded to conservative measures after adequate trial. It consists of introduction of air into the pleural cavity between the chest wall and the lung until the pressure in the cavity is sufficient to force the expanded lung to give up its air and collapse down to a fraction of its normal size. Since the air is absorbed rapidly, it must be reintroduced at intervals—once or twice weekly. The treatment is continued for a minimum of 2 years as a rule, before the lung is allowed to re-expand.

When pneumothorax fails because of **adhesions** between the chest wall and the lung, in such a position that they cannot be cut, or when there is a stiff-walled cavity which remains open in spite of pneumothorax, thoracoplasty, or permanent surgical collapse of the chest by removal of the ribs in two or three operative stages, saves many patients who would otherwise die of their disease.

Crushing one of the phrenic nerves, which temporarily paralyzes half of the **diaphragm**, is another means of decreasing the activity of the diseased lung. It may be used alone or in conjunction with pneumothorax or thoracoplasty.

The various forms of abdominal tuberculosis are treated with x-ray and ultra-violet light, as well as the usual general measures. Tuberculosis of the genito-urinary tract is largely a surgical problem. Bone disease, or tuberculous **osteomyelitis**, is treated by immobilization and sometimes by surgical fusion of diseased joints.

With recent developments in chemotherapy (**sulfonamides**, **penicillin**, etc.) a new spurt has been given to the search for a drug which will cure tuberculosis. **Streptomycin** has proved promising especially in the treatment of early exudative lesions of the lungs. Early effects suggest that it is effective also in laryngeal or tracheobronchial tuberculosis, and even in tuberculosis meningitis. So far none has been found, although a few compounds still under investigation appear promising.

The prognosis in tuberculosis depends on many factors. The type, duration and extent of disease when treatment is begun, the resistance of the patient to the tubercle bacillus are of prime importance. Early treatment increases the per cent of cures enormously. The importance of continuation of treatment, usually for a minimum of 2 years, cannot be overestimated. Since relapses are relatively common even after apparent cure, restriction of activities and regular check-up examinations for a period of years are essential. (D.M.H.)

TUBULARIAE. Hydrozoa.

TUBULIDENTATA. The **aard-varks**. An order of mammals found only in Africa. Based chiefly on the form of the teeth, which are composed of numerous subordinate parts penetrated by radiating tubules. The animals themselves are thick-bodied clumsy creatures with long snouts. The name means earth-pig and refers to their somewhat pig-like appearance. (A.W.L.)

TUBULIFORM GLANDS. Silk glands of **spiders** whose secretion is used in forming the cocoon to contain the eggs. They occur only in the female. (A.W.L.)

TUCOTUCO. Mammalia, Rodentia. Rat-like burrowing animals of South America. They have gray fur and red incisor teeth. The tail is only moderately long and is clothed with short fur. A closely related form with vestigial ears is known in Chili by the name cururo. (A.W.L.)

TUCUXI. Mammalia, Odontoceti. A fresh-water **dolphin** found in the Amazon river system. It belongs to a family differing from that which contains the bouto (A.W.L.)

TUFA. Sinter.

TUFF. Tuff or volcanic tuff is a sedimentary rock, resulting from the partial or complete consolidation of the products of explosive volcanic eruptions. Tuffs may be well sorted and stratified, due to the action of wind or water, or may have an unsorted, heterogeneous character. As particles making up a tuff become coarser the rock grades into an **agglomerate**. (E.S.C.S.)

TUKON HARDNESS. Hardness.

TULAREMIA. An infectious disease caused by *Bacterium tularense*. It occurs primarily as a fatal disease of rodents, mainly rabbits and hares. It may be transmitted to man by the bite of certain flies or ticks, or by handling the raw meat of infected rodents, usually wild rabbits. Most of the cases have been described in the United States, 43 states having reported them. The only other countries reporting cases are Norway,

Russia and Japan. The infection is not transmitted from man to man.

The incubation period of tularemia averages about 3 days. The onset is acute, with headache, vomiting, body pains and fever. The **lymph nodes** draining the area of the portal of entry on the skin often become infected and ulcerated. In certain cases the eye has been primarily infected. Severe systemic reactions, pneumonia, and cardiac involvement may occur. Convalescence is slow and it may require 6 months to a year before return to normal health occurs. One attack confers immunity. The mortality rate is about 4%. The disease is often erroneously diagnosed as influenza, typhoid, tuberculosis or undulant fever. Accurate diagnosis can be made by culturing the organism from the lymph nodes or other lesions, and by the detection of antibodies in the blood serum of the patient.

Prevention in cooks, market men, and hunters may be accomplished by the wearing of rubber gloves when dressing wild rabbits. Treatment with **streptomycin** is effective in the acute infection. (D.M.H.)

TULIP. Lily Family.

TULLIBEE. Pisces, Teleostei. A common fish (**Pisces**), *Leucichthys tullibee,* of the small lakes from Minnesota to New York and northward into Canada. One of the ciscoes or lake herrings. Also recorded as the mongrel whitefish and said to occur in small numbers in the Great Lakes. (A.W.L.)

TUMBLE-BUG. Insecta, Coleoptera. A **beetle** of the family Scarabaeidae which forms and buries balls of dung. Numerous species of scavengers in this family have the same habit. They are said to use the dung as a supply of food during periods when they remain underground, and also to bury a ball with an egg attached, to provide food for the developing larva. The balls of dung are often much larger than the beetles themselves, and their clumsy maneuvers in rolling their booty to the place where it is to be buried are responsible for the name tumble-bug. (A.W.L.)

TUMOR. 1. Any swelling or abnormal enlargement of a part of the body. 2. A growth or mass of tissue which develops in the body, serves no use, and grows independently of surrounding tissues. Such growths are divided into two classes, **benign** and **malignant** tumors. Benign tumors do not spread over the body; they cause symptoms only when large enough to interfere mechanically with the functions of surrounding structures and they rarely recur after complete excision. Examples of benign tumors are fibroids of the **uterus**, fatty and fibrous tumors, and simple cysts. Malignant tumors, **cancer** and **sarcoma**, do invade surrounding tissues, disseminate throughout the body (metastasize) by means of the blood and lymph vessels, may recur after removal, cause constitutional symptoms, and usually terminate fatally.

There are many theories regarding the cause of tumors, but as yet no adequate explanation has been produced. Every tissue in the body is capable of developing tumors; their number and variety are tremendous. They are classified on the basis of cellular structure, the tumor being named according to the tissue from which it originated. The classification is difficult and too complex to be given in full detail here. A simple classification for the more common types according to tissue composition is given below.

I. Connective-Tissue Tumors.
- A. Benign.
  - 1. Fibroma or **fibroid tumor**—fibrous tissue.
  - 2. Chondroma—cartilaginous tissue.
  - 3. Osteoma—osseous or bone tissue.
  - 4. **Lipoma**—fatty tissue.
- B. Malignant.
  - 1. **Sarcoma.** One of the large groups of tumors composed of any one of the varieties of connective tissue mentioned under benign tumors.

II. Muscle-Tissue Tumors.
- A. Benign.
  - 1. Leiomyoma—smooth muscle.

III. Epithelial Tumors.
- A. Benign.
  - 1. Papilloma—made up of surface epithethelium—skin or mucous membrane.
  - 2. **Adenoma**—made up of glandular epithelium.
- B. Malignant.
  - 1. Carcinoma or **cancer.**
    - *a.* Squamous-cell carcinoma or epithelioma, composed of flat epithelial cells.
    - *b.* Adenocarcinoma—composed of glandular epithelial cells.

IV. Endothelial Tumors. Composed of cells that line blood vessels, lymph vessels, joints, and the body cavities.
- A. Benign.
  - 1. Hemangioma—blood vessels.
  - 2. Lymphangioma—lymph vessels.
- B. Malignant.
  - 1. Endothelioma—an ill-defined group of tumors, some of which are malignant.

V. Pigmented Tumors.
- A. Benign.
  - 1. Pigmented moles or naevi.
- B. Malignant.
  - 1. Melanoma. A tumor arising in pigmented moles of the skin or in the pigmented coat of the eye, the retina.

VI. Nervous Tissue Tumors.
- A. Benign.
  - 1. Meningioma—from cells covering the arachnoid villi.
  - 2. Acoustic neuroma—from the sheath of the acoustic or 8th cranial nerve.
- B. Malignant.
  - 1. Glioma—from the several types of specialized connective tissue in the brain and spinal cord.
  - 2. Neuroblastoma—from primitive nerve cells in the adrenal gland.
  - 3. Ganglioneuroma—from adult nerve cells and fibers.

(D.M.H.)

TUNA, TUNNY. Pisces, Teleostei. A large marine fish, *Thunnus thynnus,* of the **mackerel** family. It attains a maximum weight of more than 1500 lbs. and is highly valued both as a game fish and for food. About 15,000,000 lbs. are canned annually in California.

As a game fish the tuna has no superior. It is an unusually vigorous fighter, readily taken with rod and reel on flying fish bait. Specimens over 100 lbs. are frequently caught and a record fish, more than 10′ long, was taken off the coast of Nova Scotia only a few years ago.

The tuna is also called the albacore and horse-mackerel. (A.W.L.)

TUNDRA. The tundras are the Arctic plains which, while supporting **mosses** and **lichens** in profusion, and, locally, various flowering shrubs, are treeless. The top soil is usually a black muck; the subsoil is perpetually frozen. (R.M.F.)

TUNED CIRCUIT. Resonance.

TUNED RADIO FREQUENCY. This is a type of amplifier circuit which uses resonant circuits in the grid and/or plate circuits. As commonly used it is used to denote a type **receiver** which has one or more such stages preceding the **detector,** the condenser or inductance of the resonant circuit being varied to select the particular station desired. (See **Receiver.**) (L.R.Q.)

TUNG OIL. Fixed Oils.

TUNGSTEN. Symbol: W. Atomic number: 74. Atomic weight: 183.92. Density: 19 (18.6–19.1). Melting point: 3370°. (**Isotopes:** page 290.)

Tungsten is a silver-white to steel-gray, brittle, hard metal; not oxidized by air at ordinary temperature but burns at high temperature, best dissolved by a mixture of **hydrofluoric and nitric acids.** Tungsten is used in the production of special alloy tool steels for cutting purposes (16–20% W); in electric lamp filaments and radio tubes; and in special hard alloys, e.g., "carboloy" (tungsten carbide and cobalt) and "stellite" (cobalt, 55%; chromium, 35–40%; tungsten, 3–10%); chemically related to **chromium, molybdenum,** and **uranium** elements. The chemical, paint pigment, and tanning industries use tungsten compounds.

Discovered by d'Elhujar brothers in 1783. Occurs as **scheelite** (calcium tungstate, $CaWO_4$) and **wolframite** (iron and manganese tungstate) chiefly obtained in China. The United States production in Idaho, Nevada, and California is significant. Mexico, Bolivia, Peru, Ecuador, and Argentina are potential producing countries.

Fusing the ore with sodium carbonate and nitrate yields sodium tungstate (Na_2WO_4), which is extracted with water and later acidified, whereupon tungstic oxide (tungsten trioxide, WO_3) is obtained. The oxide is reduced by heating with **carbon** or with **hydrogen** to form tungsten metal, from which by "swaging" (rapid mechanical hammering at 1500° C. in an electric furnace in an atmosphere of hydrogen) ductile wire is obtained.

Chlorides: Chlorides of the following composition are reported: WCl_4, WCl_5, WCl_6, $WOCl_4$, WO_2Cl_2.

Oxides: Tungsten dioxide (WO_2), brown solid, by reduction of the trioxide by hydrogen below 700° C., which upon continuation of the same treatment above 780° C. forms tungsten metal; ditungsten pentoxide (W_2O_5), blue solid, by reduction of the trioxide by hydrogen at 250–300° C.; tungstic oxide, tungsten trioxide (WO_3), lemon-yellow solid, converted by alkalis to soluble tungstates, by heating with **chlorine** to tungsten oxychloride (WO_2Cl_2), by heating with **hydrogen** sulfide or sulfur to tungstic sulfide (WS_3); by alkalis to tungstates. Ammonium phosphotungstate is insoluble, likewise the potassium compound, but the sodium compound is soluble in water. (R.K.S.)

TUNIC. The tough enveloping layer or **test** of the **ascidians.** It is formed of a material similar to cellulose, and is the source of the name tunicate applied to some of these animals. (A.W.L.)

TUNICATA. Urochordata.

TUNING FORK. The tuning fork is a convenient device for preserving a comparatively pure harmonic vibration frequency at nearly constant value. It is a U-shaped bar of elastic material, usually steel (but in some modern forks, of fused quartz), the prongs of which vibrate alternately toward and away from each other, with two nodes near the bend of the U. The fork may be set vibrating by striking one prong with a mallet, and will, after a moment to allow some high overtones to die out, emit a nearly pure musical tone. Large forks are often made to be driven electrically, like an electric bell or buzzer, and will then vibrate continuously for an indefinite time. Tuning forks are used in many experiments on **musical sounds,** as standards of pitch, and also for the control of electric oscillations and electric timing devices. A fork may be tuned by grinding off the ends of the prongs or by means of sliding weights attached to the prongs. Once tuned, the frequency varies only with changes in the elastic modulus of the material. This is slightly dependent upon temperature; hence, for precise work, a fork should be kept in a thermostatically controlled enclosure. (L.D.W.)

TUNING INDICATOR. In radio circuits with **automatic volume control** the output is held constant for an appreciable amount of mistuning of the circuits. Thus the loudness of the output is not a satisfactory indication of when the set is correctly tuned. To remedy this various types of tuning indicators are used. These respond to the carrier amplitude and hence are not affected by the avc. Formerly various instruments were used for this purpose, but now instruments are used only in communications receivers while ordinary home receivers use a special vacuum tube. This tube, often called a magic eye, has a willemite-coated cone-shaped plate upon which the electrons impinge, causing the coating to fluoresce. By connecting the **grid** so the carrier magnitude can control the number or pattern of the electrons hitting this coating, it can be used to indicate relative carrier strength. In any tuning, the correct setting for a given station is that which makes the carrier amplitude maximum. (L.R.Q.)

TUNNEL DRIER. Distillation, Evaporation, and Drying.

TUR. Mammalia, Artiodactyla. A wild **goat** of the Caucasus mountains. It is a large species with strong, slightly spiral horns. Although closely related to the sheep it has the characteristic beard of the goats. (A.W.L.)

TURBELLARIA. The free-living flatworms, a class of the phylum **Platyhelminthes.** Unlike the parasitic members of this phylum, these worms have a cellular ectodermal covering bearing **cilia,** with the exception of a few parasitic members which resemble the flukes and tapeworms in the absence of cilia. The free-living members of the class also have sense organs located at the anterior end of the body, including a pair of eyes and tentacles. The mouth opens on the ventral surface, either near the head or near the end of the body, and the alimentary tract (**Digestive System**) is branched in many forms to extend widely through the body. The terminal portion of the tract forms a protrusible proboscis. The turbellarians are **hermaphrodite** with very few exceptions.

Flatworms of this group are often common in small streams and ponds, and some are marine. They glide over surfaces by the action of the cilia of the lower surface, aided by the secretion of a trail of mucus, or move by undulations produced by muscular action. Their food consists of small animals, living or dead.

The class is divided into four orders:

Order Acoela. Without a hollow gut. The endodermal cells are fused together. These worms live in **symbiosis** with algae contained in the cells of the body.

Order Rhabdocoelida. Mouth anterior, leading into an unbranched gut. Chiefly fresh-water species. Some small marine forms.

Order Tricladida. Mouth approximately central. Gut with three main branches. This order includes the common fresh-water forms, *Dendrocoelum* and *Planaria,* and some species that live in moist situations on land. Some are large and brightly colored.

Order Polycladida. Mouth behind the middle of the body. Gut with many branches from a small main portion. Marine species. Some large and leaf-like. (A.W.L.)

TURBINE. **Gas Turbine; Hydraulic Turbine; Steam Turbine.**

TURBOT. Pisces, Teleostei. A large **flatfish,** *Psetta maxima,* of the European side of the Atlantic. It reaches a length of 3′ and is regarded as the best food fish of the group. On the Atlantic coast of North America a small and useless related species is commonly called the window pane. (A.W.L.)

TURBULENCE. This is a term used to describe a characteristic quality of fluids in motion. There are several concepts of turbulence which, though broadly related, differ greatly in detail. Thus turbulence is employed in the literature of such dissimilar fields as the hydraulics of liquid flow in conduits, the flow of steam in turbines, the injection of fuel into Diesel engine **combustion chambers,** the design and arrangement of **burners** for steam boiler **furnaces,** the **aerodynamics of airfoils,** and the accuracy of **wind-tunnel** research. It affects many phases of these fields, i.e., **heat transfer, thermal efficiency,** lift and **drag** forces, skin friction, comparison of experimental data, etc. Definitions of turbulence are by necessity arbitrary and depend on the purpose for which they are to be applied.

Turbulence consists of a superimposing of irregular eddy currents on a uniform flow. This would include the classical vortices of Helmhotz, with velocity gradients in the turbulent area, as well as isotropic turbulence.

The latter type is the common "turbulence" of applied aerodynamics, and will be amplified in the following discussion.

A turbulent flow might be considered to be a main flow of the centers of gravity of elementary masses of the fluid with turbulence being the irregular motions of these elementary masses about their individual centers of gravity. Turbulence is sometimes quantitatively described as the root-mean-square speed fluctuation as a percentage of the mean speed. Turbulence in air streams is characterized by high-frequency fluctuations about the mean air speed, the magnitude of fluctuation being usually less than 3% of the mean speed. (Low-frequency pulsations of greater magnitude are usually called "gusts.") These fluctuations are irregular in magnitude and direction. The magnitude has been measured directly by the *hot wire anemometer,* developed at the Bureau of Standards, and indirectly by comparison of sphere drags. Turbulence arises from the flow of air over obstacles and the breaking up of the vortices formed. Given sufficient time the viscous properties of air will damp turbulence components. Thus turbulence of the free atmosphere ought to be zero. This has been experimentally confirmed.

Until the qualifying effects of wind-stream turbulence were understood it was impossible to correlate the experimental results at different **wind tunnels** because the initial turbulence was different in each case. After measuring the characteristic tunnel turbulence and allowing for it (especially on $C_{L\max}$ and C_D) very good correlation was obtained. Low turbulence air streams can be produced by placing fine screens across the tunnel immediately after the turbulence is produced (by models, fixed vanes, and propellers) so as to break up the vortices and produce turbulence of small "grain," and then give the viscosity of the air a chance to damp out turbulence by a slow-speed return to the test section. Increasing the effective viscosity by increasing the air density through compression is of further assistance. (See **Boundary Layer, Heat Transfer, Friction Fluid.**) (F.T.M.)

TURBULENT FLOW. **Turbulence.**

TURKEY. Aves, Galliformes. *Meleagris.* A large game bird (**Aves**) of North and Central America. Wild turkeys are now abundant in some of the protected areas of the eastern states, and in the southwest they may be found in wild areas. In comparison with their former abundance, however, they are now rare. The eastern species is easily distinguished from the western by the absence of white tips on the feathers of the tail and rump. A third species occurs in Central America. (A.W.L.)

TURMERIC. *Curcuma longa.* Zingiberaceae. The name turmeric has been given to both the plant, *Curcuma longa,* and to its derivatives, a dye and a drug, which are obtained from the swollen **rhizomes** of the plant.

Curcuma, a native of southern Asia, is widely grown in India and other tropical Asian and East Indian lands, where it is used as a drug as well as a condiment and dyestuff. The plant has long smooth pointed leaves, and dull yellow flowers. To prepare it for use, the yellow-brown aromatic rhizome is cleaned and cut into pieces 1–2″ long. The cut surfaces show the bright yellow color of the substance of the rhizome. These cut pieces are dried in an oven and then ground. In western countries turmeric is sometimes used as a dye; as an ingredient to curry powder; and in chemistry, where it is a test for alkali. Other species of *Curcuma* yield products used in making Oriental tonics and medicines. (R.M.W.)

TURNBULL'S BLUE. **Ferricyanic Acid and Ferricyanides.**

TURNING. **Lathe.**

TURNING POINT. **Differential.**

TURNIP. **Brassica.**

TURNSTONE. Aves, Charadriiformes. *Arenaria.* Shore birds (**Aves**) related to the plovers and oyster-catchers. They are found chiefly in the far north, migrating southward, chiefly along the coasts, in both the Old and New Worlds. They winter as far south as Patagonia. (A.W.L.)

TURPENTINE. **Resins; Pistachio; Terpenes.**

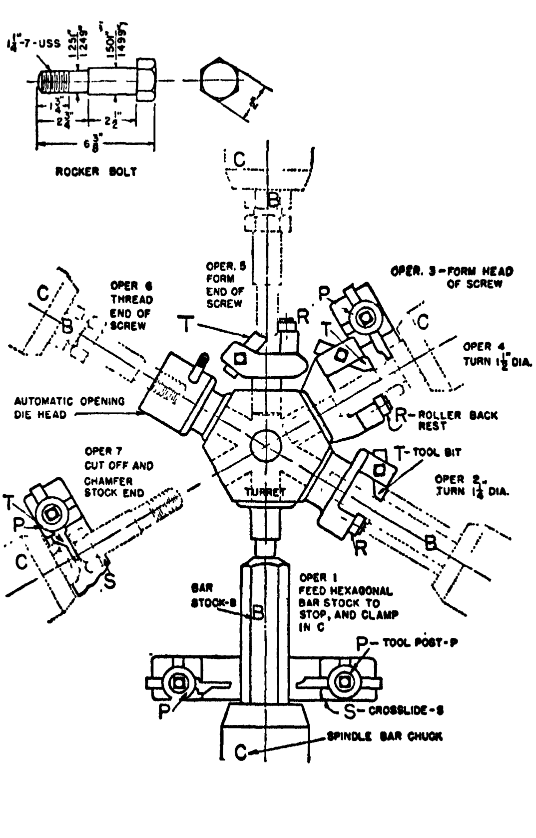
TURQUOIS. The mineral turquois is a hydrated **phosphate** of **aluminum** and **copper.** Its exact composition is doubtful, the formula may be expressed $H_5Al(OH)_2 \cdot 6Cu(OH)(PO_4)_4$; iron is often present. This mineral is found in minute **triclinic** crystals, but chiefly massive as seams and crusts. The fracture is conchoidal; hardness, 5–6; specific gravity, 2.6–2.8; luster, soft waxy; color, may be various shades of blue, bluish-green and green; essentially opaque. It takes a good polish and the sky-blue varieties have long been used as a gem material. Unfortunately many beautiful blue stones in time change their color to some greenish hue, usually not attractive, rendering them practically valueless. For hundreds of years turquois has been mined in Persia where it is found with **limonite** filling crevices in a brecciated **trachyte-porphyry;** and because it found its way into Europe through Turkey it became known as turquois, from the French word *turque,* Turkish. Other mines were worked by the Egyptians in ancient times on the Sinai Peninsula. Turquois is also found in Siberia, Turkestan, Saxony and France; and in the United States in Arizona, California and New Mexico. A blue stone that has passed for turquois is in reality odontolite, from the Greek meaning tooth, usually fossil teeth or bones colored with iron phosphate. Odontolite is softer than true turquois, has a somewhat higher specific gravity, 3.0–3.5, and may be distinguished by chemical tests, or by a microscopical examination which will reveal its organic structure. (E.S.C.S.)

TURRET LATHE. Mass-production turning and facing equipment may be classified as hand-operated, semi-automatic, and completely automatic machinery. Hand-operated equipment generally requires the attention of an operator while the work is in process; semi-automatic equipment usually requires an operator to load and unload the parts to be machined, after which the machine performs a cycle of operations and stops at its conclusion without further attention; automatic machinery requires no service from the operator except gauging the parts as they are produced, resharpening and resetting the tools when required, and filling a hopper with blanks, or in the case of bar machines, inserting fresh bar stock when the original bar has been processed. To illustrate, one operator is required for every turret lathe in use; one man can handle from two to four semi-automatic chucking machines; but six or even more automatic screw machines can, in some instances, be taken care of by a single operator.

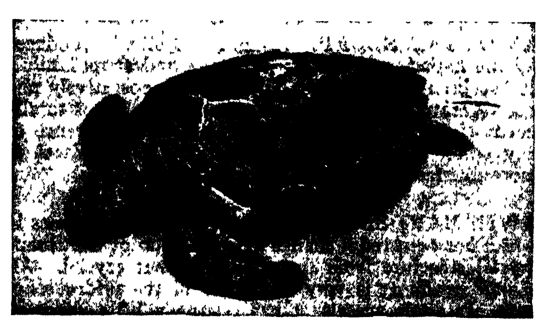
Turret lathes are used in the mass-production system of manufacture to care for the wide, diversified field of production between the engine lathe on one hand and the automatic or semi-automatic bar and chucking machine on the other. Parts which are machined in an engine lathe by being held in a chuck can be drilled and reamed by using tools held in the tailstock sleeve; and the part is subsequently bored, turned, and faced by a series of tools held in the tool post. Turret lathes operate on precisely the same principle. The single hole tailstock, however, is replaced by a six-station turret which holds six tools of such character that from six to fifteen cutting and finishing operations may be successively performed on the part without the necessity of changing the tooling equipment; and the single operation tool post is replaced by a four- or six-station turret which permits four or more cross-slide turning and facing operations.

Modern turret lathes have 5- or 6-station turrets for end cutting operations, and a four-station cross-slide turret for side cutting. The machine has an all-geared headstock, similar to that of a modern engine lathe, and a carriage which carries the turret and is free to move on the bed of the machine parallel to the spindle axis. The bed also supports and guides the turret saddle which carries the turret. Both the turret saddle and the cross-slide carriage may be power fed longitudinally or parallel to the spindle axis; the cross-slide can also be power fed at right angles to the spindle.

The figure shows a turret lathe tooled for turning rocker bolts from hexagonal bar stock. The rocker bolt is shown at the top of the figure, and the spindle and work are represented at each station as though the spindle were indexed around the turret. In operation 1, the turret is moved forward to a stop, and the bar stock B in the collet chuck is moved forward until it meets the work or stock stop shown in the turret. The turret is indexed, and the $1\frac{1}{4}''$ diameter shank of the bolt turned by using a knee tool with a roller back rest. The turret is indexed, and operation 3, forming the head of the bolt by means of the front cross-slide form tool, and operation 4, turning the $1\frac{1}{2}''$ diameter body of the bolt by a knee tool with a roller back rest, are performed simultaneously at this station. The turret is indexed, and the end of the bolt is formed by an end-facing tool with a roller back rest held in the turret. The turret is indexed, and the bolt is threaded, operation 6, by using an automatic opening die head; the thread-cutting dies can be retracted so that it is unnecessary to reverse the direction of rotation of the turret spindle to run off the die. The turret is indexed, and the bolt is cut off by means of the rear cross-slide tool T. The turret is again indexed, bringing it to the initial position shown in operation 1. (H.C.H.)



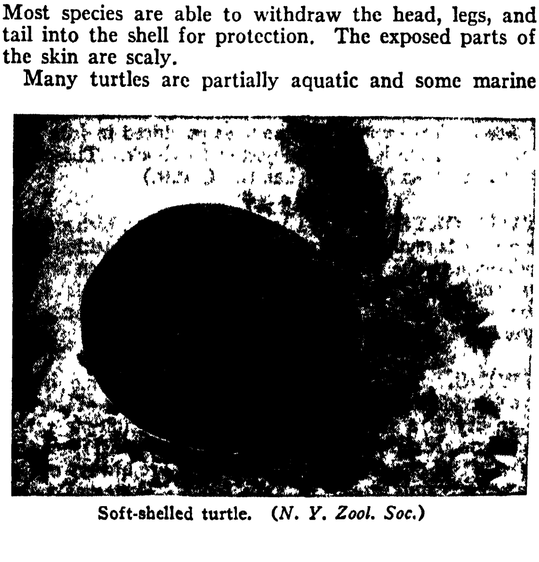
TURTLE. Reptilia, Chelonia. A reptile with a broad flattened body enclosed in a shell formed of a dorsal carapace and a ventral plastron, united at the sides.



Atlantic green turtle. (*N. Y. Zool. Soc.*)

Most species are able to withdraw the head, legs, and tail into the shell for protection. The exposed parts of the skin are scaly.

Many turtles are partially aquatic and some marine



Soft-shelled turtle. (*N. Y. Zool. Soc.*)

species leave the water only to deposit their eggs. In the latter the legs are developed as broad flippers. Turtles are to be found along almost any stream and are often abundant. The group includes both herbivorous and carnivorous species. The flesh of some species is regarded as an unusual delicacy.

Some species of turtles are known by distinctive vernacular names, as **slider, cooter,** and **terrapin,** and a number of them are called **tortoises.** (See also **Fossil Reptiles.**) (A.W.L.)

TURTLE STONE. Concretion.

TWILIGHT. Twilight is produced primarily by **reflection** of the light of the sun from the upper atmosphere of the earth, but effects of **scattering of light,** and **refraction** also enter into the period of duration of twilight. Morning twilight begins and evening twilight ends when the sun is about 18° below the **horizon,** although this value varies somewhat with the purity of the atmosphere.

The angle which the path of the sun at setting makes with the horizon depends upon the **latitude,** the sun setting perpendicular to the horizon at the **equator.** The apparent velocity of the sun on the equator is practically constant for all latitudes and all seasons, but the time required for the sun to get 18° below the horizon will be much shorter at the equator than in high latitudes. Accordingly, the duration of twilight in the tropics is much shorter than it is in high latitudes such as Scotland.

The so-called twilight arch may be observed above the eastern horizon on a clear evening as the sun sets in the west. This is a blue segment bounded by a faintly reddish arc, and is in reality the shadow of the earth cast on the upper atmosphere. (W.K.G.)

TWILIGHT SLEEP. A light anaesthesia produced by the hypodermic use of **morphine** and **scopolamine.** It has been used in labor and also pre-operatively and post-operatively. In this state the patient is not totally unconscious, but does not remember the occurrence of any pain. It is not often used in labor at present as more satisfactory drugs are available. (R.S.M.)

TWIN BANDS. Twin bands in **crystals** are zones in which has occurred a change in orientation of the atomic crystal structure from that of the parent crystal. Although twinning is very noticeable in the **microstructure** of certain metals, it has relatively little effect on the physical, mechanical, or chemical properties.

Profuse twinning occurs in many metals and alloys having face-centered cubic crystal structures when these metals are annealed after mechanical deformation (for example **copper** and most of its alloys, **nickel** and its alloys, and austenitic **stainless** and **heat resisting steels**). These are known as annealing twins.

Mechanical twins are sometimes produced in iron and low-carbon steels when subjected to shock. These are also known as Neumann bands. (R.H.H.)

TWIN CRYSTALS. Those **crystals** in which one or more parts regularly arranged are in reverse position with reference to the other part or parts. They often appear externally to consist of two or more crystals symmetrically united, and sometimes have the form of a cross or star (Dana). (R.M.F.)

TWINS. Two individuals born at the same birth. The incidence of twins is about 1 to 2% of births. Heredity is a factor in the etiology of multiple pregnancies. Identical twins are twins developing from the cleavage of one fertilized ovum. They are always of the same sex and similar in appearance. Fraternal twins are twins developing from two fertilized ova. These may be of either sex, and may or may not be of similar appearance. (D.M.H.)

TWIST DRILL. Drilling.

TWISTED CURVES. Curves in Space.

TWITCHELL'S REAGENT. This is a catalyst for the **hydrolysis of fats.** (R.K.S.)

TWO-BODY PROBLEM. The so-called two-body problem is the foundation of **celestial mechanics.** The solution of the problem requires two fundamental assumptions: (1) that two and only two objects exist in the universe, and (2) that some law of force between the two objects is given. With these assumptions admitted the two-body problem may briefly be stated as follows: given the relative positions of two objects at any instant, together with their motions and masses at that instant, to predict the positions and motions of the objects at any subsequent instant.

The two-body problem was first solved by Newton by considering the motions of the individual planets about the sun. To satisfy the first assumption of the problem Newton assumed that the force between the sun and an individual planet was so much greater than the force between any two planets, that the sun and the planet could be considered, as a first approximation, to be isolated in space. The inclusion of the forces between the different planets as well as the force between the sun and the individual planet leads to the **three-body problem.** When Newton first attacked the two-body problem no law of force between objects in space was known, but the **Keplerian laws of planetary motion** had already been empirically derived. Newton was familiar with the characteristics of **centrifugal force** and realized that no object could revolve about another (as the moon does about the earth) unless there is some force of attraction between them to counteract the centrifugal force. Considering as a first approximation that the orbit of the planet about the sun is circular he found that if the force of attraction between the sun and the individual planets varies inversely as the square of the distance then, and only then, does the so-called harmonic law of Kepler result.

Newton realized that in his establishment of a theoretical foundation for the third of Kepler's laws of planetary motion he had violated the first, for Kepler specified that the motion must always be elliptical and Newton had used the circle (a very particular ellipse). The mathematics of Newton's time was not sufficiently developed to permit of a solution of the problem of elliptical motion and Newton was forced to develop the theory of fluxions, the parent of the modern **calculus,** to accomplish his solution. Using the Cartesian system of geometry and his own theory of fluxions, Newton was able to show that all three of the Keplerian laws of planetary motion were consequences of the planets moving about the sun under the influence of a force emanating from the sun and varying inversely as the square of the distances of the objects from the sun. In a similar manner Newton was able to explain the motions of **Jupiter's satellites,** and the motion of the moon about the earth. Newton firmly believed that the force involved was the so-called force of gravitation which had been described some time previous in connection with the laws of falling bodies on the earth. He stated the law in its familiar form that: every particle of matter in the universe attracts every other with a force which varies directly with the product of the masses of the two objects and is inversely proportional to the square of the distance between them.

With the law of force between the two objects thus stated Newton was able to completely solve the two-body problem as stated in the opening paragraph of this

article. Publication of his solution was delayed for many years, because Newton was unable to verify his hypothesis numerically, since the distance between the earth and the moon was imperfectly known. Subsequent applications of the two-body problem have led to modern methods for **orbit** computation and the multitude of other problems in the field of celestial mechanics. Within recent years the two-body problem has had a number of applications in the treatment of problems in atomic structure. (W.K.G.)

TWO-CYCLE. Two-cycle refers to a sequence of operations by means of which the cycle of the **internal combustion engine** is performed. It is a shortened form of "two-stroke cycle," which may be taken to imply that the cycle is completed in two strokes of the piston. The two-stroke actions to be described here should be compared with the four-stroke described under **four-cycle.**

A two-cycle engine must be so arranged that it can be supplied with a fresh charge when the **piston** is in the extreme outward position. In general, any internal combustion engine must first introduce the fresh charge, compress it, then ignite and expand it after combustion, obtaining power, then exhaust the products of combustion. To obtain all these functions in two strokes of the piston, it is necessary to shorten the period of time that can be allotted to induction and exhaust. For this reason, the **volumetric efficiency** of the two-cycle engine is inferior to that of the four, and, although it receives a power impulse every revolution, instead of every two revolutions, the power falls short of being double that of the four-cycle engine of corresponding size and speed.

In a simple type of two-cycle engine, valves are replaced by ports in the cylinder, which are uncovered by the piston as it nears crank end dead center. One cylinder port leads to the atmosphere, and through it the burned gases are expelled by the pressure remaining in the cylinder. The other port opens from a by-pass to the crankcase, and through it a slightly compressed charge is delivered to the cylinder when the piston uncovers the port. In some types, the gas is compressed in the crankcase by the piston, but in others an external compressor of a piston or rotary type is employed The extremely short time which the ports are open renders the two-cycle engine less suitable for high speeds than the four-cycle engine. However, with certain modifications, the speed may be considerably increased without great sacrifice of efficiency. One method is to place auxiliary poppet exhaust valves in the cylinder head, mechanically operated, to aid in clearing the cylinder of burned gas and this will also aid indirectly in obtaining a better induction of the fresh charge. However, the introduction of an exhaust valve nullifies one important advantage of the two-cycle principle, namely, the absence of such valves. Crankcase compression, while simple enough in the single-cylinder gasoline engine, is complicated in multi-cylinder engines because the crankcase must be separated into sections by air-tight diaphragms so that compression can occur. This offers an obstacle to the smooth supply of fuel to all cylinders from a single carburetor. This problem has been solved in two-cylinder engines by using a special rotary valve in the wall between the crankcase sections. As Diesels do not mix the fuel with the air until after it is compressed in the cylinder, crankcase compression in them poses only the problem of subdividing the crankcase. (F.T.M.)

TWO-HINGED ARCH. Arch.

TYLOSAURUS. Cretaceous.

TYLOSES. Tyloses are balloon-like outgrowths which develop from the living **parenchyma** cells in the woody tissues of older portions of stems. The protrusions push through the **pits** in the cell wall and gradually fill the lumen, or cavity, of the cell until the latter is completely clogged. (R.M.W.)

TYMPANUM. A thin membrane associated with organs of hearing. The tympanum vibrates in response to sound waves and its vibrations are communicated to the nerve endings of the auditory organ. In **insects** the tympanum is a modified area of the integument. In **vertebrates** the tympanum or **ear** drum develops as a specialized area of the skin in the region of the ear, and persists in this condition in the **amphibians.** In the higher classes of vertebrates this area is depressed until it lies at the inner end of the canal of the outer ear. (A.W.L.)

TYPE METAL. Lead Alloys.

TYPHOID FEVER. An acute generalized infection due to a small bacillus, *E. Typhosa.* Typhoid fever is world wide in distribution. Before the days of water and milk inspection, great epidemics of the disease occurred in the summertime and took many lives. Typhoid is spread by feces-contaminated water, milk, or food. Chronic **carriers** who work as food handlers are common sources of dissemination. The organism gains entrance through the mouth and localizes in areas of the intestinal tract where lymphoid tissue occurs. Peyers' patches in the terminal part of the small intestine, or ileum, are the primary sites of localization. From here the organisms spread to the mesenteric lymph nodes, the thoracic duct, and into the blood stream.

Typhoid is usually a severe, long drawn-out disease, and complications are common. The onset is often with chills; **fever** is high and sustained for several weeks, but the **pulse** is slow. A rose-colored eruption is characteristic. The spleen is large and soft. Complications are **pneumonia, cholecystitis, thrombophlebitis,** hemorrhage from the bowel, and perforation of the bowel; the latter two carry a high mortality rate.

Treatment of the uncomplicated case is supportive, with special attention to a high caloric diet. **Sulfonamides, penicillin** and **streptomycin** seem to be inactive against the typhoid bacillus. The disease can be prevented by the injection of a **vaccine.** Immunization programs have been effective in preventing outbreaks among troops in wartime. (D.M.H.)

TYPHOON. Hurricanes.

TYRANNOSAURUS. Cretaceous; Fossil Reptiles.

U

UDAD. Mammalia, Artiodactyla. The Barbary sheep, *Ammotragus lervia,* a large African species with a growth of long hair extending from the throat down over the fore legs. The horns are long, heavy, and strongly curved. This species has been called the udad, aoudad, or audad, but according to some writers the name arui is applied to it by the Arabs. (A.W.L.)

UHF. **Radio Frequency.**

UINTAITE. **Gilsonite.**

UINTATHERIUM. **Eocene; Fossil Mammals.**

ULCER. A shallow, open sore which penetrates the skin or mucous membrane. On the skin, a variety of bacteria may be found in the ulcer, but staphylococci commonly predominate. Ulcers are usually sluggish in character, showing little tendency toward healing. They occur on the surface of the body, especially the legs, as a result of impaired circulation, and are most commonly associated with **varicose veins, diabetes,** and **arteriosclerosis.** They may also occur in specific forms in **syphilis, tuberculosis,** and other diseases. Cancerous growths may become ulcerated, especially in the later stages. Ulcers are prone to form following a trivial injury in areas of the body where circulation is poor.

Peptic ulcer, or ulcer of the stomach or duodenum, is a common disease characterized pathologically by a circumscribed area of destruction involving the lining mucous membrane and the muscle coats beneath.

Ulcers can occur lower in the intestinal tract. They accompany typhoid fever, and in certain forms of colitis are a constant finding in the large intestine. **Tuberculosis** of the bowel is accompanied by ulceration of the wall, characteristically in the **ileum.** (D.M.H., R.S.M.)

ULTIMATE ANALYSIS. One of the methods of reporting the analysis of a fuel is on the basis of the chemical elements present and their proportions by weight. Since such an analysis reports the composition of a substance in terms of its ultimate elements, it has been called the ultimate analysis. Essentially, it is a chemical analysis, as contrasted to the physical basis of the **proximate analysis.** The analysis of a fuel, solid, liquid, or gaseous, as the case may be, for the purpose of resolving it into an ultimate analysis, is a process requiring the trained knowledge of the chemist, the apparatus of a well-equipped chemical laboratory, and no inconsiderable perfection of technique. For this reason, the taking of an ultimate analysis has become a specialized subject. Through several years of fuel research and experimentation, many data on the ultimate analyses of coals from different seams have been accumulated, and it is safe to say that very few commercial seams of the present time are without a published analysis of their typical product.

Combustion calculations are essentially calculations of chemical reactions. Any quantitative work starting with chemical reactions must rest on a knowledge of weights of the elements entering into the reaction. It is to be expected, therefore, that the ultimate analysis would be required for combustion calculations. It is in the field of combustion calculations that the engineer is to be found making extensive use of the ultimate analysis of his fuel. (F.T.M.)

ULTIMATE STRENGTH. **Tension Test.**

ULTRA HIGH FREQUENCY. **Radio Frequency.**

ULTRABASIC. A term proposed by Judd in 1881 for exceedingly **mafic igneous rocks** composed largely, if not entirely, of the ferro-magnesium minerals such as **olivine** and **pyroxene.** The limiting figure of total **silica** is approximately 45%, or barely sufficient to supply the needs of the basic silicates. (R.M.F.)

ULTRAMICROMETER. **Condenser.**

ULTRAMICROSCOPE. The ultramicroscope is not an instrument of extraordinary magnifying power, as its name might suggest. The term has reference rather to a special system of illumination for very minute objects. Such objects as colloidal particles, fog drops, or smoke particles are held in liquid or gaseous suspension in an enclosure with an intensely black background (usually of the **black-body** type). They are illuminated by a convergent pencil of very bright light entering from one side and coming to focus in the field of view—the so-called "Tyndall cone" familiar in experiments on **scattering.** With this arrangement, objects too small to form visible images in the microscope produce small **diffraction** ring systems, which appear as minute bright specks on a dark field. The device is used in studying the **Brownian movement,** in the Millikan droplet method of measuring the electronic charge (see **Electron**), in observing ionization tracks in the **cloud chamber,** etc. (L.D.W.)

ULTRASHORT WAVES. **Electric Oscillations and Electric Waves.**

ULTRASONICS. Elastic waves of frequencies far beyond the range of audibility, called ultrasonic or supersonic waves, present some interesting aspects. Such waves are conveniently produced by quartz crystal oscillators (see **Piezo-Electricity**) designed for frequencies ranging up to 200 or 300 kilocycles per sec. Various acoustic phenomena may be demonstrated in these high ranges, and the waves are useful in illustrating principles of optics. For example, it is possible to construct a coarse, concave **diffraction grating** to form the **spectrum** of such sounds, or an ultrasonic **interferometer** to measure their wavelengths.

Some curious effects are observed when the oscillator is immersed in a vessel of oil. The surface of the liquid bulges up into an agitated heap and emits a spray. If the oscillator is placed at the bottom of the vessel and a horizontal metal plate is lowered into the oil, the plate experiences a distinct upward thrust which has pronounced maxima and minima as the plate is pushed downward, corresponding to the **interference** nodes and antinodes of "stationary" waves. A glass rod held between the fingers and dipped into the oil is so violently (though silently) agitated that its friction may burn the fingers. Small animals in water thus agitated quickly die, and blood corpuscles are destroyed, which suggests caution in exposing the body to such high-frequency vibrations. The waves have been used in **sounding** the depth of water. (L.D.W.)

ULTRA-VIOLET RADIATION. A range of radiation of frequencies next higher than those of the visible violet. If light from an open **arc** is passed through a quartz prism and allowed to fall on a white wall, the familiar **continuous spectrum** appears, ranging from the

extreme red to the extreme violet. But if we substitute for the white wall a suitable fluorescent screen, the spectrum is seen to extend considerably beyond the violet, that is, into the region of shorter wavelengths known as ultra-violet. This spectral region has been observed over more than three "octaves" of the radiation frequency scale, roughly from 4000 A (angströms) at the extremity of the violet to below 400 A on the border of the **x-ray** region. The ultra-violet range has pronounced photographic and ionizing effects, and so is easily detected. The chief hindrance to its study is its rapid absorption in most forms of matter; even air is a serious obstacle to the shorter ultra-violet waves. The **sun** is an intensely hot source of radiation, but its observable spectrum ceases quite abruptly just below 3000 A because, it is believed, of absorption by atmospheric gases, chiefly oxygen and ozone. (This is fortunate, as the shorter radiations may be very injurious to living tissues; sunburn is attributed in large measure to them. Like x-rays, they should be applied to the body only under the direction of a doctor.) It is therefore necessary to turn to artificial sources, chief among which are solid-electrode arcs and, especially, the **mercury arc**. Since quartz and fluorite are much more transparent to ultra-violet than is glass, it is necessary that plates, lenses, and prisms for this region be made of these materials. Silver is a much poorer reflector of ultra-violet rays than certain alloys, so that mirrors and reflection gratings are made of the latter. Schumann developed the technique of spectroscopy in the far ultra-violet (the "Schumann region") and prepared plates especially adapted to its photography; so that now, with the vacuum spectrograph and Schumann plates, the ultra-violet spectra of substances are studied almost as thoroughly as the visible.

In medicine, ultra-violet radiation is used therapeutically as a stimulating measure in certain conditions, to promote healing of indolent and sluggish wounds and for disinfectant purposes. In certain diseases it is curative, for example, in **rickets**. It is also used in lymph node tuberculosis and in certain skin diseases. In 1924 it was shown by Hess and Steenbock that various foods became activated with **vitamin** D, showing marked antirachitic powers after being exposed to ultra-violet rays. Milk is commonly treated in this way, as well as other foods. Viosterol is made by the ultra-violet irradiation of **ergosterol**. (L.D.W., R.S.M.)

UMBEL. Flower.

UMBILICAL CORD. A tube-like structure extending from the navel of the **fetus** to the **placenta** of the mother. It contains two arteries and one vein and serves as an excretory, digestive, and respiratory mechanism for the fetus. (R.S.M.)

UMBILICUS. The scar on the ventral surface of the abdomen where the umbilical cord is severed at birth in the **placental mammals**. The navel. (A.W.L.)

UMBO. A rounded prominence near the hinged edge of a **bivalve** shell. In the shells of **mollusks** an umbo appears on each valve, representing the point where the initial deposits of shell were formed. Many shells show lines of growth where the margin has extended little by little from the umbo. The lower valve of the shell of **brachiopods** extends behind the upper in a beak which is also called the umbo. This structure is perforated by the stalk of the animal. (A.W.L.)

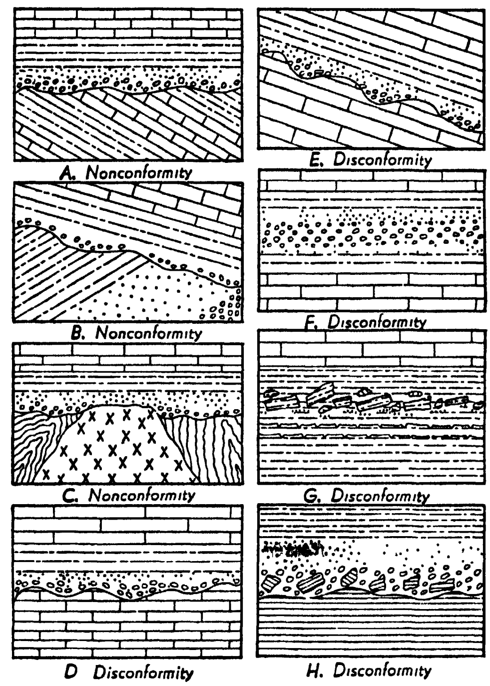
UNADJUSTED MOMENT. An unadjusted moment is a sample moment in a **frequency distribution** to which no correction for grouping has been made. (L.A.A.)

UNAFLOW. Uniflow Engine.

UNAU. Sloth.

UNCERTAINTY PRINCIPLE. Quantum Mechanics.

UNCONFORMITY. If deposition in a given area is interrupted for a time by **erosional** processes, then renewed, a dissected surface will separate the two groups of beds, which are then said to be unconformable, and the erosion surface marking their contact is called an unconformity. If this unconformable relationship of two rock groups is of limited extent, the unconformity is then said to be local, if of wide extent it is called a regional unconformity. If two groups of sedimentary rocks are separated by an unconformity on tilted beds,



Types of unconformities. (*Field, Outline, Barnes & Noble.*)

it is then called a nonconformity or angular unconformity. When the plane of erosion occurs between relatively horizontal formations it is called a disconformity. Principal types of unconformities are illustrated in this column. *A* represents a nonconformity having an irregular erosion surface, developed on the upturned edges of different formations, and covered with a basal conglomerate which grades through sandstone and shale into limestone. In *B* the nonconformable series has also been deformed together with the second wave of deformation which affected the already deformed beds beneath the unconformity. *C* represents a major nonconformity in which the erosion surface truncates highly metamorphosed formations and batholithic intrusives. The basal conglomerate rests upon a plane of erosion which, in itself, must represent a great physical hiatus or lack of stratigraphic record for this region. *D* and *E* represent disconformities which have been developed upon a prelithified surface. In *E* the disconformable formations have been subsequently deformed (tilted). *F* represents a graduational contact, or one in which erosion and depositions have been relatively continuous. *G* represents a gradational contact developed in plastic sediments, with the development of mud cracks and intraformational conglomerates. *H* represents a disconformity in which the basal breccia is composed of the lithified fragments of the older formations, plus foreign clastic material. As

the fossils above and below the disconformity are the same, the disconformity, though pronounced, signifies slight, if any, hiatus (**diastem**). Disconformities of types *F*, *G*, and *H* may represent either slight or great hiatus. (Note) The true amount of hiatus can only be measured by paleontological means. With the exception of a major nonconformity, the physical evidence of hiatus (unconformity) is seldom a safe criterion alone. Thus the terms nonconformity and disconformity have structural but not necessarily stratigraphic, or time, significance. (R.M.F.)

UNDERPINNING. Underpinning is a term used to denote all work done in connection with the construction of a new **foundation** under an existing structure or under the old foundation itself.

Before a new foundation can be constructed under any part of a structure it is necessary to provide a temporary support. In building work this temporary support is secured by means of shoring or needling. A shore is an inclined **compression member** having one end embedded in a niche in the wall and the other supported on a temporary **footing** outside of the wall. In needling, temporary **beams** called needle beams are used to carry the wall **load**. These beams are supported by temporary footings.

After the new foundation has been installed and before the temporary support has been removed, wedges should be driven between the top of this foundation and the structure, thus transferring the load to the foundation without settlement of the superstructure. (C.W.C.)

UNDERWING. Insecta, Lepidoptera. A moth whose fore wings are colored in dull shades of gray or brown, but whose hind wings are in most species brightly banded with black and some shade of yellow, orange or red. The name is used for the large moths of the family Noctuidae and the genus *Catocala,* although members of other genera are colored in a similar way. The genus *Catocala* is so extensive, with more than one hundred species in North America alone, that it has attracted the attention of specialists and has been studied in detail. For the same reason the moths are very likely to be seen without special search. They hide about buildings in the daytime, as well as on the trunks of trees. A flash of bright wings in the garage is quite likely to mean a disturbed underwing. (A.W.L.)

UNDULANT FEVER (Brucellosis, Malta Fever). A specific fever found in man, cattle, goats and other animals, caused by organisms called *Brucella melitensis* and *Brucella abortus.* Human infection usually occurs from the drinking of unpasteurized milk from infected animals or from handling infected animals. The infection in animals causes abortion.

Infection in man gives a varied picture. The onset may be acute or gradual. Fever may be slight and of intermittent nature, persisting for weeks or months. Weakness, malaise, gastrointestinal symptoms, are the rule. The mortality is low but recurrences and relapses are quite common.

Pasteurization or boiling of milk is a sure preventive. In some districts 20% of cattle are infected.

There is no specific treatment although **serum** and **vaccine** therapy may be tried. Otherwise the disease is treated with the same measures as are used in any general systemic infection. (R.S.M.)

UNDULATING MEMBRANE. A form of *organelle* found in some of the 1-celled animals. Undulating membranes of two forms appear, one in the ciliates and the other in certain flagellates. The former is composed of numerous cilia associated in a row near the oral structures of the animal. The flagellate membrane is developed in the **trypanosomes** as a delicate membrane along one side of the body, bordered by the **flagellum.** It vibrates in an undulating movement as an organ of locomotion. (A.W.L.)

UNGUICULATA. A division of the class **Mammalia** used in the older classifications for the forms with claws. If used at all in modern classifications it is regarded as a division of the subclass Eutheria containing the orders **Insectivora, Dermoptera, Chiroptera, Carnivora, Rodentia, Edentata, Pholidota,** and **Tubulidentata.** (A.W.L.)

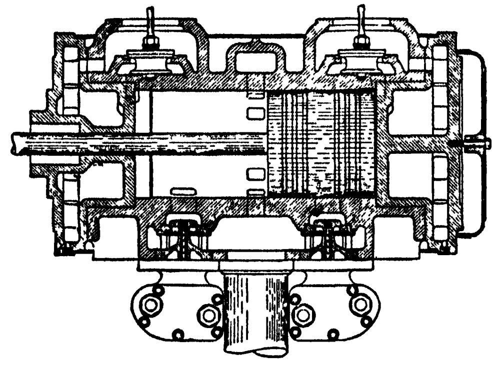
UNGULATA. An older division of the class **Mammalia** whose standing is like that of the Unguiculata. It includes the hoofed animals and related forms whose feet bear heavy nails or nail-like hoofs, embracing the orders **Artiodactyla, Perissodactyla, Proboscidea, Sirenia,** and **Hyracoidea.** Although the term is almost obsolete it persists commonly in reference to the members of the first two orders as the even-toed and odd-toëd ungulates, respectively. (A.W.L.)

UNIAXIAL CRYSTALS. Double Refraction.

UNIFIED FIELD THEORY. Fields of Force; Relativity.

UNIFLOW ENGINE. The term uniflow designates one-way flow of a fluid through a cylinder. While it is sometimes employed to differentiate between the flow of gases in two- and four-stroke cycle engines, uniflow has come principally to designate that improved type of **steam engine** in which the exhaust is arranged so that the steam flows from the end of the cylinder to exhaust ports located near the center, and does not reverse its direction of flow during exhaust, as is the case in the dual flow engine. This elimination of exhaust steam flow over inlet ports is the major advance in steam engine design in recent years, because it eliminates **initial condensation** in ports and cylinder head. The overcoming of this rather large loss places the uniflow engine in a favorable position to compete with other types of prime movers. It is more expensive to construct, but so marked are its advantages that it has come to be the only type of steam engine considered where a large efficient engine is wanted.

Except for the cylinder construction, the uniflow engine is very similar to any other steam engine. The cross-



Section of cylinder and valves of universal uniflow engine.

section through the cylinder of a uniflow (sometimes written unaflow) engine shows how a ring of exhaust ports situated at the center of the cylinder will be uncovered by the **piston** as it nears the end of an expansion stroke. It also shows why the piston must be much longer in this type engine than in the dual flow.

On the return stroke the piston covers the ports fairly early in the stroke, and a considerable amount of work would be drawn from the **flywheel** in compressing the

steam during the long back stroke were it not for the fact that this uniflow is equipped with auxiliary exhaust valves which remain open a portion of the exhaust stroke, thus delaying the point of compression and preventing the reabsorption of considerable work from the flywheel. This delayed compression does not produce higher thermal efficiencies than a full compression, but increases the power which may be developed per cubic inch of piston displacement. Some manufacturers build full compression uniflow engines. (F.T.M.)

UNIFORM CONVERGENCE OF SERIES. An infinite series $\sum_{1}^{\infty} u_n(x)$, each of whose terms is a function of x defined in an interval I, is said to be uniformly convergent in that interval if it converges for every value of x in I and if, for any arbitrary $\epsilon > 0$, an index N independent of x exists such that

$$\left| \sum_{i=n+1}^{\infty} u_i(x) \right| < \epsilon$$

for every $n > N$ and for every value of x in I.

The most important test for uniform convergence is the so-called Weierstrass' M-test:

If the terms of $\Sigma u_n(x)$ are **continuous functions** of x in an interval I, and if $|u_n(x)| \leqq M_n$ for every n and for all values of x in I and the M_n are positive constants, then if ΣM_n is convergent, the series $\Sigma u_n(x)$ is uniformly convergent in I and is also **absolutely convergent** in I.

Some of the important uses of uniform convergence are indicated by the following theorems:

If $\Sigma u_n(x)$ is uniformly convergent in an interval I and if its terms are continuous functions of x in that interval, then its sum is itself a continuous function of x in I.

A series of continuous functions which converges uniformly in an interval I may be integrated term by term, provided the limits of integration are finite and lie in the interval I.

If a uniformly convergent series be integrated term by term, the resulting series will be uniformly convergent.

Any convergent series of functions may be differentiated term by term if the resulting series is uniformly convergent. (L.L.S.)

UNIFORMITARIANISM. **Cataclysm.**

UNILATERAL TOLERANCE. **Interchangeable Manufacture.**

UNIRAMOUS LIMB. A **crustacean** appendage consisting of a single unbranching series of segments. It is derived from the **biramous appendage** by the loss of the **exopodite** and is very well illustrated by the walking legs of the **thorax** of lobsters and related forms. The **chela** of these animals is a modified uniramous appendage. (A.W.L.)

UNIT DEFORMATION. **Deformation.**

UNIT HEATER. When a means for producing heat is combined with one for circulating it within a building, the combination is known as a unit heater. There are several manufacturers who supply unit heaters commercially; usually the product takes the form of a gas- or a steam-heated surface such as a cellular core, finned tube, or pipe coil. Air is blown over this heating surface under the influence of a fan or blower, generally electrically driven. Formerly unit heaters were employed principally in industrial buildings or mercantile buildings, but in recent years the desire of owners of steam or hot-water heated homes to eliminate radiators from the rooms, and to obtain a measure of **air conditioning**, has led to the development of similar equipment for the home. The domestic equipment is considerably different in design from the heavy, rougher, industrial types, but in it, also, is generally employed a heating surface over which a silent propeller type fan blows the air which, when heated, is passed through ducts or grills into the room. (F.T.M.)

UNIT OPERATIONS. Unit operations is a study of the physical changes which take place in materials undergoing chemical processing, in order to design equipment in which to conduct these changes. Its major classifications are flow of fluids, heat transfer, evaporation, drying, air conditioning, gas absorption, distillation, extraction, mixing, separation of solids, crystallization, filtration, and crushing and grinding. (D.E.M.)

UNIT PROCESSES. Unit processes is the study of the chemical changes which take place in materials undergoing processing in order to find the best conditions for the reactions, and to design suitable equipment. The major classifications are sulfonation, nitration, reduction, ammonation, oxidation, halogenation, hydrolysis, esterification, alkylation, polymerization, and various special reactions such as the Friedel and Crafts reaction. (D.E.M.)

UNIT STRESS. **Stress.**

UNITED STATES STANDARD. **Gauge Number.**

UNIT-PRODUCTION. **Measurement.**

UNITS. **Physical Measurements; Physical Magnitudes and Physical Equations; Metric System; C. G. S. System; M. K. S. System; Electric and Magnetic Units.**

UNIVERSAL CHUCK. **Chuck.**

UNIVERSAL GRINDER. **Grinding.**

UNIVERSAL JOINT. **Coupling.**

UNIVERSE. The term universe, in its complete physical sense, should apply to all matter in existence. We know that this matter is not uniformly distributed, but rather that it is gathered into aggregates ranging in size from the smallest atom to the largest collection of matter known to astronomers.

We have considerable knowledge regarding the small aggregates which make up objects on the surface of the earth. We know something regarding the larger aggregates known as the **planets, stars, nebulae,** and other astronomical objects contained within the boundaries of the **milky way,** or galactic system. We have observational data from which theories may be formed regarding the size and structure of our own local system and the milky way as a whole, but we are now approaching the region where we have nothing more than hypotheses which await more complete confirmation.

What is beyond our milky way? Is this galactic system the largest aggregate of matter which exists in the universe? Such are questions upon which much research is being carried on at present and for which answers can by no means be considered as found. It is in search of answers for such questions that the 200-in. telescope is constructed.

This much can be said at present: we do know that there are many aggregates of matter which lie outside of the confines of our milky way. Descriptions of these extra-galactic objects will be found discussed under the title of **spirals.**

Statistical discussions indicate that the number of these objects may be as great as 10^{10}—a number comparable with the number of stars in our own galactic system. Very recent studies have shown quite conclusively that the extra-galactic objects are not uniformly distributed through space. The term "galaxies of galaxies" has been applied to these, the largest aggregates of matter thus far discovered. Far too little is known of them to permit of any discussion of their sizes and forms. (See **Population.**) (W.K.G.)

UNSTRATIFIED DRIFT. Till.

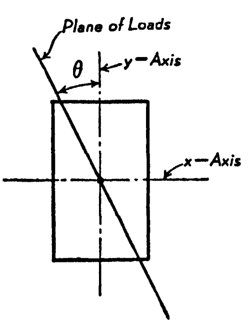
UNSYMMETRICAL BENDING. The condition which exists at any cross-section of a flexural member (see **Flexure**) when the plane of the **loads** contains the **shear** center but does not coincide with either of the two **principal planes of bending** is known as unsymmetrical bending. Under these conditions the **flexure** formula is not applicable because the **neutral axis** is not perpendicular to the plane of the loads although it does pass through the **center of gravity** of the cross-section.

The flexural stress due to unsymmetrical bending is found from the formula.

$$s = \frac{M \cos \theta y}{I_x} + \frac{M \sin \theta x}{I_y}$$

in which s = Flexural unit stress at a point.
M = **Bending moment.**
x, y = Coordinates of the point taken with respect to the **principal axes.**
I_x, I_y = **Moments of inertia** referred to the principal axes.
θ = Angle which the plane of the loads and hence the plane of the bending moment makes with the y-axis.

It should be noted that this formula, which is applicable if the stress does not exceed the **proportional limit**, may be obtained by resolving the bending moment into components parallel to the two axes. The flexure formula is then applied to each of the principal axes and the results combined by the theory of superposition. The simplest way to determine the sign of the resultant stress (+ for **tension** and − for **compression**) is to note the sign for bending about each axis and use this sign when combining the results in the formula. (C.W.C.)



UPLIFT. If water should find its way from a **reservoir** to the surface between the base of a **dam** and its foundation, it would exert a pressure upwards against the base of the dam. It would, in the extreme case, equal the full hydrostatic head corresponding to the height of the water surface above the base of the dam. This water pressure is known as uplift, and could possibly overturn a gravity type dam if it were not prevented, or allowed for in the design. Sometimes ⅔ of the static head is assumed to be acting as uplift. Uplift might be considered to be maximum at the upstream edge of the base, decreasing from that to zero at the downstream edge. Where measures are taken to prevent uplift, the foundation must be very thoroughly grouted, cut-off walls must be let into the foundation near the upstream edge of the base, and drains provided to relieve any pressure which might be built up by a slow seepage. (F.T.M.)

UPSET. Forging.

URALITE. This is a metamorphic mineral. It is a well-established fact that **pyroxene** rocks may be **metamorphosed** into **hornblende** rocks. If the hornblende thus produced is fibrous and retains the original form of the pyroxene, it is called uralite, and the process by which the change is brought about is called **uralitization.** It seems quite clear that uralitization is a chemical process which in many cases is accompanied by the generation of new minerals such as **calcite, epidote,** and **magnetite.** Uralite was first observed in rocks from the Ural Mountains, hence its name. (E.S.C.S.)

URALITIZATION. Uralite.

URANINITE. A mineral approximating the composition UO_2, but containing besides the higher oxide of **uranium,** UO_3, and oxides of **lead, thorium,** and rare earths. The uraninite may occur as black **octahedral** crystals of high specific gravity (9.0–10.63); when in masses of pitchy luster is called **pitchblende.** All uraninites and pitchblende contain a minute amount of radium. It was in pitchblende obtained from the Joachimsthal in Czecho-Slovakia that Mme Curie discovered radium. Other localities for uraninite are in Saxony, Rumania, Norway, Cornwall, East Africa, and in the United States in the pegmatites of Connecticut, North Carolina, and South Dakota, and in Gilpin County, Colorado. An important occurrence of pitchblende is at Great Bear Lake, Northwest Territories, Canada, where it has been found in large quantities associated with silver, and is now a commercial source of radium. (E.S.C.S.)

URANIUM. Symbol: U. Atomic number: 92. Atomic weight: 238.14. Density: 18.7. Melting point: $<1850°$ C. (**Isotopes:** 234 (trace), 235 (0.7%), 238 (99.3%.)

Uranium is a white metal, ductile, malleable, and capable of taking a high polish, but tarnishes readily on exposure to the atmosphere. Finely divided uranium takes fire on exposure to air, and the compact metal burns when heated in air at 170° C. Uranium metal slowly decomposes water at ordinary temperatures and rapidly at 100° C.; is soluble in **hydrochloric acid** and in **nitric acid**; and is unattacked by **alkalis.** Chemically related to **chromium, molybdenum,** and **tungsten;** and, like **thorium,** is radioactive. In the radioactive decomposition radium is formed. (See **Radioactivity.**) Discovered by Klaproth in 1789.

Uranium occurs in **pitchblende** (75–90% U_3O_8) and **carnotite** (62–65%). The oldest and most celebrated deposit of pitchblende is that of Joachimsthal in Czecho-Slovakia, known since early in the sixteenth century, in the ore from which mine the discovery of radioactivity was made. Carnotite is a **potassium** uranium **vanadate,** and occurs in southwestern Colorado and eastern Utah as an extensive deposit. Richer ores have been found in recent years in Belgian Congo, and Great Bear Lake region of northern Canada. Uranium, isotope of mass 235, has been the subject of much investigation because of its disintegration into barium and krypton when bombarded by slow neutrons. (See **Radioactivity.**) The so-called atomic bomb is really a nuclear bomb making use of the above disintegration to release its enormous energy.

Oxides: Oxides of the following composition are reported: UO_2, U_2O_5, UO_3, U_3O_8, UO_4. UO_2 and UO_3 have been well established; U_3O_8 is believed to be a mixture, $UO_2 \cdot 2UO_3$. Uranium dioxide, brown to black solid, is obtained when uranium metal is burned in air at 170° C., and when U_3O_8 is heated in **hydrogen** at 650° C.; U_3O_8, green solid, by heating any other oxide of uranium in air to 700° C.; uranium trioxide, brick-red solid, by heating uranic acid, ammonium diuranate

or ammonium uranyl carbonate to a maximum temperature of 300° C.

Salts: 1. Uranous, e.g., chloride UCl_4, green color, strong reducing agents, and not fluorescent in violet light. 2. Uranyl, e.g., chloride UO_2Cl_2, yellow color, markedly fluorescent in violet light, readily reduced in solution to uranous by **zinc** metal, **tin** metal, **copper** metal, **iron** metal, and ferrous salts. Small amounts of sodium uranate are used in ceramics to produce yellow glazes, and in the dyeing industry as a mordant. (R.K.S.)

URANOTHORITE. Thorite.

URANUS. (See tables of planetary data, page 1109.) Uranus, the first planet to be "discovered," was found accidentally by Herschel in 1781 while sweeping the sky with a 7-in. reflecting telescope of his own manufacture. His discovery stirred up a tremendous amount of popular interest in astronomy, and history relates that during the weeks following the discovery, the streets in front of Herschel's house were crowded with people eager to get a view of the telescope and a glimpse of the discoverer. Herschel named the planet Georgium Sidus (star of the Georges) in honor of the then reigning king of England, George III, but the name was never adopted on the continent. Many Europeans called the planet Herschel, in honor of the discoverer, but the name Uranus, proposed by Bode, is the one which has survived.

To the naked eye Uranus is barely visible as a sixth **magnitude** star, but in a telescope of moderate aperture the object appears as a disk. The disk has a bluish-green appearance, and no surface markings have ever been observed. Early observations showed that the planet is very much flattened at the poles, which gives evidence of high rotational speed, but it was not until 1912 that Lowell and Slipher were able to prove, by the **Doppler principle,** that the period of rotation is about 10.75 hours. The relatively high **albedo** and low densities both give evidence of a thick layer of atmosphere about the planet. Reasoning from purely theoretical grounds, on the basis of the mean distance of the planet from the sun, we find that the temperature of the surface of Uranus should be about 63° K. (−346° F.). At such a low temperature all gases except possibly hydrogen, helium, and argon should be condensed out of the atmosphere. However, within recent years, Dunham has shown the existence of a large amount of methane in the atmosphere of Uranus, which indicates that the temperature must be considerably higher than that given by purely theoretical reasoning.

One strikingly interesting characteristic of Uranus is found in the fact that the axis of rotation lies almost in the plane of the ecliptic, being inclined to it by an angle of less than 10°. Furthermore, the direction of rotation is opposite to that of all of the other members of the solar system.

Uranus has four small **satellites** less than 1000 miles in diameter. The orbit planes of these satellites lie close to the plane of the planet's equator, and hence are nearly perpendicular to the plane of the ecliptic. The satellites revolve about the primary in the same directional sense as that in which the planet rotates, i.e., in the retrograde direction. (W.K.G.)

URCHIN. 1. Mammalia, Insectivora. The European **hedgehog.** 2. Echinodermata, Echinoidea. The sea-urchins and the related flat forms called cake urchins and sand dollars. Although usually accompanied by a prefix, the name is commonly shortened, as in the case of the common green and purple urchins of the Atlantic. (A.W.L.)

UREAS. Amines and Amides.

UREASE. Enzyme.

UREDINALES. Rust Fungi.

UREDINIOSPORE. Rust Fungi.

UREIDES. Purine and Uric Acid Compounds.

UREMIA. An acute or chronic disorder resulting from retention of nitrogenous waste products in the body due to impairment of **kidney** function. The majority of cases complicate the latter stages of severe **nephritis,** but uremia may occur in kidney failure from any cause. The usual ones are various kidney diseases, mercury poisoning, reflex suppression of kidney function, etc.

The symptoms of uremia are headache, vomiting, dizziness, and **diarrhea.** Psychic disorders are frequently present, delirium, stupor, and **coma** sometimes occur. Convulsions or, more frequently, muscular twitching are frequent. Other symptoms are those of the underlying disease and the accompanying **acidosis.**

The treatment of uremia is directed toward the elimination of accumulated nitrogenous substances by aiding renal and cardiac function. The prognosis is usually poor. (D.M.H., R.S.M.)

URETER. The two tubes, each of which connects a **kidney** with the **bladder.** The urine drains from the kidney pelvis into the ureter, down to the bladder. Each ureter is about twelve to fourteen inches long and is extremely small in diameter. (See **Excretory System.**) (R.S.M.)

URETHANES. Amines and Amides.

URETHRA. The narrow passageway through which the urine flows from the **bladder** to the outside. In the female, the urethra is about 1½″ long and the external opening (meatus) lies above the **vagina,** between it and the **clitoris.** In the male, it measures about 8″, runs the entire length of the **penis;** it also serves to carry the seminal fluid to the outside. The urethra is often the site of acute and chronic infection. (See **Excretory** and **Urogenital Systems.**) (D.M.H., R.S.M.)

URIAL. Sha.

URIC ACID. Purine and Uric Acid Compounds.

URINALYSIS. The chemical and microscopical examination of the urine. (D.M.H.)

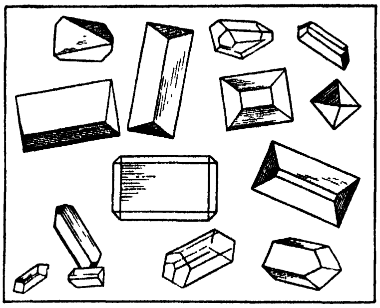
URINARY BLADDER. Excretory and Urogenital Systems.

URINE. A transparent amber fluid, slightly acid in reaction, with a characteristic odor and a specific gravity varying from 1.005 to 1.030. Urine is excreted by the kidneys. passes through the **ureters** into the **bladder,** where it is stored and is discharged through the **urethra.** The average amount excreted by the kidneys in 24 hours in health is about three pints. The amount varies somewhat according to the quantity of fluid drunk and the amount lost through the skin, lungs, and intestinal tract.

The urine may become cloudy on a vegetable diet due to precipitation of **phosphates.** In disease cloudiness may develop from the presence of **pus.**

Urine is the medium by which the body gets rid of a large portion of the end-products resulting from food **metabolism.** The waste material is composed principally of urea, an end-product of **protein** metabolism, **ammonia, hippuric acid, purine** bodies, and salts, mostly **sodium** chloride.

The important abnormal constituents of the urine which, when constantly present, signify some disease process are **albumin, glucose, acetone, pus,** red blood cells, **bacteria,** and casts of the kidney tubules. (D.M.H.)



Prismatic forms of triple phosphate crystals from urine (×250). (*Todd and Sanford, Clinical Diagnosis by Laboratory Methods, W. B. Saunders Co.*)

UROCHORDATA. Chordata. A subphylum containing the marine animals known as **ascidians,** tunicates, salpians, and appendicularians. They represent an extreme adaptation of primitive chordate structure for **sessile** or drifting life.

Urochordates are characterized by the presence of a cuticular covering called the **test** or tunic, a word associated with the name Tunicata, also applied to the group. They have a very large **pharynx,** occupying most of the body and perforated by many openings. In some species these openings lead to the exterior and in others to a peribranchial chamber opening to the exterior by a constricted **cloacal** aperture. Ordinarily, water bearing particles of food is taken into the pharynx by way of the mouth through ciliary (**cilia**) action, passes into the peribranchial space, and is discharged by the cloacal aperture. When irritated, however, the animal may contract spasmodically and discharge jets of water from both mouth and cloacal aperture. In the pharynx food is caught by an endostyle as in the **Cephalochordata.**

The Urochordates are classified as follows:

Class Larvacea. Appendicularians. Forms resembling larval tunicates, with a trunk and tail. Minute, free-swimming, and transparent.

Class Ascidiacea. The ascidians or sea-squirts. Tailed and free-swimming as larvae but sessile as adults.

Class Thaliacea. The salpians. Floating transparent forms, sometimes colonial. Moderate in size. (A.W.L.)

URODELA. The **salamanders, newts,** and related forms of tailed **Amphibia.** An order, also named Caudata. (A.W.L.)

UROGENITAL SYSTEM. A term sometimes applied to the closely associated **excretory** and **reproductive** systems of the vertebrates. The gonads and the kidneys arise from the same mass of embryonic tissue, the intermediate **mesoderm,** and as the ducts of the excretory system develop they are appropriated in part by the reproductive organs. In the male the mesonephric or Wolffian ducts persist as the vasa deferentia, connected with the testes by modified mesonephric tubules, the vasa efferentia. These parts do not persist in the female, where separate Müllerian ducts arise in association with the ovaries. Both male and female genital ducts join the **cloaca** during embryonic development, and here further intimate association is evident.

The cloaca persists in all classes, but in only a few of the primitive mammals. In most mammals a more or less complete separation takes place.

This region of the gut bears the **allantois,** an extra-embryonic membrane, as a ventral appendage, and receives dorsolaterally the mesonephric ducts, from which the metanephric ducts or ureters branch to the kidneys. The cloaca expands and the angle between the allantoic stalk and the intestine progresses in mammals until the chamber is subdivided into the dorsal rectum and the ventral urogenital sinus. The latter receives the mesonephric ducts. By its continued growth the common portion of these ducts is absorbed into its wall, so that the mesonephric ducts and ureters join it separately, the latter in front of the former. The anterior part, bearing the ureters, together with a portion of the allantoic stalk, becomes the urinary bladder. The slender posterior portion becomes the female urethra, the duct of the bladder, and in the male forms the proximal portion of the urethra. External folds flanking the opening of the urethra form the labia minora of the female, between which the vagina, derived from the united parts of the Müllerian ducts, and the urethra open separately. In the male these folds unite to form part of the penis, with an enclosed tube which becomes the distal or phallic portion of the urethra. Thus in the male the urethra remains a common duct of the excretory and reproductive systems. (A.W.L.)

UROPOD. A swimmeret of certain **crustaceans,** modified as a broadly expanded swimming appendage. The pair of uropods associated with the flattened **telson** form the fan-like tail of the **lobsters** and **crayfishes.** By powerful contractions of the abdomen this structure is used to scull the animal rapidly backward through the water. (A.W.L.)

UROSTYLE. A long rod of bone articulated with the last vertebra of the **frog** and related forms, in the skeletal axis. Although this bone is not segmented, it shows evidences of being formed from coalesced vertebrae, like the os coccyx of **primates.** (A.W.L.)

URSA MAJOR. (The greater bear.) (Map, page 380.) This **constellation** is probably best known for the asterism known in this country as the big dipper and in England as the plough or the wagon. The constellation is circumpolar for both Europe and North America, and two of the stars in the dipper, known as the pointers, are very useful in locating the star **Polaris,** since the line joining them, if extended, will pass close to the celestial pole.

The star Mizar (Zeta Ursae Majoris) at the bend of the handle of the dipper is an easy visual **double star.** Tradition says that this object was used by the American Indians as a test of vision, a person able to see this star as double being credited with good vision. The star is certainly one of the earliest doubles known, having been so named by the ancient Arabs. (W.K.G.)

URSA MINOR. (The smaller bear.) (Map, page 380.) This **constellation** is best known because of the fact that the bright star at the end of the handle of the asterism, frequently referred to as the little dipper, is at present the closest bright star to the north celestial pole of rotation. This star **Polaris** (Alpha Ursae Minoris) will be described elsewhere. Other than this star the constellation contains very few objects of interest or importance. (W.K.G.)

URTICARIA. Hives. An allergic response characterized by the appearance on the skin of firm, elevated, circumscribed lesions varying from the size of a pea to several inches in diameter. The eruption is characterized by intense itching. The patches may appear and disappear or change their position during the course of the day. Usually the hives disappear as quickly as they develop, but sometimes they may persist from 12 to 24 hours. Hives may occur from a variety of causes, some of which are not well understood. In general, urticaria occurs when a hypersensitive individual comes in contact with a specific **protein** substance. Certain protein foods,

serum or **blood injections**, or certain drugs may cause this type of eruption.

Treatment consists, when possible, of the avoidance of the offending protein. At times, desensitization with graded doses of this protein subcutaneously is successful. During an attack **adrenaline** by hypodermic injection gives prompt relief usually. (D.M.H.)

USTILAGINALES. Smuts.

UTERINE TUBES. Fallopian Tubes.

UTERUS. A portion of the female reproductive passages in which the eggs or young are retained during all or part of **embryonic** development. A uterus is found in some invertebrates, as the roundworms and **arthropods**. In the mammals, accompanying their highly specialized reproductive processes, it is important. It is formed in these animals either as a pair of chambers in the two Müllerian ducts or as a portion of the fused region of the two ducts. Uteri of the latter kind are of three fundamental forms. A duplex uterus is forked through most of its length, and is in reality a pair of chambers united at one end. In the uterus bicornis there is an unpaired chamber of considerable extent, branching in front to form two diverticula bearing the oviducts. A uterus simplex is an unpaired chamber.

The wall of the uterus contains heavy layers of involuntary muscle and its lining is glandular and partially ciliated (**cilia**). The lining is specialized for the reception of the fertilized ovum in pregnancy, and takes part in the formation of circulatory connections with the developing **embryo** through the **placenta.**

The human uterus is a hollow, muscular, pear-shaped organ situated in the lower pelvic cavity between the **bladder** and the **rectum.** The broader portion of the uterus is the upper portion, at each end of which the **fallopian tubes** enter. The lower portion is called the **cervix** and projects downward into the **vagina.** The virginal uterus is small, measuring about 3″ long, 2″ broad, and 1″ in thickness. During pregnancy the uterus enlarges enormously and may extend upward to the ribs. After pregnancy the uterus is always a little larger than its original state. After the **menopause** the organ becomes smaller.

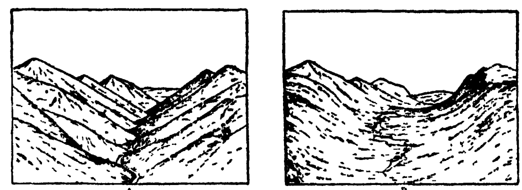
Since the uterus is suspended and held in position by ligaments, its position may become disturbed. Anteversion indicates that the uterus is inclined too far forward, while retroversion indicates that the organ is displaced backward toward the rectum.

The function of the uterus is to receive the ova from the ovaries through the fallopian tubes. If the ovum is fertilized it is retained and development takes place within the uterine cavity. When development is complete the fetus is expelled from the uterus by contractions of the uterine muscular wall, aided by contractions of the abdominal muscles.

The uterus may become involved in infectious processes, especially after childbirth and **abortions,** particularly of the criminal variety. **Tumors** are common in the uterus, both of the benign and malignant variety. The most common benign tumor that occurs in the uterine wall is a fibroid. Removal of the uterus is called hysterectomy. The operation to correct malposition is called suspension of the uterus. (A.W.L., R.S.M.)

UTILIZATION FACTOR. When a **transformer** is used to supply a **rectifier** system the current wave forms are normally irregularly shaped and hence the losses are different than would be expected at first glance, the transformer running hotter for a given current than if it were supplying a **resistance** load. The ratio of the d-c power output to the normal a-c rating for the same heating losses is the utilization factor of the transformer. (L.R.Q.)

U-VALLEY. A river valley whose transverse profile has been changed from the V- to the U-shape by the work of a glacier. While the ice tongue is occupying the valley, any tributary glaciers or streams are unable



Diagrams showing a stream-cut valley (A), and as it appears after glaciation (B). (*After U. S. Geological Survey*)

to cut below the surface of the ice lying in the main valley. When the glacier finally melts the tributary valleys do not enter the main valley at grade but appear as hanging valleys. The stream which flows in a U-valley is called a misfit stream because it could not have transported the large glacial boulders among which it flows. (R.M.F.)

UVAROVITE. Garnet.

UVULA. A soft mass of tissue which hangs downward from the posterior part of the soft palate above the base of the tongue. When it is too long and causes irritation or tickling in the throat it may be shortened by astringent solutions, or in extreme cases by surgery. (R.S.M.)

V

VACCINATION. The process of introducing a **vaccine** into the body for the purpose of immunization against disease. The immunity is the result of the stimulation of **antibody** production against the organism contained in the vaccine. Vaccination was first used against smallpox, but is now carried out as a method of immunizing against many diseases including **whooping cough, typhoid fever, cholera, yellow fever** and **rabies**. Vaccination against the common cold, dysentery, meningococcus meningitis, streptococcal infections, etc., have met with little or no success. (D.M.H.)

VACCINE. A preparation which on injection will induce an active **immunity** in the body. Vaccines are made up of dead or attenuated infectious agents—**bacteria** or **viruses** and each one is specific: the intracutaneous inoculation of tetanus vaccine protects the individual against tetanus, and rabies vaccine protects against rabies, etc. (D.M.H.)

VACCINIA (Cowpox). An eruptive disease of cows, the virus of which, when inoculated intracutaneously in man, gives protection against smallpox.

Vaccinia is believed to be **smallpox** modified by long passage through an animal. This so alters or attentuates the smallpox **virus** that a local lesion only is produced when the virus is inoculated into man (vaccination).

It has been known by country people for centuries that cowpox will protect against smallpox, but it remained for Jenner in 1798 to put vaccination on a practical basis.

Revaccination should be done (1) at intervals of 7 to 10 years, (2) repeatedly when previous vaccinations fail to "take," (3) when exposed to a smallpox patient.

If smallpox occurs in a patient who has been vaccinated many years before so that its effect has worn off, the disease assumes a less serious form than without previous vaccination. (R.S.M.)

VACUOLE. A small globule of clear fluid in the cytoplasm of a **cell**. In preparations for microscopic study the contents of the vacuole are usually dissolved away, so that an open space alone remains, but even vacuoles whose contents are undisturbed usually appear vacant because of their transparency. In the multicellular body fat cells afford a good illustration of vacuoles as globules of fat accumulate in them. One-celled animals also offer a good example in the contractile or pulsating vacuole. This is a globule of clear liquid that forms and discharges periodically, sometimes at a fixed point in the cell. It is interpreted as an organ for the removal of surplus water with dissolved wastes from the **protoplasm**. (See **Cell**.) (A.W.L.)

VACUUM. A perfect vacuum would be a region entirely devoid of matter. Because of diffusion and the volatility even of solids, this condition is merely an ideal. Even if we imagine it to be attainable, the old concept of a vacuum as mere emptiness is modified by evidence leading to the conclusion that so-called "space" is capable of participation in processes of a physical nature. Faraday's notion of **fields of force**, involving stresses in space, and the undulatory theory of **light** (not to mention the more recent relativistic aspects of the subject), have profoundly influenced scientific thinking in regard to space by endowing it with physical properties.

Experimentally a vacuum is simply a region of very low pressure, usually attained by some form of **air pump**. A pressure of a mm. or so of mercury would be called a "rough vacuum," while one of 0.0001 mm. is a "high vacuum." The best vacuum obtainable by artificial means at present is probably of the order of 10^{-8} mm.; though such pressures cannot at present be measured with certainty. (L.D.W.)

VACUUM THERMOCOUPLE. A device for measuring very feeble electric currents, either alternating or direct, by means of their heating effect. The current to be measured is passed through a short, very fine platinum wire enclosed in a small, evacuated glass bulb. In good thermal (but not electric) contact with the center of this wire is placed one junction of a small thermocouple composed of platinum platinum-rhodium wires (or other metals), the other junction being kept at the constant temperature for which the instrument has been calibrated. When the unknown current is turned on, it heats the fine platinum wire slightly, and sets up a change of electromotive force in the couple which bears a definite relation to the heating current, as determined by calibration with known currents. This voltage change may, if necessary, be amplified by a d-c **amplifier** in order to make it measurable. The glass bulb containing the thermocouple must be housed in a heat-insulating, opaque box or case to prevent heat from reaching the couple by either radiation or conduction, and thoroughly evacuated to avoid convection. (L.D.W.)

VACUUM TUBE. Tube, Electron; Crookes Tube; Ionized Charge; Triode.

VACUUM-TUBE VOLTMETER. Instruments, Electrical.

VADOSE. A geologic term referring to a type of circulating underground water. (R.M.F.)

VAGINA. A sheath. The term is most familiar in reference to the terminal portion of the female genital passages, which receives the intromittent organ of the male during **copulation**. This canal extends from the **vulva** upward to the **cervix** of the **uterus**, and is 3–3½" long. The term vagina is also used in anatomy to designate other sheath-like structures, such as the fibrous sheath of tendons. This structure is called a vagina fibrosa when solid and a vagina mucosa when it contains a fluid-filled cavity surrounding the tendon. (A.W.L., R.S.M.)

VALENCE. Valence is the capacity of an **atom** to combine with other atoms to form a **molecule**. It is specified as the number of **hydrogen** atoms or twice the number of **oxygen** atoms with which one atom of the element under question will combine. Thus nitrogen has the valence 3,2,4,5 in the compounds NH_3, NO, NO_2, N_2O_5. A further distinction is made by considering positive and negative valences. If the hydrogen is assigned the valence of plus one, and oxygen that of minus two, and if the valences in a compound are made to total up to zero, we have a formal scheme of positive and negative valences. In ammonia, NH_3, the three hydrogen atoms each with a valence of plus one exactly balance the one nitrogen atom with the valence of negative three. Many atoms possess more than one valence,

but the principal valence is correlated with the periodic table and the **atomic structure** of the atom. (See **Chemical Composition.**) The inert gases have the valence zero. The principal positive valence is the number of the group in which the element falls in the periodic table. Thus hydrogen is one, **lithium** also one, **boron** three, etc. The negative valence is eight minus the number of the group in the periodic table. Negative valences greater than four do not occur. For example, oxygen has the valence of eight minus six, that is two negative in H_2O (water); and nitrogen has the valence of eight minus five, that is three negative in NH_3 (ammonia).

On the basis of modern electronic theory of atomic structure we can classify the different types of valence. The guiding principle is that the atoms tend to assume an inert gas electronic structure of eight **electrons** in the outer shell (in the case of hydrogen it is two). To do this the atom either loses to, gains from, or shares with other atoms, electrons. This process leads to molecule formation. The following are the principal types of valences and their electronic interpretation.

Electrovalence or polar valence is associated with a transfer of an electron from one element to the other in order to complete by such a transfer the octet of each element. Thus in sodium chloride the sodium atom has one valence electron outside a closed octet of eight. By loss of this electron the **sodium** atom becomes positively charged sodium **ion** because the nuclear positive charge exceeds that of the electrons by one. On the other hand, the **chlorine** atom has a grouping of seven electrons in the outer shell. It picks up another electron to complete its outer shell to an octet, but in so doing obtains a total charge of one minus, becoming a chloride ion. The result is that in sodium chloride we are not dealing with sodium atoms and chlorine atoms but with sodium and chloride ions. This is experimentally substantiated. The forces holding the ions together are the **electrostatic forces,** which are equal to the product of the electronic charges on the ions divided by the product of the separation squared times the dielectric constant of the medium. Thus when the sodium chloride **crystal** is placed in solvent of high **dielectric constant** such as water, the forces between the ions are weakened and the ions float away from each other. In other words, electrolytic **dissociation** takes place. It must be noted that polar valences have no specific directional effects in space. The electrostatic attraction is best satisfied by a close packing of the ions. Inasmuch as there are large stray electric fields present in polar compounds, they possess a high melting point and considerable hardness.

Homopolar or covalent bonds are formed by a different mechanism. Here again we have as the basis the tendency of each atom to complete its outer shell of electrons to eight, or in the case of hydrogen to a doublet. In contrast to polar valence, in covalence we have no direct transfer of electrons, but merely a sharing. In the case of molecular hydrogen each hydrogen atom with its one electron shares this electron with the other hydrogen. The result is that each atom in the molecule has at least part of the time a complete shell of two electrons. The electrons can be visualized as traveling in orbits encompassing the two hydrogen nuclei. It is a property of the covalent bond that it is not weakened by electrolytic solvents and that it has a definite direction in space. These directional effects of covalent bonds are expressed in stereochemistry. Thus, for example, the four valence bonds of the carbon atoms are arranged to extend from the center of a tetrahedron to the four corners. Furthermore, since there is a one-to-one saturation of the electron forces, the stray electric fields are negligible, the melting points are low, and the crystals are soft.

Another type of bond which occurs in solids is the metallic bond. It can be considered as an extreme case of sharing of electrons in that an electron gas (present in the crystal lattice) is shared not by two ions but by all the ions in the lattice. This electron gas is responsible for the metallic properties of certain solids, especially for thermal and electrical conductivity. (R.K.S.)

VALLEY BREEZE. On hot days, uneven terrain gives rise to uphill breezes, i.e., from the valley up mountain or hill slopes. This breeze is known as a valley breeze; it is an anabatic wind. With sunset, the breeze dies. Valley breezes are seldom strong. (P.E.K.)

VALVE. For the meaning of this term as used in engineering, see **Valves.** For the meaning of valve as used in radio, see **Rectifiers.**

In zoology, a valve is a structure that regulates the flow of materials through a tubular organ. It may consist either of a muscular band in the wall of the organ or of a system of flaps that close together to impede flow in one direction.

The valves of the alimentary tract (**Digestive System**) are of the former type, consisting of a **sphincter** muscle encircling the tract within a projecting ridge of its lining. The chief valves are the **pyloric** at the union of the stomach with the **duodenum** and the ileo-colic at the junction of the small and large intestines.

In the **circulatory system** valves are highly developed in the vertebrate **heart** and appear in some tubular vessels. The latter, in **vertebrates,** are limited to the **lymphatic** vessels and veins of the extremities. They consist of paired folds of the lining with their convex surfaces toward the passage. Pressure against this surface separates the flaps of the valves, while pressure against their concave faces forces them together and blocks the passage.

In the heart the passages from veins to heart, from auricles to ventricles, and from heart to arteries are guarded by valves composed of two or three flaps, and in the fishes (**Pisces**) the proximal part of the ventral aorta is in some species developed as a valvular conus arteriosus. In the **mammalian** heart the openings of the pulmonary artery and aorta are guarded by valves of three parts, known as the semilunar valves. The valve between the right auricle and ventricle is also 3-parted, and is called the tricuspid, while the mitral valve between the left auricle and ventricle has only two flaps. These last valves are reinforced by slender chordae tendineae extending from their edges to the opposite walls of the ventricles. The heart also has a valve of Thebesius or coronary valve at the opening of the coronary sinus and a Eustachian valve at the opening of the inferior vena cava. (A.W.L.)

VALVE GEAR. The mechanical linkage by which the valves of an engine derive their motion and timing from the crankshaft rotation is called, collectively, the valve gear. The term is not restricted to any type of engine but is in more frequent use, perhaps, in the steam engine field. Here, both the internal combustion and steam engine gear will be described.

With very few exceptions, the internal combustion engine uses a poppet valve, which is actuated by a short reciprocation, the amplitude of which is well within the ability of a cam to produce. The cam is also an economical method of converting rotation to reciprocation for multi-cylinder engines because of the comparative ease with which a number of cams may be machined on a single shaft. The poppet valve is retained against its seat by a strong spring. When it is to be opened, a rod or lever is pressed against it, and moved far enough to create the necessary valve lift. This lifting motion is derived from the cam through a cam follower, and tappet rods or push rods, as illustrated in Figs. 1 and 2. The camshaft itself is driven from the

crankshaft. Camshaft drive must be positive, so gears or chains are always used.

Two variations of valve gear suitable for in-line engines are pictured in Fig. 1. As both types are drawn

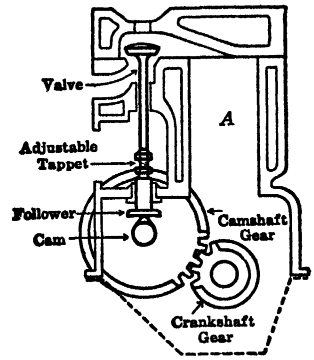


Fig. 1*A*. L head valve arrangement.

for the same bore and stroke, the figures demonstrate the effect of valve placement and valve gear space needs upon the engine shape. These sketches are intended to be illustrative of valve gear only and many essential engine details (i.e., valve springs, piston, etc.) are purposely omitted. Fig. 1*A* represents a common arrangement of the gear in an L head four-cycle gasoline engine. The camshaft is gear-driven from the crankshaft at half speed. The cam bears against a flat follower which raises a tappet, whose pressure against the valve stem then accomplishes the valve opening. The beginning of valve motion is a function of the mesh of the gears and can be altered by placing different teeth in mesh. The height and duration of valve lift are determined by the cam profile. Because of the likelihood of unequal thermal expansion of the valve gear and the cylinder barrel a slight clearance is introduced between tappet and valve stem to prevent the valve from continuously riding open when hot. This clearance should be precisely maintained within a thousandth of an inch of the builder's recommendation. Adjustments, either at the tappet or rocker arm (case B) are provided for this purpose. To prevent valve gear noise arising from the cyclical closure of this clearance, special devices such as hydraulic tappets have sometimes been used. These keep the above-mentioned clearance closed when the engine is running but yield and compensate for expansion before the valve will ride from its seat in closed position. The overhead valve (*B*) requires a few more parts in its valve gear but is often used by engine builders on account of thermodynamic benefits associated with this location.

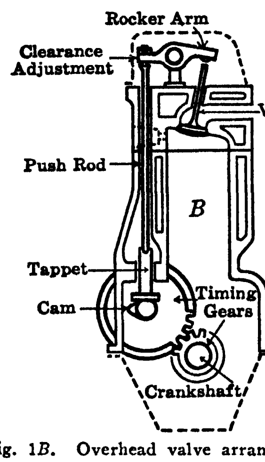

Fig. 1*B*. Overhead valve arrangement.

Some radial engines have been built with a short two-cam camshaft for each cylinder. However, a more common gear for these engines is the multiple lobe cam mounted on a drum (Fig. 2). A radial engine is built

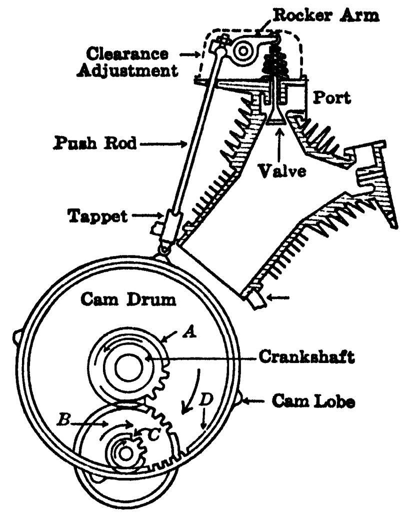

Fig. 2. Radial engine valve gear.

with an odd number of cylinders for each row so that cylinders may be fired alternately (i.e., firing order 1–3–5–7–9–2–4–6–8 for nine cylinders) in the interest of good dynamic balance. A plate cam with four lobes, revolving oppositely to the crankshaft rotation at one-eighth speed will accomplish the operation of the inlet valves necessary for this type of firing order. Another group of four lobes offset from the inlet group will attend to the requisite exhaust valve motion. The gear *A* is mounted tightly on the crankshaft and turns gears *B* and *C* which are integral and mounted on a fixed pivot. *C* meshes internally with gear *D* which is cut on the inside of the cam drum. The cam drum has a bearing on the crankshaft. The combined reduction of *A*, *B*, *C* and *D* is 8:1 and it will be observed that *D* has rotation opposite to *A*.

The steam engine valve gear (Fig. 3) is found in varied forms of many mechanical details. Furthermore,

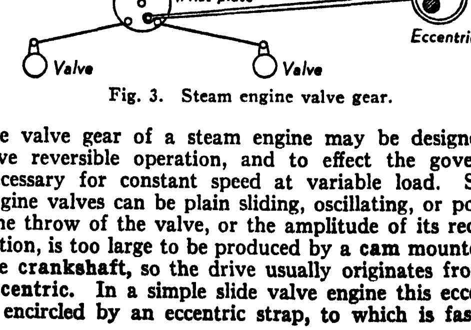

Fig. 3. Steam engine valve gear.

the valve gear of a steam engine may be designed to give reversible operation, and to effect the governing necessary for constant speed at variable load. Steam engine valves can be plain sliding, oscillating, or poppet. The throw of the valve, or the amplitude of its reciprocation, is too large to be produced by a cam mounted on the crankshaft, so the drive usually originates from an eccentric. In a simple slide valve engine this eccentric is encircled by an eccentric strap, to which is fastened

an eccentric rod. The eccentric rod is pinned to the valve stem so that the rotation of the crankshaft will reciprocate the valve. Steam engines which are governed by the cut-off method have the governor action interposed between the crankshaft and the eccentric, that is, the eccentric is not keyed to the shaft, but is free thereon, being maintained in a position relative to the engine crank, determined by the load and controlled by the governor.

Engines with oscillating valves derive their motivation from an eccentric on the crankshaft, but there is interposed between the eccentric rod and the valve a wrist plate and valve reach rods. The Corliss engine is like this. In a simple slide valve engine the eccentric angle leads the crank angle in the direction of rotation by a definite amount. If two eccentrics are provided, one on either side of the crank by this same angle, then the engine could be operated forward or reverse if the valve could be driven from either of the eccentrics. This idea is incorporated in the Stephenson valve gear. In locomotive practice, more flexibility of control than is possible in the simple valve gear just described is desired, and the gear used in most locomotives is a type

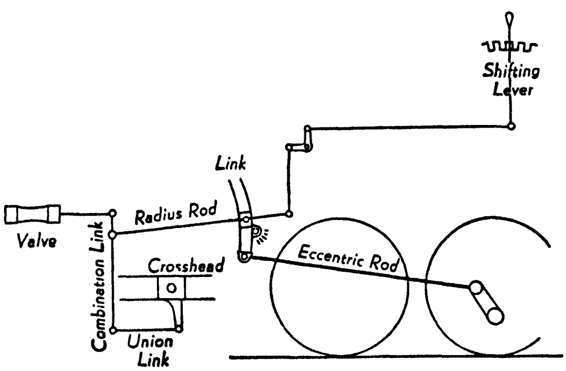

Fig. 4. Walschaert's locomotive valve gear.

which derives part of its motion from the crosshead, and part from the crankshaft. A detailed description of this gear is not in order; however, a skeleton diagram of the linkage is given in Fig. 4. (F.T.M.)

VALVES, ENGINE. Engine valves are the closures of the ports of entry or exit of the working medium of engines—steam, Otto, or Diesel. Correct execution of the thermodynamic cycle of operation of a heat engine is dependent upon precision timing of the valve motion, admitting and releasing the working medium:

Valve types may be classified as:

1. *Sliding.* *D* slide valves, piston valves, and other steam engine types.
2. *Oscillating.* Corliss valve.
3. *Poppet.* Reciprocating, but not sliding. Mushroom and tulip valves of internal combustion engines. Balanced poppet valves for steam engines.

Valves are actuated, and timed relative to the cycle of operation, by the kinematics of the valve gear. (See **Otto Engine, Steam Engine, Valve Gear.**) (F.T.M.)

VALVES, PIPE. A pipe valve is a pipe line accessory used to start, stop, and regulate fluid flows. It consists of a body to house it and to give a means of connecting it to the pipe, a valve seat, a valve, a valve stem, a top, a means of operating the stem—usually screw and hand wheel, and a packing to prevent leakage around the stem as it emerges from the top. Valves are furnished for either screwed or flanged connection. They are made of brass, bronze, malleable iron, cast iron, cast steel, and forged steel. Cast and forged steel are employed in high pressure-temperature service. Valve sealing materials (sometimes constituting the valve seat, sometimes attached to the valve face) include rubber for cold water, brass and bronze for ordinary temperatures, stainless steel, monel metal, and various other alloys for high temperatures.

Fig. 1. Fig. 2.

Fig. 1. Section through a gate valve. A. Hand wheel; B. Wheel nut; C. Spindle; D. Packing nut; E. Gland; F. Packing box; G. Packing box nipple; H. Spindle collar; I. Bonnet; J. Solid wedge; K. Body.

Fig. 2. Section through angle type of globe valve. A. Hand wheel; B. Index plate; C. Hand wheel nut; D. Spindle; E. Packing nut; F. Gland; G. Packing box; H. Bonnet; I. Disk holder; J. Composition disk or washer; K. Body.

Valves most used are the ordinary hand-operated globe and gate valves, and the check valves. These are classified thus:

1. Globe valves (straight and angle).
   a. Inside screw; outside screw.
   b. Screw bonnet top; bolted yoke top.
2. Gate valves (straight and angle).
   a. Rising stem; non-rising stem.
   b. Wedge valve (split and solid); parallel seat valve.
3. Check valves (lift and swing types).
   a. For vertical pipe.
   b. For horizontal pipe.

The globe valves do not allow a line to drain completely; also, they offer more frictional resistance than gate valves. They are frequently used in very small

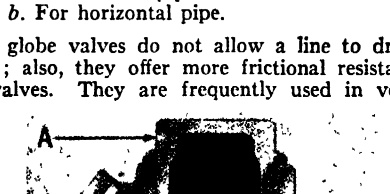

Fig. 3. Horizontal swing check valve. (*Jenkins Brothers.*) A. Cap; B. Hanger pin; C. Hanger; D. Hanger nut; E. Disk; F. Body.

lines (both water and steam) and where the valve is to be used for throttling, as they can be closely regulated and the seats, which are liable to be cut away in throt-

tling service, can be more easily replaced than in gate valves. Gate valves are used in large pipe lines, in high-pressure steam lines, and in all service where small friction loss is wanted. The gate valves are more expensive than the globe, and their longer stems require more clearance space for operation.

Special valves of a great many types are also employed in piping systems. (F.T.M.)

VAMPIRE. Mammalia, Chiroptera. Tropical American blood-eating **bats**, *Desmodus rufus* and *Diphylla ecaudata*. These animals are provided with incisor teeth formed to produce a peculiar wound that bleeds very freely without giving pain. They differ from ordinary bats in locomotion, elevating the body on the legs and folded wings and walking thus on all-fours, scarcely making themselves felt by the animal on which they have alighted. They have been proved to drink blood by lapping, and not by sucking it from the wound. (A.W.L.)

VAN DER WAALS' EQUATION. **Characteristic Equations.**

VANADINITE. The mineral vanadinite corresponds to the formula $(PbCl)Pb_4(VO_4)_3$, being composed of **lead chloride** and **lead vanadate** in the proportion of 90.2% of the former and 9.8% of the latter. It crystallizes in the **hexagonal** system, is usually prismatic, but the crystals are often skeletal or cavernous; it may be found in crusts. Its fracture is uneven; brittle; hardness, 2.75–3; specific gravity, 6.7–7.2; fresh fractures show a resinous luster; color, yellow, yellowish-brown, reddish-brown, and red; streak, white to yellowish; translucent to opaque. Vanadinite, by no means a common mineral, occurs as an alteration product in lead deposits. It is found in the Urals, Austria, Spain, Scotland, Morocco, the Transvaal, Argentina, and Mexico. In the United States it occurs in Arizona, New Mexico, and South Dakota. It is used as an ore of vanadium and to some extent of lead as well. It is interesting to note that this mineral was first described as a chromate upon its discovery in Mexico in 1801. It was not until the discovery of the metal vanadium in 1830 that the true nature of this compound was known. (E.S.C.S.)

VANADIUM. Symbol: V. Atomic number: 23. Atomic weight: 50.95. Density: 5.69. Melting point: 1710° C. No isotope, but of single atomic form: 51.

Vanadium is a silver-white, very hard (Mohs' scale of hardness 7) metal; oxidizes upon being exposed to air, and upon ignition forms the pentoxide; insoluble in **hydrochloric acid**, slowly dissolves in **hydrofluoric**, nitric, or **sulfuric acids** (hot, concentrated), or **aqua regia**; insoluble in **sodium** hydroxide solution. Discovered by Del Rio in 1801. Subsequent investigations made by Sefstrom, Wohler, and Berzelius, all about 1830, and by Roscoe in 1868, are of great interest.

Most of the vanadium of commerce is used in the form of ferro-vanadium (30–40% V) in the manufacture of special alloy **steels** to which vanadium (not usually exceeding 1%, and as low as 0.2%) imparts hardness and toughness, and increases the elastic limit and resistance to shock or impact. Vanadium steel is used for tools and in the construction of vehicles.

Vanadium occurs as **patronite**, containing vanadium pentasulfide, in Peru, as **carnotite**, potassium uranyl vanadate, in Colorado and Utah, as **vanadinite**, lead vanadate, in Arizona, New Mexico, South East Africa, and northern Rhodesia. Ships burning Venezuelan or Mexican petroleum fuel oil recover vanadium oxide from the boiler and stack dust. In Italy the refining of bauxite ore (for aluminum) yields vanadium, and in Germany some iron ores contain vanadium. Vanadium and radium ore is found in southwestern Colorado and southeastern Utah; in Arizona a complex ore of gold, silver, and lead contains vanadium and molybdenum; and extensive deposits of phosphate rock in Idaho may prove to be our principal source of vanadium. The sulfide ore is roasted to remove **sulfur**, and the residue fused with sodium carbonate, forming sodium vanadate. This last is extracted with water and excess of sulfuric acid is added, causing precipitation of vanadium pentoxide, which is later reduced by carbon or aluminum at high temperatures.

Chlorides: Vanadium dichloride (VCl_2), green crystalline solid, a strong reducing agent; vanadium trichloride (VCl_3), pink crystalline solid; vanadium tetrachloride (VCl_4), reddish-brown liquid, boiling point 148° C.

Hydroxides: Vanadium dihydroxide ($V(OH)_2$), brown precipitate by reaction of **sodium** hydroxide solution with hypovanadous acid (one of the most powerful of reducing agents) lavender solution; vanadous hydroxide ($V(OH)_3$), green precipitate by reaction of sodium hydroxide solution with vanadous salt green solution.

Oxides: Vanadium monoxide (VO), gray solid; vanadium trioxide (V_2O_3), black solid; vanadium dioxide (VO_2), dark blue solid; vanadium pentoxide (V_2O_5), orange to red solid. The last is the most important oxide; formed by the ignition in air of vanadium sulfide, or other oxide, or vanadium; used as a catalyzer, e.g., the reaction sulfur dioxide gas plus oxygen of air to form sulfur trioxide, and the oxidation of naphthalene by air to form phthalic anhydride.

Sulfides: Vanadium monosulfide (VS); vanadium trisulfide (V_2S_3), most stable; vanadium pentasulfide (V_2S_5).

Vanadium is usually encountered as vanadate (vanadium of valence plus 5), which in acid solution is reduced by zinc metal successively to blue (vanadium of valence plus 4), green (vanadium of valence plus 2). The oxidation-reduction relations of vanadium element are among the most interesting of all the metals.

Common tests for vanadium are:

1. Inorganic and organic reducing agents convert the vanadates into blue vanadyl compounds.

2. Vanadic acid treated with hydrogen peroxide produces a reddish-brown color insoluble in ether (difference from chromates). (R.K.S.)

VANDYKE. **Drawing Reproduction.**

VANILLIN. **Aldehydes, Ketones, and Related Compounds.**

VANISHING POINT. **Perspective.**

VAN'T HOFF LAW. **Equilibrium.**

VAPOR CYCLE. A vapor cycle is so named from the fact that it uses the same **vapor** over and over again, passing it around a closed loop and subjecting it to various **thermodynamic** changes by means of which useful energy is produced from raw heat.

In the process of conversion of the heat of a **fuel** into a useful form of energy there are three essentials: First, a heat absorber where the heat liberated by **combustion** of the fuel is absorbed by the working medium; second, a heat utilizer in which as much of the heat as is available is taken from the working medium and converted into a useful form of energy; third, the working medium itself passing back and forth between the first two—a carrier of heat energy. The thermodynamic aspects of its passage from the heat absorber to the heat utilizer and back again constitute the vapor cycle. (See **Rankine Cycle, Regenerative Cycle, Reheating, Mercury Vapor Cycle.**) (F.T.M.)

VAPOR LOCK. Volatility of **gasoline** makes for easier starting of an **engine** using it, but creates one

undesirable feature, namely, vapor lock. This phenomenon is associated with the fuel supply to internal combustion engines. It occurs mainly in the fuel lines conveying a volatile fuel such as gasoline. If the fuel line from supply tank to engine has many bends and fittings, if it is exposed to engine heat, or if parts of it are under vacuum, bubbles of fuel vapor may form in the lines, causing irregular engine operation, or even stoppage. While this condition might sometimes occur initially in a fixed engine supply system, once remedied it is not liable to recur. On the other hand, vehicular engines may be operated under more varied conditions of temperature and altitude; hence are more frequently troubled with vapor lock. Manufacturers of automobiles and other surface vehicles had to design gasoline supply systems with possible vapor lock in mind. Except for unusual extremes of operating conditions, such vehicles seldom encounter vapor lock nowadays. When an automobile engine is used at high altitude or in desert heat without special modification of the fuel system, some trouble may develop from vapor lock. Temporary relief may be secured by chilling the fuel lines and insulating them from engine heat.

Airplane builders also encounter vapor lock difficulties, due principally to altitude. Except for small, low-ceiling airplanes, fuel pumps have superseded gravity supply. When fuel pumps were first introduced vapor lock troubles disappeared—only to reappear as airplanes began to be operated at altitudes above approximately 15,000′. Stoppages persisted in occurring after experimental elimination of the possibility of fuel vaporization. Then it was found that considerable air was dissolved in the fuel, and began to separate from it and airbind pumps and other parts of the supply systems at high altitudes. Although this might have been called "air lock," it remained customary to refer to all such phenomena as vapor lock. Upon installation of separators which allowed removal of gas and vapor from strategic points in the system, engines could be operated to very high altitudes without vapor lock trouble. (F.T.M.)

VAPOR PRESSURE. The vapor pressure of a substance (solid or liquid) is the pressure exerted by its vapor when in **equilibrium** with the substance. For pure substances it depends only on the temperature. The simplest way to measure the vapor pressure of a substance is to introduce a small amount of it into the closed end of a barometer tube and note the decrease in the height of the barometer. (See table below.)

The vapor pressure of a **solvent** is lowered on dissolving the solute in it. This lowering for dilute solutions is proportional to the mole fraction of the solute (**Raoult's Law**). The lowering of the vapor pressure of the solution can be related to the lowering of the freezing point and the elevation of the boiling point. These phenomena serve as a basis for **molecular weight** determinations. If both components of the solution are volatile, each lowers the vapor pressure of the other and the ratios of the two substances in the liquid and vapor phase are not necessarily the same. Use is made of this fact to separate the two substances by **distillation.** (See **Deliquescence, Efflorescence,** and **Water.**) (R.K.S.)

VAPOR PRESSURE THERMOMETER. Thermometry.

VAPORS. A substance in the gaseous state, but below its critical temperature, is called a vapor. If a pure liquid partly filling a closed container is allowed to stand, the space above it becomes filled with the vapor of the liquid, which develops a pressure. This **vapor pressure** increases up to a certain limit, depending upon the temperature, where it becomes constant, and the space is then said to be saturated.

Such a body of vapor is not subject to all of the laws of gases. If the space occupied by it is diminished without change of temperature, there is no increase in pressure, but instead part of the vapor condenses. And if the temperature is raised, the pressure goes up not at a uniform but at an increasing rate, because of both the expansion of the liquid and the further **evaporation** from it. The relation of vapor to liquid takes on a curious aspect as the **critical state** is approached, in which the vapor and the liquid have equal density.

The **characteristic equations** applying to vapors are of various forms, differing somewhat from those for gases. A typical empirical equation of the sort, proposed by Callendar to represent the behavior of steam, is

$$v = \frac{RT}{p} + f(T) + c,$$

VAPOR PRESSURE OF SOME SUBSTANCES AT VARIOUS TEMPERATURES IN MILLIMETERS OF MERCURY EXCEPT AS STATED

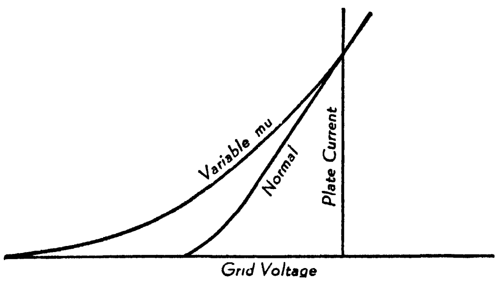
in which R is the ideal gas constant, c is a constant to be obtained empirically, and $f(T)$ is a slowly varying function of the absolute temperature T. (L.D.W.)

VARIABILITY. Dispersion.

VARIABLE. A symbol which represents any one of a set of numbers (or elements of any kind) is said to be a variable. The elements of the set are called values of the variable, and the set of elements itself is called the range of the variable. (L.L.S.)

VARIABLE MU TUBE. This is a vacuum **tube** with a **grid** so constructed as to give a variable **amplification factor.** To accomplish this the spacing of the grid wires is not constant but varies regularly along the grid. The result is that the mutual conductance characteristic of the tube approaches the grid-voltage axis very gradually rather than abruptly as in tubes of other types. The figure shows the characteristics of both conventional and variable mu tubes. Since the slope



of this curve is the mutual conductance of the tube, it will be apparent at once that the mutual conductance of the variable mu tube may be varied over a wide range by varying the operating bias of the tube. This property is utilized in all standard **automatic volume control** circuits, the gain of the tube being controlled by the bias voltage which is obtained from the rectifier **carrier.** (L.R.Q.)

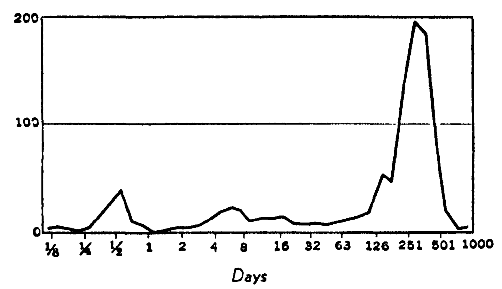
VARIABLE SPEED TRANSMISSION. Speed Changers.

VARIABLE STARS. Any star whose light is known to fluctuate is called a variable star. There is evidence that the ancients noticed certain temporary stars, now known as **novae,** and that the star **Algol** was recognized by them as a variable. The first definite record that we have of observation of a variable star is in connection with observations of **Mira** during the late 16th and early 17th centuries. In 1844, Argelander published the first catalogue of variable stars which contained eighteen entries. The publication of this catalogue stirred up a great deal of interest in variable stars and they became objects of much search and study.

At the present time most variable stars are discovered from examination of photographic plates, taken at different times, of the same region of the sky. At present over 10,000 variables are known, and it is estimated that at least 5% of all stars are at least slightly variable. When a variable star is first observed it is assigned a serial number in order of discovery within the year, together with the year of discovery (e.g., 256,1923 designates the 256th variable discovered in 1923). After a sufficient number of observations have been taken to confirm the variability of the star and the fact that it is really a discovery, the star is assigned letters, in accordance with a system established by Bayer, followed by the genitive case of the **constellation** within which the object is located (e.g., RZ Herculis). Novae are not included in this system of classification, being referred to by "nova" followed by the genitive case of the constellation and the year of discovery (e.g., Nova Herculis 1934).

The observation of variable stars consists essentially in systematic **photometric** observations of the objects over long periods of time. The methods employed are essentially those of stellar **photometry** and these will be found discussed elsewhere in this volume. The observations are carried on not only by professional astronomers at many observatories all over the world, but also by an enthusiastic group of amateurs who have banded themselves together in societies for the purpose of carrying on this valuable work. In the United States, the American Association of Variable Star Observers, commonly known as AAVSO, has its headquarters at the Harvard College Observatory, holds two general meetings each year, and its membership contributes thousands of observations annually. Its membership is open to anyone who is interested in astronomical observing, whether or not he has any equipment other than eyesight and enthusiasm.

When a sufficient number of observations of the magnitude of a variable have been obtained, a **light curve** is plotted and the study of the characteristics of the object is undertaken. Variable stars divide themselves into two natural groups: the periodic and non-periodic variables. In the accompanying figure the number of periodic variable stars within certain limits of period is



Distribution of periods of variable stars. (*Russell, Dugan and Stewart, Astronomy, Ginn & Co.*)

plotted as ordinate against the logarithm of the period in days. Examination of the figure indicates that there are three principal groups of periodic variables: one group with periods of less than 1 day, a second with periods between 3 and 50 days, and a large group with periods between 120 and 750 days. Periodic variables with periods under 50 days are known as **Cepheids,** while those with periods greater than 100 days are known as **long-period variables.** The non-periodic variables are divided into two groups: the novae and the **irregular variables.** We sometimes find **eclipsing binaries** referred to as eclipsing variables, but they are not variables in the exact sense of the term, since the apparent variation in light is not due to any intrinsic variability within the stars themselves, but is due to changes in configuration of the objects as seen from the earth. (W.K.G.)

VARIABLES OF STATE. Characteristic Equations.

VARIANCE. The variance is the square of the **standard deviation;** also the number of **degrees of freedom** of a system. (L.A.A., L.D.W.)

VARIATE. A variate is a particular value of the **variable.** The variable may be the temperature, but 70°, 72°, 73°, ···, etc., are variates. (L.A.A.)

VARIATE DIFFERENCE CORRELATION. Variate difference correlation consists of the **correlation** of the first differences of the two **variables** instead of cor-

relating the variables themselves. It is sometimes used in time series. (L.A.A.)

VARIATION. This term has a number of uses. It is applied in connection with the compass; and this topic is discussed in the article on **compass correction.** The term variation is also used in mathematics and biology, and these usages will be discussed in that order in this article.

Variation is a simple and important type of mathematical relationship between variables, which is of very frequent occurrence in physical problems.

If two **variables** x and y are related by the **power function** relationship $y = kx^n$, where k and n are constants, we say that y varies as x^n, or y varies as the n^{th} power of x, or that y is proportional to x^n. The factor k is called the constant of variation, or the constant of proportionality, or the proportionality factor.

Special cases are:

1. $(n = 1)$. If two variables are so related that their **ratio** is always constant, so that $y/x = k$ or $y = kx$ (k a constant), we say that y varies directly as x (or that y is proportional to x). The notation $y \propto x$ is sometimes used to express the fact that y varies directly as x.

2. $(n = -1)$. If two variables are so related that their product is always constant, so that $xy = k$ or $y = k/x$ (k a constant), we say that y varies inversely as x (or that y is inversely proportional to x).

Other types of variation are defined as follows:

If a variable z varies directly as the product of two variables x and y, so that $z = kxy$ (k constant), we say that z varies jointly as x and y.

If a variable z varies jointly as x and the **reciprocal** of y, so that $z = kx/y$, we say that z varies directly as x and inversely as y.

A common type of variation is one where a variable varies directly as the product of two variables and inversely as the square of another variable (as in the law of gravitation).

Instead of expressing variation statements by equations, we may express them as **proportions.** Thus, if y varies directly as x, we may write $y_1 : y_2 = x_1 : x_2$; and if y varies inversely as x, we may write $y_1 : y_2 = x_2 : x_1$.

In biology, variation is the deviation of organisms from the mean development of their kind. Very few individuals are even approximately identical in form, although some species show a much wider range of variation than others.

The probable cause of variation is the interaction of diverse heritages with varying environmental conditions in the formation and maintenance of individuals. The study of **heredity** has disclosed an intricate reproductive mechanism for the maintenance of diversity in the heritage as one source of variation, and environmental conditions have been found correlated with variation in many cases.

As actual difference in living things variation is particularly interesting in the field of **evolution.** Here the heritability of variations is important, since evolutionary change sufficient to account for the origin of species can only be attained through a long succession of generations. Characteristics due to the variable heritage are obviously heritable. They are subject to change only through the process of **mutation,** as far as we know, hence this process becomes an important source of variations. Efforts to determine the cause of mutations have shown that they may result from the incidence of unusual environmental conditions, such as x-rays, terrestrial radiation, and radium emanations, and from more usual factors such as heat and moisture. Thus the most advanced information on the subject leads to the initial premise that variations are due to the intricacies of reaction between variable heritages and environments.

The actual variation of existing species has been studied extensively and is the subject of an extensive literature. Differences between individuals may be sexual, seasonal, or due to specialization within colonies. These types of variation are often extreme, resulting in individuals of very different structure and appearance. On a lesser scale the similar individuals of any species show incidental differences of no fundamental importance. (L.L.S., A.W.L.)

VARIATION OF LATITUDE. In the latter part of the 18th century the mathematician Euler predicted, from purely theoretical considerations, that the **latitude** of every point on the surface of the earth should be varying. The amount of this variation depends upon the shape, the elasticity, and other physical characteristics of the earth, together with the attractions of external objects, such as the **moon,** for our rotating **planet.** The first actual observations of variation of latitude were made in 1888, nearly a century after Euler's prediction, by the careful observations of the astronomer Kustner.

The effect may be described by considering the motion of a wheel, the bearings of which have become so worn that the axle fits loosely in the hub. When considering variation of latitude alone we consider the axis of the earth as fixed in space in spite of the fact that we know that it is actually slowly moving due to **precession** and nutation. As the earth slips slightly about on this axis the position of the pole of rotation wanders about over a small area in the vicinity of the average position of the pole. By definition the plane of the **equator** is perpendicular to the axis of rotation of the earth, and if this line moves, so also must the equator move. Since latitude is measured from the equator, the motion of the equator must produce a variation of latitude.

The actual amount of variation of latitude is a small quantity, the total area over which the pole moves being about the size of a baseball diamond. Nevertheless, small as the effect may be, it is appreciable and the date should be very carefully specified whenever defining boundary lines by means of latitude.

During the past 50 years a great mass of observational material has been gathered, but as yet the problem has not been completely solved. At present an international campaign is under way in connection with which a number of stations all over the earth are constantly at work observing the latitudes of their localities by use of the **zenith telescope.** (W.K.G.)

VARICELLA. Chickenpox.

VARICOCELE. Enlargement and dilatation of the veins surrounding the spermatic cord in the male. When this condition is marked the knot of varicose veins forms a swelling in the upper scrotum. Surgical interference is not wise unless the condition causes severe symptoms.

Ovarian varicocele is a similar condition in the female of the veins in the ligaments near the ovary. (R.S.M.)

VARICOSE VEINS. An enlarged tortuous condition of the superficial veins of the body. This disorder is most often seen in the legs and thighs.

Varicose veins are directly caused by any disorder that destroys or weakens the **valves in the veins,** whether it be infection or increase in the venous pressure such as from a **tumor,** pregnant uterus, or constriction of the leg from tight circular garters, or from constant standing, etc. A tendency toward varicose veins seems to be hereditary, and is probably due to the inheritance of weak valve structure in the veins, the basic cause of varicosities.

The symptoms caused by varicose veins are pain, cramps, or tired feeling in the legs, swelling of the ankles and legs when the condition is marked Complicating the later stages of varicose veins are **thrombophlebitis,** varicose **ulcers,** and **eczema.** Varicose ulcers over the legs are chronic and show little tendency to

heal because of the poor circulation. The eczema results from poor skin nutrition, also on a circulatory basis.

The treatment of varicose veins includes elevation of the extremities and rubber bandages to improve the venous return and prevent edema. Surgical ligation or excision of the veins obliterates the superficial venous channels and forces the blood to return by the deep veins. This objective is also accomplished by the injection of chemical sclerosing solutions into the veins, causing occlusion of the vessel lumen, fibrosis, and final complete obliteration of the diseased veins. (D.M.H., R.S.M.)

VARIEGATION. **Albinism.**

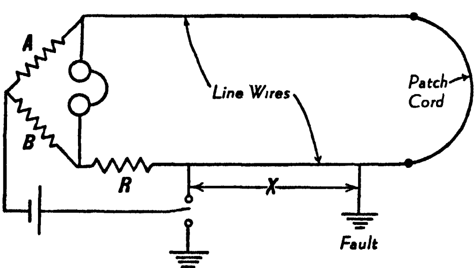
VARIOLA. **Smallpox.**

VARIOLES. Variolite.

VARIOLITE. A fine-grained basic rock that contains **spherulites** made up of fibers of **feldspar** and **augite** in radial development.

The spherulites themselves are known as varioles, and the texture of such rocks is said to be variolitic. The term is derived from the Latin *variola*, smallpox, given to the rock because of resemblance of the pea-like or pustular forms of the varioles on weathered surfaces to smallpox pustules. (E.S.C.S.)

VARLEY LOOP. This is a bridge-type measurement used by telephone engineers to locate line faults. The circuit is shown in the figure. The method differs



Circuit for Varley loop.

from the **Murray loop** in that the **resistance** of the line loop may be measured by throwing the switch up and balancing the bridge without changing any connections. When the switch is thrown down and the bridge again balanced, the distance X to the fault may be determined from the equation

$$X = \frac{BR_L - AR}{r(A + B)}.$$

Where A, B, and R are shown on the figure, R_L is the loop length times the resistance per ft., r. (L.R.Q.)

VARNISHES. **Pigments, Paints, Varnishes.**

VAS DEFERENS. **Urogenital System.**

VASCULAR ELEMENTS. The vascular elements of a plant are the tissues which serve to conduct materials in the plant. The principal tissues of the vascular system are the **xylem** and **phloem.** (R.M.W.)

VASCULAR SYSTEM. This is a complex system of cells and tissues called **xylem** and **phloem,** and serving to conduct water, mineral salts, and food through the plant. It also gives strength and support to the plant. It composes the bulk of the tissues of roots and stems of woody plants. (See **Translocation;** see also **Circulatory System** for a discussion of the vascular system of animals.) (R.M.W.)

VASCULAR TISSUE. **Blood, lymph,** and related fluids of the body. These liquids are regarded as tissues because they consist of characteristic cells lying in an intercellular substance. The liquid condition of the intercellular substance is responsible for their fluidity. (A.W.L.)

VECTOGRAPH. **Stereoscopic Photography.**

VECTOR ADDITION. Let **a** and **b** be any two vectors (Fig. 1). To add vector **b** to vector **a**, we place the origin of **b** at the terminus of **a**, then the vector **c** extending from the origin of **a** to the new terminus of **b**

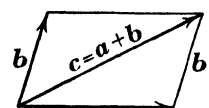


Fig. 1.

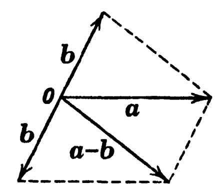

Fig. 2.

is defined as the sum (or resultant) of **a** and **b**, and is denoted by $\mathbf{a} + \mathbf{b}$. This operation is often called composition of vectors.

Vector addition obeys the **commutative** and **associative** laws of algebra: $\mathbf{a} + \mathbf{b} = \mathbf{b} + \mathbf{a}$, $(\mathbf{a} + \mathbf{b}) + \mathbf{c} = \mathbf{a} + (\mathbf{b} + \mathbf{c})$.

To subtract a vector **b** from a vector **a**, we take the negative of **b** and add $-\mathbf{b}$ to **a**. (Fig. 2.)

The components of a vector **a** are any vectors whose sum is **a**. The components most frequently used are parallel to a set of rectangular coordinate axes; these are called rectangular components. The operation of finding components of a given vector is often called the decomposition of the vector.

In order to be able to express a vector in terms of its rectangular components in convenient form, we take unit vectors parallel to the X, Y, Z axes of a **rectangular coordinate** system and denote them by $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$, $\hat{\mathbf{k}}$, respectively.

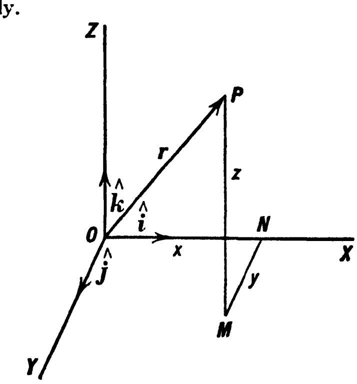

Fig. 3. Vector components.

In terms of the unit vectors $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$, $\hat{\mathbf{k}}$, we may express any given vector **r** with origin at the origin of the coordinate system by the form (Fig. 3)

$$\mathbf{r} = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}},$$

where x, y, z are the rectangular coordinates of the terminus of **r**. Then $x\hat{\mathbf{i}}$, $y\hat{\mathbf{j}}$, $z\hat{\mathbf{k}}$ are the rectangular components of **r**.

If $\mathbf{r} = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$, then the magnitude of **r** is $r = \sqrt{x^2 + y^2 + z^2}$, and the direction of **r** is given by the direction cosine relation $\cos\alpha : \cos\beta : \cos\gamma = x : y : z$.

If two vectors **a** and **b** have rectangular components a_1, a_2, a_3 and b_1, b_2, b_3 in magnitude, then to add **a** and **b**, we have

$$\mathbf{a} + \mathbf{b} = (a_1 + b_1)\hat{\mathbf{i}} + (a_2 + b_2)\hat{\mathbf{j}} + (a_3 + b_3)\hat{\mathbf{k}}.$$

Let a vector **a** have rectangular components a_1, a_2, a_3 (in magnitude) with respect to a first set of rectangular coordinate axes X, Y, Z, and components a'_1, a'_2, a'_3 (in magnitude) with respect to any other set of rectangular axes, with the same origin. Let the relations of the axes be given by the following scheme of direction cosines:

	X	Y	Z
X'	l_1	l_2	l_3
Y'	m_1	m_2	m_3
Z'	n_1	n_2	n_3

where l_1, l_2, l_3 are the cosines of the angles which the X, Y, Z axes make with the X' axis, and similarly for the m's and n's. Then the formulae for **transformation of coordinates** are:

$$\begin{aligned} x' &= l_1x + l_2y + l_3z, & x &= l_1x' + m_1y' + n_1z', \\ y' &= m_1x + m_2y + m_3z, & y &= l_2x' + m_2y' + n_2z', \\ z' &= n_1x + n_2y + n_3z, & z &= l_3x' + m_3y' + n_3z'. \end{aligned}$$

Then the vector components must transform in a similar way:

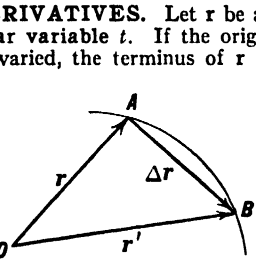
$$\begin{aligned} a'_1 &= l_1a_1 + l_2a_2 + l_3a_3, & a_1 &= l_1a'_1 + m_1a'_2 + n_1a'_3, \\ a'_2 &= m_1a_1 + m_2a_2 + m_3a_3, & a_2 &= l_2a'_1 + m_2a'_2 + n_2a'_3, \\ a'_3 &= n_1a_1 + n_2a_2 + n_3a_3, & a_3 &= l_3a'_1 + m_3a'_2 + n_3a'_3 \end{aligned}$$

(L.L.S.)

VECTOR ANALYSIS. The name Vector Analysis is usually applied to the study of the properties and applications of **vectors**. It may be described also as the Algebra, the Geometry, and the Calculus of Vectors.

The principal topics relating to Vector Analysis are: **Vectors, Vector Addition, Vector Multiplication, Scalar Product of Two Vectors, Vector Product of Two Vectors, Triple Products of Vectors, Vector Geometry, Vector Derivatives, Vector Integrals, Line Integral of Vector Function, Surface Integral of Vector Function, Gradient of a Scalar Function, Divergence of a Vector Function, Curl of a Vector Function, Linear Vector Function, Dyadics.** (L.L.S.)

VECTOR DERIVATIVES. Let **r** be a **vector function** of a **scalar variable** t. If the origin of **r** is kept fixed and t is varied, the terminus of **r** will describe a



curve. Let A and B be two neighboring points on this curve, and let **r** and **r**$'$ be their position vectors, then $\mathbf{r}' - \mathbf{r} = \Delta\mathbf{r}$ is a vector increment of **r**; it is a vector having the direction of the secant AB, which approaches the **tangent to the curve** at A as B approaches A. Let Δt be the change (increment) in t corresponding to the increment $\Delta\mathbf{r}$ of **r**. Form the ratio $\Delta\mathbf{r}/\Delta t$. If $\lim_{\Delta t \to 0} \frac{\Delta\mathbf{r}}{\Delta t}$ exists, it is called the **derivative of r** with respect to t, and is denoted by $\frac{d\mathbf{r}}{dt}$. It is a vector tangent to the curve described by the terminus of **r**.

If $\mathbf{r} = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$, and if x, y, z are functions of a scalar variable t, then

$$\frac{d\mathbf{r}}{dt} = \hat{\mathbf{i}}\frac{dx}{dt} + \hat{\mathbf{j}}\frac{dy}{dt} + \hat{\mathbf{k}}\frac{dz}{dt},$$

$$\frac{d^2\mathbf{r}}{dt^2} = \hat{\mathbf{i}}\frac{d^2x}{dt^2} + \hat{\mathbf{j}}\frac{d^2y}{dt^2} + \hat{\mathbf{k}}\frac{d^2z}{dt^2}.$$

If **r** is the position vector of a particle and if t is the time, then $\frac{d\mathbf{r}}{dt}$ will represent the vector velocity and $\frac{d^2\mathbf{r}}{dt^2}$ the vector acceleration of the particle.

If **r** is constant in magnitude but variable in direction, then $\frac{d\mathbf{r}}{dt}$ is perpendicular to **r**.

Let **u**, **v**, **w** be vector functions of a scalar variable t. Then the vector derivatives of various types of **products of vectors** are given by the following formulae:

$$\frac{d}{dt}(\mathbf{u} \cdot \mathbf{v}) = \frac{d\mathbf{u}}{dt} \cdot \mathbf{v} + \mathbf{u} \cdot \frac{d\mathbf{v}}{dt},$$

$$\frac{d}{dt}(\mathbf{u} \times \mathbf{v}) = \frac{d\mathbf{u}}{dt} \times \mathbf{v} + \mathbf{u} \times \frac{d\mathbf{v}}{dt},$$

$$\frac{d}{dt}[\mathbf{u} \cdot (\mathbf{v} \times \mathbf{w})] = \frac{d\mathbf{u}}{dt} \cdot (\mathbf{v} \times \mathbf{w}) + \mathbf{u} \cdot \left(\frac{d\mathbf{v}}{dt} \times \mathbf{w}\right) + \mathbf{u} \cdot \left(\mathbf{v} \times \frac{d\mathbf{w}}{dt}\right),$$

$$\frac{d}{dt}[\mathbf{u} \times (\mathbf{v} \times \mathbf{w})] = \frac{d\mathbf{u}}{dt} \times (\mathbf{v} \times \mathbf{w}) + \mathbf{u} \times \left(\frac{d\mathbf{v}}{dt} \times \mathbf{w}\right) + \mathbf{u} \times \left(\mathbf{v} \times \frac{d\mathbf{w}}{dt}\right).$$

If we have given a vector function of several independent scalar variables, its **partial derivatives** may be defined in a manner similar to that for scalar functions of several variables.

The symbolic vector expression

$$\hat{\mathbf{i}}\frac{\partial}{\partial x} + \hat{\mathbf{j}}\frac{\partial}{\partial y} + \hat{\mathbf{k}}\frac{\partial}{\partial z}$$

is denoted by Δ and is usually called "del" (occasionally "nabla"). When applied directly to a scalar function of position, we obtain the **gradient** of the function; when applied by the **scalar product** process to a vector function of position, we obtain the **divergence** of the function; and when applied by the **vector product** process to a vector function of position, we obtain the **curl** of the function. (L.L.S.)

VECTOR GEOMETRY. Let **r** be a **variable vector**, with origin at O and let s be a **scalar** variable. Then $\mathbf{r} = s\mathbf{a}$ is the equation of a straight line through O, parallel to **a**; and $\mathbf{r} = \mathbf{b} + s\mathbf{a}$ is the equation of a line through the terminus of **b** and parallel to **a**. The equation

$$\mathbf{r} = \mathbf{a} + s(\mathbf{b} - \mathbf{a}) = s\mathbf{b} + (1 - s)\mathbf{a}$$

is the equation of a line through the ends of two vectors **a** and **b**. If we have given three vectors, **a**, **b**, and **c**, with the same origin, they terminate in the same straight line if

$$x\mathbf{a} + y\mathbf{b} + z\mathbf{c} = 0 \text{ and } x + y + z = 0.$$

The equation of a straight line through the end of **b** and parallel to **a** may also be written $\mathbf{a} \times (\mathbf{r} - \mathbf{b}) = 0$.

Let **r** be a variable vector, and let s and t be scalar variables. Then the equation of a plane through the end of **c** and parallel to **a** and **b** is $\mathbf{r} = \mathbf{c} + s\mathbf{a} + t\mathbf{b}$. The equation of a plane through the ends of three non-coplanar vectors **a**, **b**, **c** is $\mathbf{r} = s\mathbf{a} + t\mathbf{b} + (1 - s - t)\mathbf{c}$. The condition that four vectors **a**, **b**, **c**, **d** with the same origin terminate in the same plane is

$$x\mathbf{a} + y\mathbf{b} + z\mathbf{c} + w\mathbf{d} = 0 \text{ and } x + y + z + w = 0.$$

The equation of a plane perpendicular to a and through the end of $\mathbf{b}$ may be written $\mathbf{a}\cdot(\mathbf{r}-\mathbf{b})=0$. The equation of a plane through the end of $\mathbf{b}$ and parallel to $\mathbf{c}$ and $\mathbf{d}$ may be written $(\mathbf{c}\times\mathbf{d})\cdot(\mathbf{r}-\mathbf{b})=0$. The equation of a plane through the ends of three vectors $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ with the same origin is $(\mathbf{r}-\mathbf{a})\cdot(\mathbf{a}-\mathbf{b})\times(\mathbf{b}-\mathbf{c})=0$, or $(\mathbf{a}\times\mathbf{b}+\mathbf{b}\times\mathbf{c}+\mathbf{c}\times\mathbf{a})\cdot(\mathbf{r}-\mathbf{a})=0$.

The vector to a point of division of the segment joining the ends of $\mathbf{a}$ and $\mathbf{b}$ is $\mathbf{r}=\mathbf{a}+s(\mathbf{b}-\mathbf{a})$, where s is the ratio of the partial segment AP to the total segment AB, where A and B are the ends of $\mathbf{a}$ and $\mathbf{b}$.

If r is a variable vector, the equation of a circle (or of a sphere), with center at the origin of $\mathbf{r}$, is $\mathbf{r}=\mathbf{a}$ or $\mathbf{r}\cdot\mathbf{r}=\mathbf{a}\cdot\mathbf{a}$ (written $\mathbf{r}^2=\mathbf{a}^2$). If the center of the circle is at the end of $\mathbf{c}$, the equation of the circle is $(\mathbf{r}-\mathbf{c})^2=\mathbf{a}^2$ or $\mathbf{r}^2-2\mathbf{r}\cdot\mathbf{c}=\mathbf{a}^2-\mathbf{c}^2=$ constant. If the origin is on the circumference of the circle, $\mathbf{c}=\mathbf{a}$, and the equation of the circle is $\mathbf{r}^2-2\mathbf{r}\cdot\mathbf{a}=0$. (L.L.S.)

VECTOR INTEGRALS. Vector integration, as an operation, may be defined as in the case of a scalar function, as the **inverse operation** to vector differentiation.

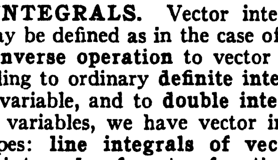
Corresponding to ordinary **definite integrals** of functions of one variable, and to **double integrals** of functions of two variables, we have vector integrals of the following types: **line integrals of vector functions** and **surface integrals of vector functions.** (L.L.S.)

VECTOR MULTIPLICATION. There are two distinct kinds of products of two **vectors**: the **scalar product** and the **vector product.**

Combining these two types of products, we get two kinds of **triple products of vectors,** and also several products of four vectors, giving rise to **reciprocal systems of vectors.** (L.L.S.)

VECTOR PRODUCT OF TWO VECTORS. The vector product (or cross product) of two **vectors** is defined as a vector perpendicular to their plane in the sense of advance of a right-handed screw rotated from the first to the second of these vectors through the smaller angle between them, and having a magnitude equal to the product of the magnitudes of the two vectors by the sine of the angle between them.

The vector product is represented in magnitude by the area of the parallelogram of which the two given vectors are adjacent sides.



The vector product of $\mathbf{a}$ by $\mathbf{b}$ is denoted by $\mathbf{a}\times\mathbf{b}$ in the Gibbs notation, by $[\mathbf{a}, \mathbf{b}]$ in another common form of notation, and by V $\mathbf{ab}$ in the Hamiltonian notation.

We have:

$$\mathbf{a}\times\mathbf{b}=(ab\sin\theta)\hat{\mathbf{n}},$$

where θ is the angle between $\mathbf{a}$ and $\mathbf{b}$, and $\hat{\mathbf{n}}$ is the unit normal vector to $\mathbf{a}$ and $\mathbf{b}$.

The vector product $\mathbf{a}\times\mathbf{b}$ does not obey the **commutative law,** but we have

$$\mathbf{a}\times\mathbf{b}=-\mathbf{b}\times\mathbf{a}.$$

It is, however, **distributive:**

$$(\mathbf{a}+\mathbf{b})\times\mathbf{c}=\mathbf{a}\times\mathbf{c}+\mathbf{b}\times\mathbf{c}.$$

If $\mathbf{a}$ is parallel to $\mathbf{b}$, then $\mathbf{a}\times\mathbf{b}=0$, and conversely. It follows that $\mathbf{a}\times\mathbf{a}=0$ for any vector $\mathbf{a}$.

For the unit vectors $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$, $\hat{\mathbf{k}}$, we have:

$$\hat{\mathbf{i}}\times\hat{\mathbf{i}}=\hat{\mathbf{j}}\times\hat{\mathbf{j}}=\hat{\mathbf{k}}\times\hat{\mathbf{k}}=0,$$

$$\hat{\mathbf{i}}\times\hat{\mathbf{j}}=\hat{\mathbf{k}},\quad \hat{\mathbf{j}}\times\hat{\mathbf{k}}=\hat{\mathbf{i}},\quad \hat{\mathbf{k}}\times\hat{\mathbf{i}}=\hat{\mathbf{j}}.$$

If $\mathbf{a}=a_1\hat{\mathbf{i}}+a_2\hat{\mathbf{j}}+a_3\hat{\mathbf{k}}$, $\mathbf{b}=b_1\hat{\mathbf{i}}+b_2\hat{\mathbf{j}}+b_3\hat{\mathbf{k}}$, then $\mathbf{a}\times\mathbf{b}$ $=(a_2b_3-a_3b_2)\hat{\mathbf{i}}+(a_3b_1-a_1b_3)\hat{\mathbf{j}}+(a_1b_2-a_2b_1)\hat{\mathbf{k}}$

$$=\begin{vmatrix}\hat{\mathbf{i}} & \hat{\mathbf{j}} & \hat{\mathbf{k}}\\ a_1 & a_2 & a_3\\ b_1 & b_2 & b_3\end{vmatrix}.$$

(L.L.S.)

VECTOR PRODUCTS. Vector Multiplication.

VECTORIAL ANGLE. Polar Coordinates in a Plane.

VECTORS. Line-segments, as AB and BA, in which opposite senses are distinguished, are called directed line-segments.

A directed line-segment is also called a vector. A vector then has magnitude (length), direction and sense.

A physical quantity which has the three attributes of magnitude, direction and sense may be called a vector quantity. Examples of vector quantities are displacement of a particle, velocity and acceleration of a particle, force acting on a body, etc.

If a vector is a directed line-segment AB, in which the sense is from A to B, we call A the origin and B the terminus of the vector and sometimes denote it by the symbol $\overrightarrow{AB}$.

A vector is frequently denoted by a single letter, printed in bold-face type, as $\mathbf{a}$.

A scalar is a number.

By a scalar quantity we shall mean a physical quantity whose measure is completely expressed by a scalar or number; it has only magnitude. Examples of scalar quantities are temperature, weight, potential, etc.

Scalars are denoted by light-face type.

The magnitude (or length) of a vector $\mathbf{a}$ is often denoted by a or by $|\mathbf{a}|$. The unit vector having the same direction and sense as $\mathbf{a}$ but of unit length is sometimes denoted by $\hat{\mathbf{a}}$.

To multiply a vector $\mathbf{a}$ by a positive scalar m, we multiply the magnitude of $\mathbf{a}$ by m, leaving the direction and sense unchanged.

The negative of a vector $\mathbf{a}$ is the vector of the same magnitude and direction but of opposite sense.

There is great diversity of notation in vector analysis, particularly with regard to products of vectors. (L.L.S.)

VEE-BELT. Belting.

VEERING WIND. Any clockwise change in wind direction is known as veering of the wind. It is opposite to backing. (P.E.K.)

VEERY. Aves, Passeriformes. A **thrush,** *Hylocichla fuscescens,* of eastern North America, also called Wilson's thrush. (A.W.L.)

VEGA. Vega (α Lyrae) is the second brightest star visible in northern latitudes. It is visible during some portion of every clear night throughout the year, and dominates the summer skies. Because of its distinctly bluish tinge it is one of the most beautiful stars of the northern skies and references to it are found in all of the ancient literatures. At one time Vega was the pole star and, because of **precession,** the pole will be close to Vega about 11,500 years hence. Lockyer claims that the temples at Denderah in Egypt were oriented to this star as early as 7000 B.C.

Vega is of interest astronomically for it is the brightest star in the general vicinity of the **solar apex** or the point on the celestial sphere toward which the **sun** is moving, carrying all other members of the **solar system** along with it. (W.K.G.)

VEGETABLE IVORY. Vegetable ivory is obtained from the fruits of various **palms** of the genus *Phytelephas,* known as ivory palms. These plants, natives of the wet forests of tropical America, have short thick stems and erect, **pinnate** leaves of very large size. The plants are **dioecious.** The staminate (see **Stamen**) flowers are borne on an elongate fleshy **spadix;** while the pistillate (see **Pistil**) flowers occur in groups of six or seven. Each flower gives rise to a berry, the six or seven berries of a group being united. This fruit has a hard outer layer, covered with woody protuberances, and contains several seeds. During development these seeds contain a milky-white fluid, which hardens as the seed matures, and which is the endosperm of the seed. It becomes almost as hard as ivory, and is used in making billiard balls, buttons, and a variety of small articles. (R.M.W.)

VEIN. For the use of this term in anatomy, see **Circulatory System.** For its use in botany, see **Leaf.** In geology the term vein is understood to refer to small or large fissures which have been filled with mineral matter by deposition from aqueous solutions, including "liquors" and gaseous emanations from magmas. Lode means essentially the same thing as vein, being an old Cornish mining term referring to the formations which would "lead" or direct the miner to the desired minerals. (E.S.C.S.)

VELARIUM. A flange of thin tissue projecting from the margin of a jellyfish over the concave surface of the body. Unlike a true **velum** it contains neither muscles nor a nerve ring. This structure is well developed in the order Cubomedusae (**Scyphozoa**) and increases the resemblance of these animals to the **hydrozoan** medusae. Also called the pseudovelum. (A.W.L.)

VELIGER. A form of **larva** found in the phylum **Mollusca.** Some mollusks hatch as a **trochophore** and later develop into a second free-swimming larval stage, the veliger. In this stage a ciliated (**cilia**) ring called the **velum** is developed and the foot becomes larger. The shell becomes coiled in the veliger stage of some **gasteropods.** (A.W.L.)

VELOCITY. The time rate of change of position. (Unless angular velocity is specified, this term is understood to refer to linear motion, which may be emphasized by the expression "linear velocity.") Strictly, the velocity of a moving point must specify both the speed and the direction of the motion, and is therefore a **vector;** though the term is sometimes more loosely used as merely synonymous with speed. The velocity of a point is the time rate of the distance s from a fixed origin O, expressed as the **vector derivative** of s with respect to the time, ds/dt (Fig. 1); while the speed is the magnitude of the velocity and is not a vector. If the direction of motion is constant, so that the motion is in a straight line (but not necessarily with constant speed), and if the line of motion is clearly understood, it is convenient to treat the distance s and the velocity ds/dt as scalars with respect to some zero point on that line and with appropriate algebraic signs (Fig. 2); otherwise they must be regarded as vectors. If the velocity is variable, account must be taken of the **acceleration.** Examples of both curved and rectilinear motion are treated under **kinematics.** (L.D.W.)

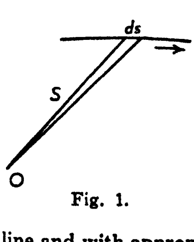


Fig. 1.

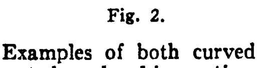

Fig. 2.

VELOCITY CURVE. A plot of **radial velocity** of a star as ordinates against time as abscissae is known as the velocity curve for the star. The method of formation of a mean velocity curve is similar to that described for the determination of a mean **light curve.** The use of the velocity curve for determining the **orbit** of a **spectroscopic binary** is discussed elsewhere. (W.K.G.)

VELOCITY HEAD. **Fluid Flow.**

VELOCITY OF LIBERATION. **Rocket Flight.**

VELOCITY MODULATION. This is a form of electron **modulation** in which the electrons passing through a resonant cavity in a tube such as the **klystron** are acted upon by a modulating field in such a manner that their velocities cause them to pass through the collector cavity in groups. (L.R.Q.)

VELOCITY RATIO. **Belting, Chain, Gearing.**

VELUM. 1. In **hydrozoan** medusae, a thin flange of tissue projecting from the margin of the body over its concave surface, leaving a restricted circular opening. The velum contains a nerve ring and muscles. It aids in locomotion by the contraction of the body to force jets of water from the concave subumbrellar surface. 2. In the **veliger** larva of **mollusks,** a ciliated (**cilia**) organ adjacent to the mouth. It is formed of the postoral ciliated ring of the trochophore larva together with the preoral ring, and serves as an organ of locomotion and to bring food to the mouth. 3. The double ciliated ring surrounding the oral end of the body of a **rotifer.** (A.W.L.)

VELVET ANT. Insecta, Hymenoptera. A **wasp** of the family Mutillidae. The females of these insects are wingless and consequently are antlike in form, but they differ in the absence of the dorsal prominence on the slender waist that characterizes the ants. They are densely hairy insects, usually brightly banded with some shade of red or yellow, black, and sometimes white. The males differ in other details than the presence of wings, hence it is difficult to associate the sexes unless they are taken together. Velvet ants are parasitic in the nests of other insects and some have been reported as parasites on the tsetse fly. (A.W.L.)

VENA CAVA. A main venous trunk returning blood to the **heart** in **vertebrates.** Above the fishes the paired condition of the venous system is modified, and in the **reptiles,** birds (**Aves**), and **mammals** the posterior parts of the body are drained by the tributaries of a single trunk vein, the posterior vena cava. In the mammals the paired condition of the anterior venous system also disappears, giving rise to an anterior vena cava. Owing to the erect posture of man these vessels are also known as the superior and inferior venae cavae. The name is also applied to a venous trunk in the **cephalopod** mollusks. It drains the head and subdivides to form the **branchial veins** to the gills. (A.W.L.)

VENDACE. Pisces, Teleostei. A fresh-water fish related to the salmon, found in lakes of Ireland. (A.W.L.)

VELAMEN. **Root.**

VENEER. **Wood.**

VENTILATION. This is the process of changing the air in any space by natural or mechanical means. In its simplest form ventilation results from the effect upon buildings of winds, or from the natural levity of heated air. Air blown horizontally against a building creates a small **plenum** to windward and a small **vacuum** to leeward. Through openings intentionally created, such as opened windows, doors, ventilators, etc., this pressure difference will cause a ventilating current to flow. Also

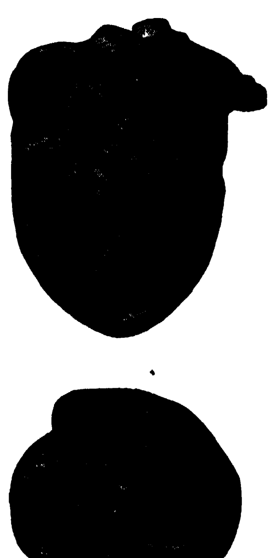
through cracks in walls, clearances around window sash, and the like, unintentional and unwanted ventilation may be brought into existence. Natural ventilation can be secured in the absence of atmospheric motion by providing elevated outlets (roof ventilators, stacks, air shafts) so that cool air may displace warm air upwards and out of the vents.

Mechanical systems of ventilation are more adaptable to continuous positive control of air flow. The vitalizing air pressure of these systems is usually created by a **centrifugal fan,** although axial flow and propeller fans are sometimes used. Ducts of sheet metal, wood, and other materials of construction carry the air to and/or from the space to be ventilated. Quietness in operation and even distribution of air (i.e., no drafts) are especially sought in these systems when installed in public buildings, dwellings, offices, and stores. Vibration absorbent mountings for fan and motor, low fan feeds, moderate air velocities, and acoustical duct linings are some of the means of reducing noise level. This level should not be above that usually existing in the spaces being ventilated, for example, from 30 to 50 decibels in dwellings and offices.

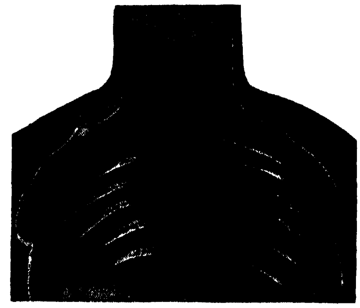
The minimum quantity of air in circulation consistent with human comfort has been the subject of extensive observations by the American Society of Heating and Ventilating Engineers and by others. In the usual space allotment of dwellings (approx. 400 cu. ft. per person) about 1½ changes of air per hour will satisfactorily ventilate from both the chemical and thermal standpoint. This amounts to about 10 cu. ft. air per person per min. In workrooms, auditorium, schoolrooms and other places of congregation the free space allotment per person is less and the required number of air changes greater.

In conclusion, be it noted that ventilation is one aspect of **air conditioning,** for the latter term is concerned not only with quantity of air circulated, but also with its quality. (F.T.M.)

VENTRICLE. 1. A strongly muscular chamber of the **heart** from which **blood** is pumped to various parts of the body. In the **mollusks** it is a single chamber and in the vertebrates it is single in the more primitive forms, including fishes, amphibians, and some reptiles. In the reptiles its subdivision is begun, and in the crocodilians right and left ventricles appear. This division is complete in the birds and mammals. 2. A cavity of the vertebrate **brain.** The first and second ventricles are in



Cavities of the heart, showing valves between the heart chambers.



Heart and main vessels. (Lungs removed.)

the cerebral hemispheres. The third is formed of the persisting median cavity of the first primitive brain vesicle. The fourth ventricle is the cavity of the third primary vesicle, and all other remnants of the original cavities become narrowed passages. The ventricular system contains cerebrospinal fluid. (A.W.L.)

VENTURI METER. Flow Meter.

VENUS. (See tables of planetary data, page 1109.) Venus may be called the earth's twin **planet,** for in size, density, and general constitution, if not in all physical characteristics, Venus is much like the earth. This planet is one of the most conspicuous objects in the sky and may easily be viewed in full daylight with the naked eye, provided attention is directed to the proper point in the heavens. For this reason Venus is frequently used by navigators for obtaining a **Summer line** in the daytime to use in conjunction with an observation of the sun.

Venus, like **Mercury,** has its orbit between the earth and the sun and never appears very far away from the sun. Since at maximum elongation Venus appears either in the eastern sky at sunrise, or in the western sky at sunset, this is the planet that is most commonly referred to as the morning or evening "star." Like Mercury the ancient astronomers had two names for it; calling it Phosphorus as the morning star, and Hesperus as the evening. As Venus passes about in its apparent path from inferior conjunction back to inferior conjunction again it goes through a series of **phases** exactly as does the moon. In fact, this change in phase of Venus was one of the tests proposed by the anti-**Copernicians** prior to the invention of the telescope. At inferior conjunction Venus is closer to the earth than any other astronomical object except the moon (and an occasional asteroid or comet), having a distance of only 26,000,000 miles. Since at superior conjunction the planet has a distance of nearly 160,000,000 miles the changes in apparent diameter are very great and, as a matter of fact, Venus appears the brightest to us (i.e., has the largest apparent area) when in the crescent phase similar in shape to the moon when about 5 days old.

Telescopically Venus is not a particularly interesting object except insofar as the phase changes are interesting. There are very few and very faint surface markings; in fact, the markings are so faint and so illusive that the determination of the rotation period of the planet by direct observation is practically impossible. The application of the spectroscope, by applying the **Doppler-Fizeau principle** to the spectral lines, indicates that the rotation period is considerably longer than that of the earth, 30 days being a fair compromise between various discordant results.

The high reflecting power of the planet, together with a value for **surface gravity** comparable with the value for the earth, lead to the conclusion that Venus has a dense **atmosphere.** A tremendous amount of research has been applied to the problem of the constitution of the atmosphere of Venus. Delicate and exacting tests have failed to indicate the presence of either water vapor

or oxygen in the atmosphere of Venus, although there is considerable evidence of the existence of carbon dioxide. The absence of water vapor precludes the possibility of any large bodies of water on the planet and makes the existence of any forms of life such as we know them on the earth highly improbable.

Comparatively little is known concerning the surface conditions of Venus because the dense atmosphere of the planet prevents observations being made of the surface. Measurements of the surface temperature of the planet indicate a range of from 333° K. (140° F.) on the sunlit portions, down to 253° K. (−4° F.) for the dark regions.

At rare intervals Venus passes through inferior conjunction at a time when the sun is close to the node of its apparent path. At such times the planet will transit the disk of the sun and, since the planet will then be quite close to the earth, the transits may be used for the determination of **solar parallax.** The last transits occurred in 1872 and 1882 and the next ones will come in 2004 and 2012. (W.K.G.)

VENUS' FLY-TRAP. *Dionaea muscipula.* **Insectivorous Plants.**

VENUS' GIRDLE. Ctenophora, Cestida. A transparent marine animal of ribbon-like form. The longitudinal axis of the body lies across the width of the ribbon, hence the body is short and is greatly elongated on one transverse axis and very short on another. (A.W.L.)

VERATRINE. Alkaloids.

VERDET CONSTANT. Faraday Effect.

VERMIFUGE. A drug used to rid the intestinal tract of worms or intestinal **parasites.** (D.M.H., R.S.M.)

VERNAL EQUINOX. The point of intersection of the ecliptic and the equator where the sun apparently passes from south to north of the earth's equator is known as the vernal equinox. The direction of the vernal equinox is the fundamental direction in the equatorial and ecliptic systems of **spherical coordinates** from which right ascension and celestial longitude are measured. The sun is in the direction of the vernal equinox on approximately March 21 and this date indicates the beginning of the spring season in the northern hemisphere. On the ancient **calendars** the passage of the sun through the vernal equinox indicated the beginning of the new year. Some 2000 years ago the vernal equinox was in the **constellation of Aries** and was frequently referred to as the first of Aries. Astrologers frequently use this same terminology for the position of the sun on March 21 in spite of the fact that, due to **precession,** the vernal equinox has shifted into the constellation of **Pisces.** (W.K.G.)

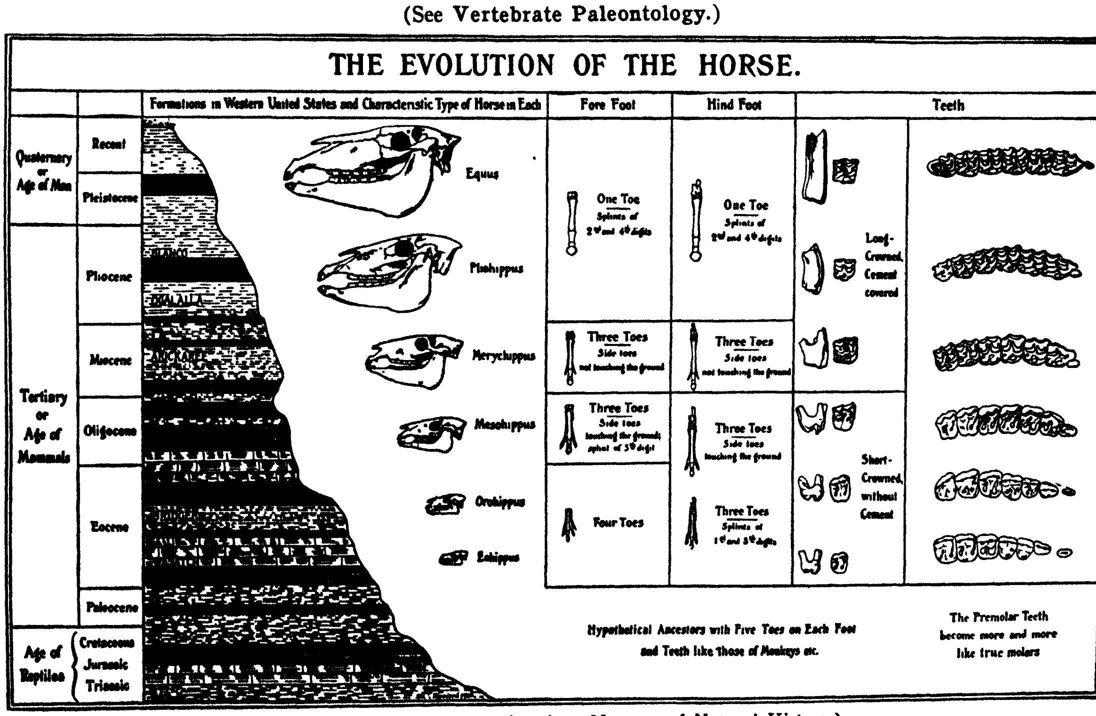
VERNALIZATION. This term is applied to the low-temperature treatment of seeds before sowing which shortens the time to flowering of the plants which develop from them. This technique is employed principally with cereals and especially with winter wheats. It is used as a widespread agricultural practice chiefly in Russia. Vernalization of the grains of a winter wheat so shortens its life cycle that it can be grown as a spring wheat. Grains of the Turkey Red variety of winter wheat, for example, can be vernalized by soaking them to a moisture content of about 60% and exposing them to a temperature of 1–3° C. for 9–10 weeks while holding them at approximately that water content. The grains are then sowed, the plants developing from them reaching the heading stage in 110–120 days from the beginning of the cold treatment. Unvernalized seeds of the same variety require about 150 days from sowing to reach the heading stage under the same conditions. (B.S.M.)

VERNIER. Measurement.

VERNIER CALIPER. Measurement.

VERONAL. Barbital.

(See Vertebrate Paleontology.)



Evolution of the horse. (*American Museum of Natural History.*)

VERTEBRA. One of the thirty-three bones making up the spinal column. In man, there are seven cervical, twelve dorsal, five lumbar, five sacral and four coccygeal vertebrae. (R.S.M.)

Vertebral column. (*Cunningham, Textbook of Anatomy, Oxford Press.*)

VERTEBRATA. Animals with a bony or cartilaginous skeleton enclosed within the body. A subphylum of the phylum **Chordata.**

The vertebrates are distinguished from the lower chordates by the greater complexity of the **nervous system,** including a well-developed **brain,** as well as by the replacement of the **notochord** by a spinal column in most forms.

The group is divided into six classes:

Class **Cyclostomata.** The **hagfishes** and **lampreys,** or round-mouthed eels. A group with a persistent notochord and without hinged jaws.

Class **Pisces.** The fishes. Animals of aquatic habit, relatively few species leaving the water at all. They breathe by gills.

Class **Amphibia. Frogs, salamanders** and related forms. Moist-skinned animals, usually with an aquatic larval stage in which gills appear. Some are permanently aquatic and some exclusively terrestrial.

Class **Reptilia. Lizards, snakes, turtles, crocodiles,** etc. Never with gills, even though aquatic. Skin scaly.

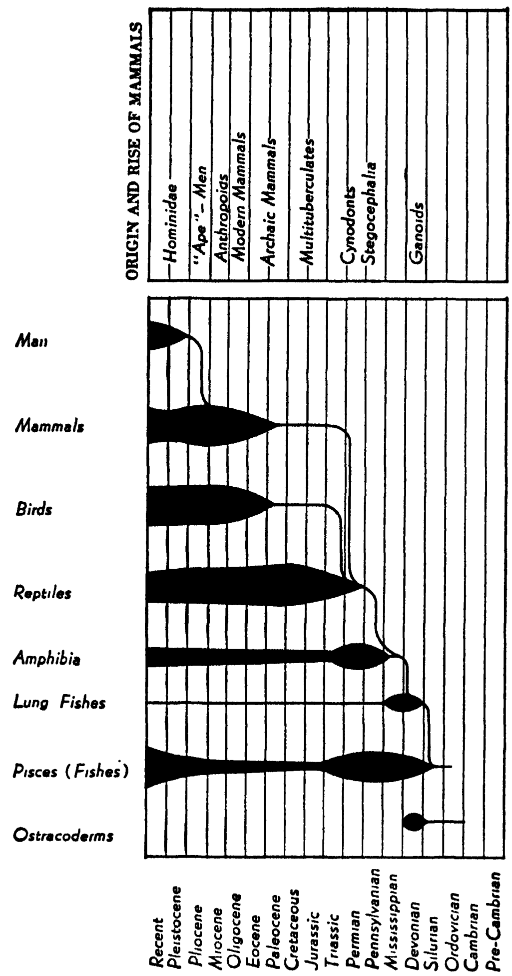
Class **Aves.** The birds. Skin clothed with feathers and scales. Mostly flying species.

Class **Mammalia.** Skin clothed with hair in most species. Young nourished with milk secreted by the mother. (A.W.L.)

VERTEBRATE PALEONTOLOGY. The study, description and geologic use of vertebrate **fossils** in relation to paleobiological and stratigraphic problems. The science of vertebrate paleontology is primarily founded upon vertebrate zoölogy, and especially comparative osteology. Since thousands of vertebrate fossils, ranging in age from the late **Palezoic** to the **Pleistocene** have been figured and described, it is not possible to list them all in a general science encyclopedia. Also there is no single reference work in existence which covers the entire subject. For detailed information one must consult special bibliographies which list the generic and specific references in a large number of special papers and monographs. The chart on p. 1535 presents various data relating to the evolution of the horse. From the paleontological point of view the vertebrates may be classified as illustrated in the geologic chart at right above. Further information regarding the geologic and paleontologic terms used on these charts will be found elsewhere in this encyclopedia. (R.M.F.)

VERTICAL CIRCLE. Any great circle on the **celestial sphere** which passes through the **zenith** and **nadir** is known as a vertical circle. Since the zenith and nadir are poles of the **horizon,** a vertical circle must be perpendicular to the horizon. The vertical circle which cuts the horizon at the north and south points is known as the local **meridian,** while that vertical circle which cuts the horizon at the east and west points is known as the prime vertical. (W.E.G.)

VERTICAL CURVE. Grade.



Geologic range of the vertebrates. (*Field, Geology Manual Part II, Princeton University Press.*)

VERTICAL LIFT BRIDGE. Bridge.

VERY HIGH FREQUENCY. Radio Frequency.

VESSELS. A vessel or trachea is a linear series of water-conducting cells formed in the **xylem** of **angiosperms** by the dissolution of the end walls of the cells in the linear row. The lateral walls are thickened and contain many **pits,** usually of small size. There is no **protoplast** in a vessel. It is particularly adapted for the conduction of water in the plant.

For development, see **Cambium.** (R.M.W., B.S.M.)

VESUVIANITE. The mineral vesuvianite is a very complex **silicate** of **calcium** and **aluminum** with **fluorine** which may also contain varying amounts of **boron, iron, lithim, magnesium, manganese potassium, sodium** and **titanium.** A suggested formula is $Ca_6Al(OH,F)Al_2(SiO_4)_5$. Its **tetragonal** crystals are usually short, somewhat stoutish, prisms, sometimes pyramids, but columnar to massive varieties are common. It is essentially without cleavage; fracture, uneven; brittle; hardness, 6.5; specific gravity, 3.3–3.5; luster, vitreous to greasy or resinous; color, commonly some shade of brown or green, but may be reddish, bluish or yellowish; may be transparent, but is usually translucent. It has been used as a gem but is not a particularly desirable stone. This mineral was formerly called idocrase, having been named by Haüy from the Greek words meaning *form*

and *mixture* because it resembled crystals of other species, scarcely a valid distinction. Werner gave it the name vesuvianite from Mt. Vesuvius where it was first found in blocks of limestone appearing as inclusions in the **lava**. Vesuvianite is not a constituent of the **igneous rocks**, but rather a contact **metamorphic** mineral resulting from the alteration of impure **limestones** and **dolomites**. It is usually associated with **diopside, wollastonite, epidote, grossularite, garnet**, etc. There are many localities worthy of mention among which are: The Urals, Czechoslovakia, Rumania, Trentino and Monzoni in Italy, as well as at Mt. Vesuvius and Mt. Somma, Switzerland, Mexico and Japan. In the United States vesuvianite is found in Androscoggin and York Counties in Maine; Orange County, New York; Sussex County, New Jersey; Garland County, Arkansas; and Riverside and Tulare Counties in California. (E.S.C.S.)

V-FLAT. **Belting.**

VHF. **Very High Frequency.**

VIBRACULUM. A modified form of individual in the **bryozoan** colony. These colonies contain the complex polypides and two reduced forms whose functions appear to be the protection of the entire group against the lodging of **sessile** animals. These forms are the **avicularium** and the vibraculum. The latter is no more than a bristle or filament that moves back and forth, sweeping across the surface of the colony. Numerous vibracula sometimes act synchronously in this movement. (A.W.L.)

VIBRATION SPECTRUM. **Molecular Spectra.**

VIBRATIONS AND WAVES. These terms are used in very broad senses and apply to a large variety of phenomena and processes. "Vibration" commonly refers to a to-and-fro motion, but we shall have to extend the meaning to include any periodic physical process, such, for example, as a cyclic variation in electric or magnetic field intensity. When an elastic body is deformed and released, it is in general set into oscillation such that the displacement of any particle from its equilibrium position is a more or less complicated harmonic function of the time (see **Harmonic Motion** and **Harmonic Analysis**). The vibration may or may not be symmetrical with respect to the neutral position; in any case the maximum displacement is called the amplitude of the vibration. By analogy, the same terms and the same analysis are applied to vibrations of any type.

If a vibratory disturbance occurs at any point in a medium having sufficient continuity to transmit displacements from one part to another, a train of waves is propagated outward from the seat of the disturbance. The speed of propagation depends upon the closeness of coupling between adjacent particles of medium and the consequent magnitude of the restoring forces; and upon whatever reaction of the medium corresponds to mechanical inertia. In some cases also the speed varies with the frequency, as with light in a material medium. In any case the wavelength, viz., the distance traversed during a complete vibration period, is related to the frequency of vibration and the speed of propagation by the simple equation $v = \nu\lambda$ in which v is the speed, ν the frequency, and λ the wavelength. Thus, if sound waves of frequency 250 vibrations per sec. are traveling with a speed of 1000 ft. per sec., the wavelength is 4′. In case the vibrations are of complex character and the different components travel with different speeds, the resulting "wave group," traveling with its characteristic **group velocity**, may be very sharply defined and may thus constitute a "wave packet," resembling a single pulse or unrepeated wave. (See **Interference**.)

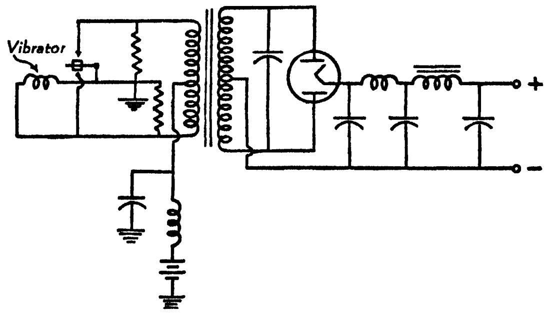
The theorem of Fourier states that any vibration or wave train, however complex, can be resolved into simple harmonic components of various amplitudes and frequencies and in various phases. Of these components, the one of lowest frequency (and in the case of elastic vibrations, usually of greatest amplitude) is the "fundamental"; the others are "overtones."

The character of a wave process may be described mathematically by means of a "wave equation" which specifies the condition at any point of the wave field in terms of the position and of the time; or graphically by one or more "wave form" curves, of which the ordinates represent the periodically variable displacements at any point, and the abscissas the time. (See **Wave Propagation**.)

In applied dynamics, vibrations might be classified as natural and artificial. An outstanding example of the former is the earthquake. Almost any rotating machinery furnishes examples of the latter. Civilized man comes into contact with artificial vibrations constantly, but only occasionally with those of a natural type. Sometimes vibration can be an asset; witness the use of vibrators to jar a **pattern** loose from molding sand, vibrators in therapeutical work, and a few others. In the main vibration is a nuisance, possibly destructive, indicative of wear and inefficiency, likely to produce weakening of a structure, and fatiguing physically and mentally. Man-made vibrations are much more likely to be encountered in damaging amounts in cities than in rural areas. There is considerably more machinery in and about the cities. Most of the streets are hard-paved. They carry a high average density of traffic, and further, there are subways, elevated railroads, and a concentration of commercial vehicles which produce all sorts of disturbances on the crust of the earth. In a region of large modern buildings these vibrations might enter the structural steel skeleton of the building below ground level, and be felt throughout the whole structure. Concrete in monolithic construction transmits vibrations exceptionally well. This condition has reached such proportions that the prevention of vibration, or a very effective damping of it, is of definite financial value, and hence the economic incentive to attack vibration from an engineering standpoint is provided. By the use of suitable vibration-absorbing materials, and with proper isolation of machines having vibration, or, better still, the more scientific balancing of rotating apparatus, much has been done to reduce vibration to a point where it is not objectionable. This work has appeared in many different fields, as is brought out by illustrations of vibration control taken at random. In the automotive field, the number of cylinders of engines has been increased so that there will be a smoother flow of power due to overlapping power impulses, vibration dampers have been designed and applied to crankshafts, and engines have been mounted in resilient supports like rubber. The widespread use of pneumatic tires has helped more than anything in reducing vibration from passing vehicles. The spring suspension of many pieces of rotating machinery, which were once rigidly bolted to their foundations, is a further example. Most domestic refrigerators will be found to have the rotating refrigerating unit flexibly supported so that a minimum of vibration will be transmitted. Buildings may be insulated partially from vibration if the problem is considered at the time of laying the foundations, but not much can be done about it once the building is finished. (See **Mechanics, Balancing, Noise and Vibration, Critical Speed.**) (L.D.W., F.T.M.)

VIBRATOR. The vibrator is a rapidly acting automatic **switch** for alternating the polarity on a **transformer** primary fed from a d-c source, thus in effect converting the d-c supply to a c. so the transformer can function. It is widely used in automobile and other portable radio or electronic apparatus. Formerly a double-type vibrator was widely used, the second part being connected to the transformer secondary and serv-

ing as a rectifier for the output voltage. The tendency now is towards the use of a single or non-synchronous vibrator and some other type rectifier. A typical application is shown in the diagram. The vibrator is pulled



against the lower contacts by the vibrator winding. This shorts the vibrator winding so it releases and the vibrator reed throws over to the other contacts due to the spring action of the reed. This removes the coil short and thus the coil is again energized and pulls the reed back and so the cycle is repeated. It can be seen that this operation connects the ground terminal of the battery to first one end and then the other of the transformer winding. This produces current flowing first one way and then the other in the primary (actually in the two halves of the winding) so there is induced in the secondary a voltage determined by the turns ratio of the transformer. This secondary voltage is then rectified and filtered to give the high-voltage plate supply needed in most electronic applications. (L.R.Q.)

VICKERS HARDNESS. Hardness.

VICUNA, VICUGNA, VICUNIA. Mammalia, Artiodactyla. A wild South American animal, *Lama vicunia,* related to the guanaco and the domestic llama and alpaca. The vicunia is the smaller of the two wild species. It lives in the mountains of Ecuador, Peru, and Bolivia. (A.W.L.)

VIDEO FREQUENCY. This is the frequency band of the **television** picture signal, i.e., it corresponds to the audio frequency of conventional radio. These frequencies range from a few cycles per second to several million, imposing severe requirements on any **amplifier** circuits passing them. (L.R.Q.)

VIERENDEEL GIRDER BRIDGE. Rigid Frame.

VILLARD EFFECT. This is a special phase of the Clayden effect and was discovered by Villard in 1900, who found that a latent image on a photographic plate, or film, which had been produced by x-ray is partially destroyed upon exposure to diffused white light. (C.B.N.)

VINCENT'S ANGINA. Stomatitis.

VINCENT'S INFECTION. Stomatitis.

VINE. Stem.

VINEGAR EEL. Nemathelminthes, Nematoda. A minute roundworm, *Anguillula aceti,* found in the "mother" of vinegar. It reaches a length of 2 mm. The worms have been found in other situations, including the human bladder. (A.W.L.)

VINEGARONE. Whip Scorpion.

VIOSTEROL. Vitamin D.

VIPER. Reptilia, Sauria. A poisonous **snake** with a pair of long tubular fangs near the front of the upper jaw. Most species of vipers are also characterized by the relatively short and thick body and the broad triangular head. The group includes the typical vipers of the Old World and the **pit vipers** of North and South America.

The Old World vipers include a number of Asiatic, European, and African species bearing the name viper and in addition the two species known as the asp and eja. The Egyptian horned viper is sometimes known as the cerastes from the name of the genus to which it belongs. The African puff-adder is a viper, named from its habit of inflating the body when disturbed. This name has unfortunately been borrowed for an entirely harmless snake of the eastern states, related to the hog-nosed snake. It is variously known as the puffing or spreading adder or blowing viper. When disturbed it flattens its body and makes an impressive bluff, but it is quite harmless.

Many of the Old World vipers are dangerous. Their poison is similar in nature to that of the pit vipers. (A.W.L.)

VIREO. Aves, Passeriformes. *Vireo.* A small quietly colored bird (**Aves**) of a family related to the warblers. The vireos are mostly gray to olive gray above and white below. Some species show traces of contrasting black or yellow. They build beautiful cupped nests, suspended in the crotch of a twig. (A.W.L.)

VIRGINIUM. Chemical Composition, I. Elements.

VIRGIN'S BOWER. Buttercup Family.

VIRGO. (See map, page 380.) Virgo, the sixth sign of the **zodiac,** is one of the earliest-named among the constellations. In every known literature we find references to this constellation and always connected in some manner with a maiden and the harvest. Among the Egyptians, Virgo was associated with Isis and was said to have formed the milky way by dropping innumerable wheat heads in the sky.

Astronomically, the constellation is famous for the large number of **nebulae** found in it. Sir William Herschel found no less than 323 of these objects in this part of the sky and more recent observations have raised the number to over 500. A large number of variable stars are also to be found in the constellation. The brightest star in the constellation is the well-known star **Spica.**

Since Virgo is a feminine sign, it is generally considered **astrologically** as unfortunate, although those born under this sign are supposed to be thrifty and ingenious. (W.K.G.)

VIRTUAL TEMPERATURE. Air free from water vapor has a certain density for fixed temperature and pressure. If, however, some water enters the air as vapor and the pressure held constant, the density will decrease slightly because the molecular weight of water is 18, compared to 28.97 for air. Also, if the air remains water-free and the temperature increases slightly, the density will also decrease. Virtual temperature of air is that temperature required to maintain its density constant if its water-vapor content is removed. Virtual temperature in air containing water is always greater than existing temperature.

$$T_v = \frac{T}{1 - 0.379e/P}$$

where T_v = Virtual temperature.
T = Existing temperature.
e = Vapor pressure of water vapor.
P = Total pressure of the air. (P.E.K.)

VIRTUAL WORK PRINCIPLE. **Equilibrium of Forces; Least Energy Principle.**

VIRULENCE. This term is used in describing pathogenic organisms. It is indicative of the disease-inciting power of these organisms. Variations in virulence occur not only among different species of microorganisms but also among strains of the same species. **Bacteria** gain or lose their virulence according to environmental conditions outside and within the body. This accounts in part for the presence of **epidemics** at certain times and the rise and fall and severity of epidemics. (R.S.M.)

VIRUS. An ultra-microscopic infectious agent. Diseases caused by viruses include **measles, mumps, chicken pox, smallpox, rabies, poliomyelitis, encephalitis,** the common cold, **herpes, dengue, influenza** and many others.

Viruses are filterable; that is, they are so small that they will pass through the pores of a porcelain filter. Information about their size—which varies between 10 and 150 millimicra in different species, has been collected by indirect means, using filtration and sedimentation data; recently with the development of the **electron microscope,** certain of the larger viruses have been photographed and their actual shapes seen.

Viruses are thought to be living organisms, capable of multiplication. They cannot be grown outside living tissue, and therefore must be identified indirectly. This is done by studying the **pathology** produced in experimental animals on inoculation of virus-infected tissue; by determining the host range, that is the animals which are susceptible to a given virus; and by testing immunological responses, i.e., specific **antibodies** in infected animals. These characteristics are more or less specific for each virus. Different tissue specificities are also characteristic. Thus the dermatropic agents attack primarily skin: smallpox, chicken pox, and measles viruses are included in this group. Rabies, encephalitis and poliomyelitis viruses are primarily neurotropic, and attack nervous tissue. (D.M.H.)

VIRUS DISEASES. Many diseases, both plant and animal, are called virus diseases. The organisms causing these diseases are too small to be seen except with the aid of the **electron microscope** by means of which the larger viruses have been photographed. Recent investigations indicate that they are individual giant protein molecules.

Virus diseases attack herbaceous plants more frequently than they do woody plants, and often cause serious damage, especially to such cultivated plants as **tobacco, potato** and **sugar-cane.** The number of virus diseases is great, but the host range for any one virus is usually rather strictly limited. Virus diseases are classified by the effects they produce rather than by their properties. These effects vary greatly with the different diseases. Leaves of the tobacco plant when infected with tobacco mosaic disease become spotted with light areas, and are rather stunted. Mosaic disease of the cucumber causes the leaves to become irregularly mottled and somewhat wrinkled. Virus diseases may not be fatal but do greatly reduce the vigor of the plant and also diminish the value of the crop produced by such plants.

These diseases are transmitted from plant to plant through wounds. Very commonly sucking insects serve as carriers, transferring the virus, which seems able to exist within the insect body, to another plant which becomes infected through the insect bite. Once within the plant the virus spreads rapidly. In some forms the virus seems to be carried into the seed and to infect the new plant when the latter develops from the seed. A great deal of experimental work has been done on the causative agents of virus diseases, which has shown among other things that they are remarkably tolerant to substances which would destroy other organisms, to high temperatures, and prolonged desiccation. (B.S.M., R.M.W.)

VISCACHA. Mammalia, Rodentia. *Viscaccia.* A large stoutly built burrowing animal of the South American pampas, related to the chinchillas. The contrast between these animals has been likened to that between our related squirrels and woodchucks, the one gracefully built and the other a clumsy burrowing form. (A.W.L.)

VISCERA. Organs lying more or less freely in the cavities of the body. Usually applied to the **heart** and **lungs** as thoracic viscera and to the **stomach, intestines, spleen, liver** and **pancreas,** and some of the **reproductive** organs as abdominal viscera. The singular form, viscus, is rarely met. (A.W.L.)

VISCERAL ARCH. The column of tissues persisting between adjacent gill **slits** in the wall of the vertebrate **pharynx.** The arch is lined with endodermal tissue and covered outside with ectodermal. It contains a bony or cartilaginous support belonging to the **visceral skeleton** and an **aortic arch.** In the fishes the gills are supported by these arches. (A.W.L.)

VISCERAL CLEFT. **Grill Slit.**

VISCERAL MASS. A compact mass of tissue containing some of the internal organs of the **mollusks.** It forms the main part of the body. (A.W.L.)

VISCERAL SKELETON. A portion of the vertebrate skeleton supporting the walls of the **pharynx** and forming the jaws and hyoid apparatus. In the primitive condition it consists of a series of bony or cartilaginous arches extending from the ventral wall of the pharynx upward in the **visceral arches.** Seven pairs of these structures persist in the fishes. The most anterior of the visceral arches forms part of the upper and all of the lower jaw, supported by skeletal structures derived from this source. The skeleton of the second arches and variable derivatives of those following constitute a hyoid apparatus supporting the base of the tongue. Other components of the visceral skeleton become the cartilages of the larynx and upper part of the trachea.

One of the most remarkable transformations of this part of the skeleton is the migration of small bones of the first and second arches into the middle **ear** as the hammer, anvil, and stirrup which bridge the cavity in the mammals. (A.W.L.)

VISCOMETER. **Viscosity.**

VISCOSITY. A property of fluids, either liquid or gaseous, which may be briefly described as a resistance to flow. When a solid is subjected to shear, a **stress** develops in it, increasing with the shear until a condition of static equilibrium is reached by virtue of the **elasticity** of the solid. On the other hand, when a fluid starts to flow, while there is likewise a **shearing** stress, the opposing reaction is of the nature of an internal friction, and the equilibrium attained when the flow becomes steady is brought about by the viscosity of the fluid opposing the shearing motion. As one layer of the fluid moves past an adjacent layer, the interaction of molecules at the boundary and the passage of molecules across the boundary both ways results in the transmission of energy from the faster to the slower, and hence tends to check the relative motion. This reaction is proportional to the rate of shear, thus:

$$\text{shearing stress} = \eta \times \text{rate of shear.}$$

The constant η is called the viscosity coefficient of the fluid. For liquids, it decreases, in general, with rise of

temperature; with gases, it increases. Thus, molasses becomes more fluid but air becomes less so, at a higher temperature.

When a fluid flows through a capillary tube because of a pressure difference Δp at the opposite ends, the volume per unit time is given by Poiseuille's law:

$$\frac{V}{t} = \frac{\pi r^4 \Delta p}{8\eta l},$$

in which r is the radius and l the length of the capillary. The viscosity coefficient may thus be measured, since it is easy to measure r, l, and Δp and to observe the rate of flow V/t. Several types of viscometer depend upon this principle.

Stokes derived an expression for the force necessary to keep a small sphere of radius r moving at a uniform speed v through a given fluid: $f = 6\pi\eta vr$; an expression very useful in studying drops or other spherical particles falling freely in the air. (L.D.W.)

VISCOSITY MANOMETER. **Pressure Gauges.**

VISE. Clamping and holding tools used in machine shops. Essentially, a vise consists of one stationary and one movable jaw, adjusted by means of a screw and nut. Bench vises are used for hand operations, such as chipping and filing, and are usually fastened to a shop bench. Hand vises are small tools fitted with a handle, and are designed to be held in one hand while the other holds a small file, engraving tool, etc. Machine vises are used in milling, drilling, and other machine tool processes, and are usually constructed so that they may be clamped to the machine table by clamps or **tee bolts.** Machine vises are usually made with replaceable jaw plates, so that special or false jaws may be substituted. (See **Milling.**)

Machine vises used for mass-production work are sometimes made with cam-actuated jaws, to permit quick-acting operation; vises actuated by compressed air are also extensively used. (H.C.H.)

VISIBILITY. That greatest distance toward the horizon at which an unaided normal eye can clearly distinguish prominent objects without aid of optical devices. In measuring visibility, officially, it is necessary that the value given exist over more than half the horizon. (P.E.K.)

VISIBILITY FACTOR. **Photometry.**

VISION. The formation of mental images of the shape and color of objects through the reception of light rays reflected from their surfaces to sensory organs known as **eyes.** While some organs included in this category are supposed to be merely sensitive to light and capable of perceiving its intensity and the direction of its source, others are either known or supposed to form sharply defined images like our own.

The compound eyes of **arthropods** are supposed to form fairly definite images by a process known as **mosaic vision.** The interpretation of such organs is necessarily theoretical since they are conspicuously different from our own. Their action is certainly very different from that of the camera eye of man.

For, from the optical standpoint, the human eye is merely a **camera,** with the retina substituted for a photographic plate. The optical system, however, extends continuously from the cornea back to the retina, instead of being localized in an objective. It consists of four transparent media: cornea, aqueous humor, "crystalline" lens, and vitreous humor, bounded by curved interfaces. The crystalline lens is of non-uniform refractive index, and is flexible like rubber, so that its shape and focal length can be controlled by a set of muscles; it is in this way that the focusing or "accommodation" is accomplished. The lens casts a sharp inverted image on the sensitive **retina.** Each rod or cone affected by the light sends an impulse to the visual centers in the brain. Here the mental image resulting from the total stimulation of the retina is formed.

The normal human eye forms clear images of objects 18′ away or more without effort. Closer objects require accommodation by the contraction of the ciliary muscle, which permits the lens to become more convex. For this reason close vision is more tiring than distant. Cephalopods and fishes on the contrary must accommodate for distant vision. The change is accomplished by the contraction of muscles which draw the retina and lens closer together. In amphibians and reptiles the lens is moved farther from the retina for close vision.

In the human eye a blind spot occurs at the point of entrance of the optic nerve where only nerve fibers exist. A depression in the retina at the axis of the eyeball, called the fovea, is the point of most acute vision. Here very few nerve fibers intervene between the nerve endings (rods and cones) and the source of light. Certain areas of the retina are also different in their sensitiveness to light of various lengths. Although color vision is conditioned by a number of variations in stimuli, the retina has certain normally characteristic visual fields. Red and green are perceived by a limited central area and blue and yellow by this area and a surrounding extension. The marginal field perceives only black and white and the grays.

The perception of size, shape, and distance depends partly on experience and partly on comparison with other known objects in view. The relative distances of objects are determined by stereoscopic vision through the mental association of slightly different images formed by the two eyes. Animals whose eyes are directed outward from the sides of the head are incapable of this type of vision. The same principle is used in stereoscopic photography. Two pictures made simultaneously from slightly separated points of view are examined through the stereoscope so that each eye sees one member of the pair. The difference in images may also be noted by closing or covering one eye at a time while looking at some object. (See **Binocular Vision.**)

Defects of vision in man include various forms of color-blindness, due to hereditary abnormality of the cones in the retina, and malformations of the eyeball that interfere with the formation of sharp images. When a normal eye is relaxed the image focuses directly on the retina; such an eye is called emmetropic. If the ball is slightly elongated the rays focus slightly in front of the retina during relaxation and the individual is said to be short-sighted or myopic. In the opposite condition light rays come to a focus behind the retina of the short eye, which is said to be long-sighted or hyperopic

The commonest form of color-blindness is the red-green type. The condition varies but in general red and green register as different degrees of yellow. A more extreme form called monochromatic color-blindness results in the perception of all colors as shades of gray. (See **Color.**)

Other adjustments of vision related to the intensity of illumination have been recorded. They involve various structural adaptations of the eyes to secure maximum stimulation for dim light and the familiar contractile iris to cut down the amount of light entering the eye. (A.W.L., R.S.M.)

VISUAL BINARIES. A visual **binary star** is one for which the angular separation between the two components is great enough to permit the system to be observed as a **double star** in a telescope. The **resolving power** of the **telescope** employed is an important factor in the detection of a visual binary and as telescopes of larger and larger aperture are built there will be an ever increasing number of visual binaries discovered. Also, the brightness of the objects is an important factor in the detection of the double character of a star, it being easier to see as separate objects two faint stars separated by a small angular distance, than two bright

stars separated by the same angular distance. Adopting certain arbitrary definitions as to what shall be considered a visual binary, Aitken estimates that about 1 star out of every 18 is a visual binary.

Visual binary stars are studied from observations taken either with a **filar micrometer** or a **stellar interferometer.** The brighter star of the pair is known as the primary and the fainter as the secondary. The **position angle** of the secondary with respect to the primary is measured, together with the angular distance between the two components. The time of the observation is also recorded. After a sufficient number of observations have been obtained they are plotted in polar **coordinates,** using the primary star as origin. Through these plotted points the most probable ellipse is drawn, the only restriction on the ellipse being that the **Keplerian Law of Areas** must be satisfied. The ellipse thus drawn is known as the apparent ellipse.

This apparent ellipse is the projection of the actual elliptical **orbit,** of the secondary with reference to the primary, on the plane perpendicular to the line of sight of the observer. From this projected ellipse the complete **elements** of the orbit may be computed, the semimajor axis, a, being expressed in **angular units** unless the **stellar parallax** of the system is known. (W.K.G.)

VITAMINS. A group of substances which are present in varying amounts in certain animal and plant tissues. Vitamins are necessary for normal nutrition, growth, and function of the body. The quantities needed are often extremely minute, but since the body cannot (with a few relative exceptions) manufacture its own supply, vitamins must be supplied in the diet. Their absence or partial deficiency produces various characteristic diseases and disturbances of body growth and function.

Biological, rather than chemical, methods are responsible for the discovery of vitamins, and for much of our early knowledge of them. These methods proved the necessity for their supply to the organism, as well as the properties of vitamins, a summary of which is given in the accompanying table.

In this country, extreme deficiency states of a particular vitamin are not as common as they are in other parts of the world. But milder forms of deficiency diseases, especially rickets and pellagra, are not infrequent. Deficiency in diet is not the only factor involved, for disturbances in absorption from the gastrointestinal tract may result in deficiency states even though adequate quantities of vitamins be supplied in the diet. The requirements for certain vitamins are enormously increased during certain periods of life—during the ages of active growth, and during pregnancy and lactation.

Vitamin A is a fat-soluble vitamin necessary for growth. Another function is concerned with vision in dim light. Such vision is mainly a function of specialized cells, the rods of the retina, and is dependent on an adequate supply of the pigment, visual purple, a compound of vitamin A and a protein. (See **Vision.**) One of the earliest manifestations of vitamin A deficiency is, therefore, night blindness, or diminished vision in dim light. The vitamin is also necessary for the maintenance of the epithelial tissues (**epithelium**) in a normal state. In its absence, specialized epithelial cells undergo **atrophy,** and change to a more primitive type; this may seriously interfere with the function of the involved part. Thus the surface of the conjunctiva and **cornea** of the eye

VITAMINS

Designation	Date of Discovery	Properties	Main Effects of Deprivation in Man	Dietary Sources
A.	1913	Fat-soluble, relatively Heat stable, relatively Well stored by the body	Night blindness, xerophthalmia, dermatosis	Fish oils, liver, egg yolk, butter, carrots and leafy green vegetables
The B complex B_1 thiamin	1926	Water-soluble Heat Stable Poorly stored by the body	Beri-beri, polyneuritis, cardiac enlargement and failure, loss of appetite	Lean pork and beef. Peanuts, dried peas and beans, oatmeal, wheat, green peas, and beans
Nicotinic acid.	1867 1939	Water-soluble Heat stable	Pellagra, dermatitis, stomatitis, gastro-enteritis, psychosis	As thiamin, plus milk, egg yolk
B_2 (G) riboflavin.	1933	Water-soluble Heat stable	Cheilosis and angular stomatitis, glossitis, dermatitis	Liver, lean meats, egg yolk, peanuts, pears, peaches, milk, whole grain wheat, carrots, peas, spinach
C Ascorbic or cevitamic acid	1932	Water-soluble Heat stable	Scurvy	Citrus fruits, tomatoes, turnips, sweet potatoes, leafy green vegetables
D.	1922	Fat-soluble, relatively Heat stable, relatively Well stored in the body	Rickets	Fish liver oils, egg yolk, butter, cream
E Alpha-tocopherol.	1922	Fat-soluble Heat stable	Habitual abortion, neuro-muscular disorders	Wheat germ oil, leafy vegetables, eggs
K.	1939	Fat-soluble Heat stable. Not well stored	Hemorrhagic disease of the newborn, bleeding associated with obstructive jaundice, sprue, etc.	Kale, spinach, carrot tops tomatoes, liver

become hard, dry, and may ulcerate. **Xerosis**, xerophthalmia, and keratomalacia are the diseases which represent various stages in this process. The epithelium of the skin and its specialized structures are affected too: the skin becomes rough, dry, scaly, and the sweat glands dry up. The epithelial cells of the respiratory and genitourinary tracts may also be involved. Vaginitis of the so-called senile type may be a manifestation of A deficiency.

Vitamin A is absorbed from the intestine and transported by the blood and lymph to the liver, where it is stored. In the liver the precursors of the vitamin, chiefly alpha- and beta-carotene, are converted into vitamin A.

The B group of vitamins is a complex which contains three well-established compounds (thiamin, nicotinic acid, and riboflavin) and several recently discovered constituents whose functions and requirements for man are not yet completely understood—(pyridoxine, folic acid, pantothenic acid, biotin, inositol, anti-gray hair factor, etc.). Only the three whose properties and functions are well known will be discussed here.

Vitamin B_1, thiamin, the deficiency of which results in **beri-beri** was the first to be differentiated from other members of the B complex. It has been isolated and synthesized in pure crystalline form. In practice it is used in the form of the hydrochloride. It is present in both blood cells and serum in small quantities, and is excreted in the urine in amounts which reflect intake and storage. In animals, it has been demonstrated to be abundant in liver, heart, kidneys and voluntary muscle.

Vitamin B_1 plays an important role in the fundamental processes of oxidation in the body. In the oxidation of carbohydrate it is active as a coenzyme—carboxylase. Although much is known of the chemistry of thiamin in the body, little is known of the mechanism by which the clinical picture of B_1 deficiency is produced. The vitamin seems necessary for the maintenance of the health of nerve tissue, intestinal and cardiovascular function, appetite, and growth. Lack of thiamin produces **beriberi**, polyneuritis, dilatation and hypertrophy of the heart, edema, and muscular atrophy. Alcoholics are prone to thiamin deficiency, because of their tendency to substitute alcohol for the normal diet. Peripheral neuritis is seen most commonly in alcoholics. All of these manifestations respond promptly to adequate therapeutic doses of thiamin.

Nicotinic acid, although discovered in 1867, was not known to be important for man until 1939. Deficiency of nicotinic acid produces pellagra in humans, and "black tongue" in dogs. Nicotinic acid in the form of the amide forms a part of one of the essential **enzyme** systems, used for transferring oxygen in oxidations concerned with fundamental life processes in the cell. How this function is related to the physiological and structural changes (**dermatitis, glossitis, proctitis, dementia**) resulting from its deficiency is not known. The vitamin is widespread in body tissues and is stored relatively well. It is available in pure form as nicotinic acid and nicotinic acid amide for clinical use. In addition to its use as a specific for pellagra, the drug is now being used because of its vasodilating action in **angina pectoris**, intermittent claudication (cramping pain in the legs on exercise, due to a diminished blood supply), and **thrombophlebitis.**

Vitamin B_2 (G) is a complex pigment with a green fluorescence called riboflavin or lactoflavin. The clinical picture resulting from deficiency of this vitamin was first described in 1938; the outstanding findings are cheilosis, stomatitis at the angles of the mouth, seborrheic **dermatitis, glossitis,** and vascularization of the **cornea.** The lip and mouth lesions have been familiar to clinicians for many years, but their relation to a vitamin deficiency is recent knowledge. Riboflavin deficiency frequently accompanies **pellagra** and the typical lesions of both nicotinic acid and riboflavin deficiency are often found in that disease.

Riboflavin, like nicotinic acid, forms an oxidation **enzyme** and, as such, acts as an oxygen carrier to the cell. The mode of production of the clinical picture of deficiency is again unknown. The vitamin is widely distributed in the cells, and rather large amounts are excreted in the urine. Little is known of its absorption and storage. Riboflavin is available in pure form for clinical use. It is, however, very unstable to light and air, and solutions must be used soon after preparation.

Vitamin C is ascorbic or cevitamic acid. Its deficiency results in **scurvy**, a disease characterized by weakness, anemia, swelling of the gums and multiple hemorrhages. The vitamin is a powerful oxidation-reduction agent. It has been isolated in pure form. It cannot be synthesized by the human body, although there is considerable difference among species in this respect: rats, chickens, and dogs can synthesize it, while guinea pigs cannot. When supplied in the diet, it is completely absorbed in the intestine and distributed widely throughout the body. Its concentration in the blood reflects the concentration in the tissues and forms the basis of a laboratory test to measure its deficiency.

Vitamin C is necessary for the maintenance of the so-called intercellular cement substance of mesothelial tissue or structures derived from it, such as connective tissue, bone, capillaries, etc. In C deficiency these tissues become abnormally fragile, and hemorrhages are common, especially in the gums and into the joints. All signs and symptoms respond promptly to treatment with ascorbic acid.

Vitamin D is a fat-soluble vitamin which is necessary for the absorption of **calcium and phosphorus**, and is concerned directly in the metabolism of bone. It is a specific in the prevention and treatment of **rickets**, childhood **tetany**, and **osteomalacia**. It is necessary for the formation of bone and teeth, and large amounts are therefore required in childhood. In some unknown way, it is related to the action of the **parathyroid** glands. Vitamin D is not a single substance, but only 2 of the 10 or 11 sterols known to have antirachitic properties are of importance medically. These are activated ergosterol (Viosterol) and 7-dehydro-cholesterol. The D substances are activated sterols, complex substances often closely asociated with fats in plants and animals. **Cholesterol** is an important sterol which is present in the skin; activation of cholesterol by **ultraviolet** light changes the compound and produces vitamin D. This is the way in which man obtains the greater part of his vitamin D, relatively little being taken in with food. The vitamin can be stored in the liver. It is toxic in very large doses far outside the range for therapeutic use.

Vitamin E is a fat-soluble vitamin essential for reproductive processes in certain animals; its necessity for man has not been established. In the female white rat, deficiency of vitamin E results in premature death and resorption of the fetus *in utero*. The possible corresponding condition in humans is habitual abortion. The evidence that the two situations are related by a common etiology is now less convincing than formerly, and there is considerable doubt that vitamin E plays any role in humans. The relationship to certain of the neuromuscular disorders is still under investigation.

Vitamin E is a tocopherol, a solid alcohol present in relatively large amounts in wheat germ oil, from which it was first isolated. It has been isolated in pure form and has been synthesized. There are several tocopherols, alpha being the most active of the naturally occurring ones. The mechanism by which vitamin E produces its effect is not known, nor is it known whether it is important in biologic processes in the cell.

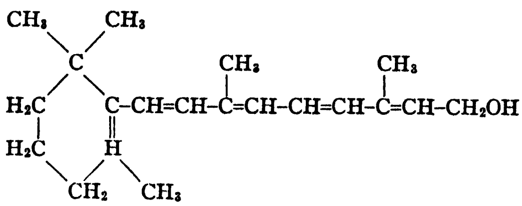
Vitamin K is a recently described factor necessary for the adequate production of prothrombin, a substance which is present in the blood and plays an active role in the clotting mechanism. Vitamin K deficiency results in a low prothrombin level and is therefore asso-

ciated with several hemorrhagic states: the bleeding tendency accompanying obstructive **jaundice**, hemorrhagic disease of the newborn, and bleeding associated with diseases of the gastrointestinal tract, such as **sprue**, **celiac disease**, etc.

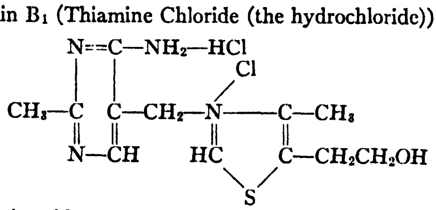
Vitamin K is a substituted derivative of naphthoquinone and occurs in several forms. It has been isolated in pure form and synthesized and is available for clinical use. As a preventive of hemorrhagic disease of the newborn, it is highly effective and is now often given routinely to mothers just before delivery.

STRUCTURAL CONFIGURATIONS OF VITAMINS

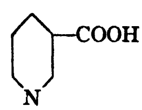
Vitamin A:



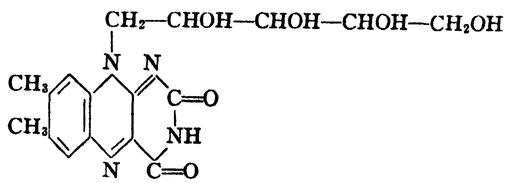
Vitamin B_1 (Thiamine Chloride (the hydrochloride)):



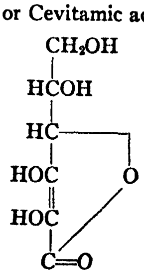
Nicotinic acid:



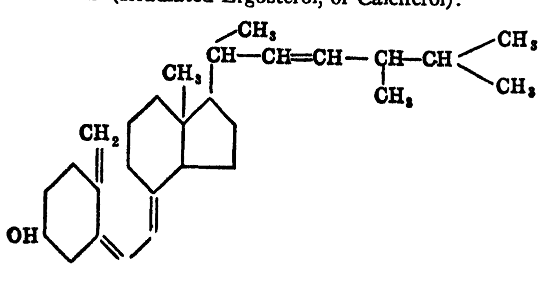
Vitamin B_2 (G) (Riboflavin):



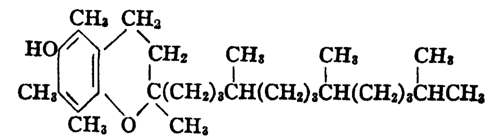
Vitamin C (Ascorbic or Cevitamic acid):



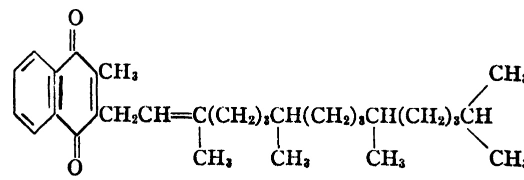
Vitamin D (Irradiated Ergosterol, or Calciferol):



Vitamin E (Alpha-tocopherol):



Vitamin K:



(R.K..S, D.M.H.)

VITELLARIUM. A yolk-forming organ. The term is applied in the flatworms (**Platyhelminthes**) to a long series of glandular bodies associated with the **oviducts**. They form both the yolk and the shells of the eggs. The same name designates a portion of the ovary of **rotifers**. This organ is divided into a germarium where the egg cells are produced and the larger vitellarium. (A.W.L.)

VITRAIN. A term proposed by M. Stopes, in 1919, for a glassy variety of **coal** which occurs in bituminous coal as bright narrow and easily friable bands which may be distinguished from **clarain**, especially with the aid of the microscope. (R.M.F.)

VITRELLA. A crystal cell of the group between the cornea and the retinula in the compound **eye** of **arthropods**. (A.W.L.)

VITREOUS ENAMEL. Porcelain Enamel.

VITRIFIED BOND. A molded grinding wheel made from clay or flint, abrasive, and water, burned at a high temperature for several days. (H.C.H.)

VITRIOL. Term applied to **sulfates**. Oil of vitriol, concentrated **sulfuric acid**; blue vitriol, **copper** sulfate crystals; green vitriol, **ferrous** sulfate crystals; white vitriol, **zinc** sulfate crystals. (R.K.S.)

VITROPHYRE. A vitrophyre is a volcanic glass carrying sporadic distinct crystals of **feldspar** and other minerals; in short, a **porphyritic** glass. (E.S.C.S.)

VIVIANITE. The mineral vivianite is a hydrous **iron phosphate**, $Fe_3P_2O_8 \cdot 8H_2O$, its **monoclinic** crystals are usually prismatic or bladelike but may be in massive forms. Vivianite has one perfect **cleavage**; hardness 1.5–2; specific gravity, 2.58–2.68; luster, pearly on cleavage faces, otherwise vitreous; colorless, when freshly exposed, but becoming blue or brownish with the alteration of the ferrous to ferric iron; transparent to translucent. Vivianite is an associate of **pyrrhotite**, **pyrite** and **copper** and **tin** ores. It is found also in clay beds forming the so-called "blue iron earth" which is common and of wide distribution in peat bogs. Vivianite is found in Rumania, Bavaria, Cornwall in England, Australia, Bolivia, Greenland and elsewhere in Europe. In the United States it occurs in New Jersey, Delaware and Colorado. This mineral was named by Werner after the English mineralogist J. G. Vivian, its discoverer. (E.S.C.S.)

VIVIPARITY. A reproductive process involving the internal nourishing of the young by the body of the

mother during the early stages of development and their birth when sufficiently advanced to carry on essential processes of life. It contrasts with oviparity, in which reproduction is accomplished by the formation and discharge of eggs, and ovoviviparity, in which the eggs hatch in the body of the mother, but there are no special adaptations for the direct prenatal **nourishing** of the young.

Both viviparity and ovoviviparity necessitate internal **insemination.** They are not limited to particular groups of animals but occur in many forms of invertebrates and vertebrates, including roundworms, rotifers, insects, fishes, reptiles and mammals. Although most of the forms below the mammals are probably ovoviviparous, there is good evidence for the interpretation of some of the parasitic flies as truly viviparous, since the larvae are produced just prior to their transformation into pupae. True viviparity is at its maximum, however, in the mammals, but even here a transition occurs from the oviparous monotremes to the true mammals, including man. The young are nourished prior to birth by interchange with the blood stream of the mother through the **placenta.** (A.W.L.)

VIVISECTION. The dissection of living animals. The practice of vivisection has aroused so much emotional opposition that it has been widely publicized in the daily press. In the strict sense, scientists do dissect living animal to learn of processes taking place in their bodies more accurately than is possible without this procedure. Such studies are conducted, however, with the greatest possible humanity. Animals are anesthetized for operative procedures and are killed painlessly at the end of experimental study. If the destruction of life is to be regarded as cruelty, then our use of domestic animals as food is on a par with vivisection.

The study of processes and relations within the body of the animal while it is still a living organism has been of incalculable benefit to medicine and has been directly responsible for the saving of many human lives. As an example among recent discoveries, the functions of the adrenal cortex were discovered through experiments with cats from which the glands had been removed. The animals were kept alive by administering extracts of the adrenal cortex of other species, and the final perfection of these extracts so that they could be administered safely to human beings provided the first alleviation for Addison's disease. (A.W.L.)

VOGESITE. A term proposed by Rosenbusch, in 1887, for a **syenitic lamporphyric igneous rock** in which the characteristic minerals are generally **hornblende** or **augite** and **oligoclase** or **andesine** feldspar. (R.M.F.)

VOLATILE. Coal, Proximate Analysis.

VOLATILE OILS. The volatile oils are distinguished from the **fixed oils** by the fact that a drop of one of these oils does not leave a spot on paper. Members of certain plant families, such as the **Mint Family,** contain a larger percentage of such oils than do other families. But volatile oils are in no sense restricted to any small group, nor are they found only in certain tissues. Sometimes, certain parts may be principally used for the oils, as the seeds of the **Carrot Family.**

Various methods are used in extracting the oils from the plant tissue. Many are distilled with water or steam, the oil being carried over with the distillate. In others, as for example oil of bitter almonds, the oil develops in the tissues only after **fermentation.** It is then obtained by **distillation.** Another method, and one especially used for more delicate and valuable oils, is called "enfleurage." In this method the flowers containing the oil are spread as a thin layer over a layer of lard or olive oil. The latter absorbs the delicate oil in the flowers, after which distillation may separate the volatile oil from the other.

Volatile oils are much used as perfumes, flavorings, drugs and solvents. Attar of Roses, or Rose oil, from **Roses,** is one of the most valuable. Jasmine oil, from *Jasminum grandiflora* (Oleaceae) petals is somewhat less valuable. It is obtained by absorbing the oil from the petals of the plant in olive oil. Geranium oil, from several species of *Pelargonium,* cultivated mainly in Southern France and Spain, is much used to adulterate rose oil. Bay oil, from the leaves of *Pimenta acris* (Myrtaceae), a native of the West Indies, is much used in perfumes, toilet preparations and bay rum. From the leaves and flowers of many members of the Mint Family fragrant perfume oils are obtained: *Lavendula vera,* used by the Romans to scent their baths, gives lavender oil, an expensive perfume oil, while *L. spica* yields Spike oil, a cheaper oil than lavender. Dried lavender plants are frequently used in bedding and clothing to impart to them a delicate fragrance. Another mint, *Rosmarinus officinalis,* yields oil of rosemary. Certain grasses also yield fragrant oils. Among these are *Cymbopogon citratus,* a native of India and Ceylon, from which is obtained lemon grass oil, used as an adulterant for lemon oil, as well as for its own fragrance, and *Cymbopogon Nardus,* from which citronella oil is obtained. The latter is used as a repellent for mosquitoes and other insects. These two grasses are cultivated to a limited extent for their oils. Verbena oil is a valuable product from *Verbena triphylla* and other species (Verbenaceae). Neroli oil is obtained from the flowers of the orange tree (Rutaceae); this oil is used in cologne and in liquors. From another member of this family comes **Bergamot oil.** The Laurel Family (Lauraceae) has many members which yield volatile oils. From *Cinnamomum zeylanicum* come cinnamon oil and cinnamon-leaf oil, used not only in perfumes but also in medicines and as a flavoring. The green leaves of *Cinnamomum Cassia,* a native of the East Indies and India, give cassia oil, an expensive and consequently much adulterated oil used in perfumes and medicines. The bark and roots of *Sassafras officinale,* a tree native in southern United States, yield sassafras oil, used in making cheaper perfumes. From *Cananga Odorata* (Anonaceae) comes oil of cananga, called also Ylang ylang, "Flowers of Flowers," a very expensive oil. The tree is a native of southeastern Asia. Various species of Iris, particularly *Iris germanica,* yield orris root and orris oil, the dry powdered rhizome being used. The powder has an odor suggestive of violets, and is used in compounding medicines, sachets and tooth powders. Southern Italy leads in the production of orris root.

Among volatile oils are many primarily used in flavoring and as drugs. Many of these come from members of the Mint Family. One of them is oil of peppermint from the leaves and stems of *Mentha piperita.* The states of Michigan, Indiana, and New York grow much of the native crop, but are far behind Japan in production. Oil of peppermint is mostly menthol, and is used is flavoring chewing gum, tooth pastes, and as an inhalant and perfume. It is commonly adulterated. From *Mentha spicata,* or Spearmint, comes oil of spearmint, used as a drug, as a flavoring in cooking, and in preparing mint sauce, in chewing gums and in cheaper perfumes. The principal producing regions are New York, Michigan, India and Russia. Clove oil is obtained from the flower buds of the Clove tree, *Eugenia aromatica.* It is used as a drug and for flavoring and in perfumes. *Artemisia absinthium,* one of the **Composite Family,** yields oil of wormwood, used in medicine, as a worm repellent, and in the preparation of absinthe. Oil of anise seed is obtained from the seeds of *Pimpinella Anisum,* a member of the **Carrot Family** indigenous to Egypt and now widely cultivated. The oil is used in perfumes, as a drug, and in liqueurs. Anise seed oil is also used to make a trail which will be followed by

foxhounds. Many other members of the **Carrot Family** have aromatic oils in the seeds. Star anise, so named because of the star-shaped fruit, from *Illicium verum* (Magnoliaceae), is a similar oil. Camphor oil is obtained from the **Camphor** Tree, *Cinnamomum Camphora*. Lemon oil comes from the skin of the lemons, *Citrus Limonium*. Bitter almond oil is extracted from *Prunus communis*, of the **Rose Family**. Juniper oil is obtained from *Juniperus communis*, a Conifer. It is used in medicine, also in varnish making, and in gin. Among leguminous plants the genus *Eucalyptus*, especially *E. globulus*, yields from the leaves oils known as eucalyptus oils, used in making perfumes, as antiseptics, in scented soaps and toilet preparations, also in concentrating ores by the flotation process. The trees are natives of Australia, and have been introduced into California.

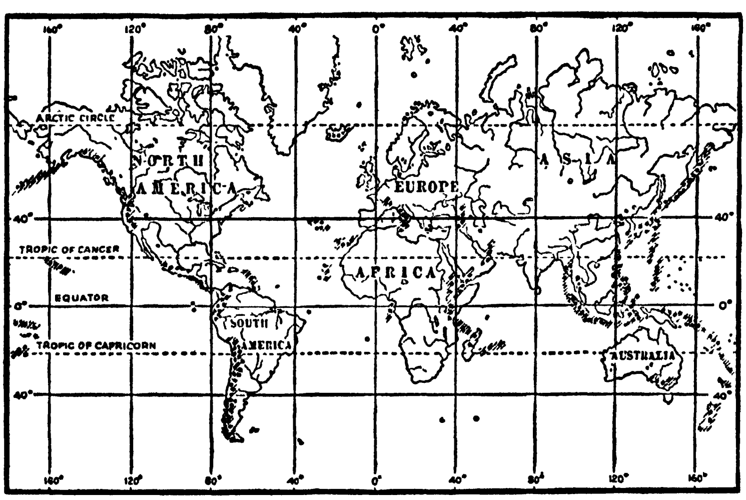
Oil of turpentine, also called spirits of turpentine, is obtained by the distillation of exudates of *Pinus ponderosa* and *P. Taeda* (Coniferae). It is used as a solvent in making paints and varnishes, and also in medicine. Venetian turpentine, obtained from the European Larch, *Larix europea*, is a similar product. (See **Hydrocarbons**.) (R.M.W.)

VOLCANIC BOMB. **Lapilli.**

VOLCANITE. A term proposed by Hobbs, in 1893, for a volcanic rock from the Lipari Islands largely composed of the minerals **anorthoclase** and **augite**. (R.M.F.)

VOLCANO. A volcano is a conical mountain built up around a vent in the crust of the earth. It is formed of lava and fragmental material which has flowed out in a highly heated and liquid state, or from matter ejected by explosive eruptions, or both. It is convenient to classify volcanoes as of three types: 1. The explosive type from which solid fragmental material and gases are erupted. This material may consist of blocky pieces, often ejected in a partly fluid condition, *lapilli*, or dust, the latter often incorrectly called ash. 2. The effusive type, characterized by quiet eruptions of liquid lava with little or no explosive violence. Such lavas are very fluid and frequently flow for many miles. 3. The intermediate type which may at times erupt explosively with accompanying flows of lava. Typical highly explosive eruptions have been: that of Krakatao in the Straits of Sunda, Dutch East Indies, which in 1883 blew up about a cubic mile of rock which rose as dust over 15 miles in the atmosphere; and that of Mt. Pelée on the Island of Martinique, West Indies, which occurred in 1902. The latter eruption was without lava and consisted of a great cloud of incandescent gases and dust, which destroyed the city of St. Pierre and almost its entire population of about 28,000 inhabitants. Mauna Loa and Kilauea in the Hawaiian Islands are examples of the effusive type of volcano and Mt. Vesuvius is an excellent example of the intermediate type. Most of the active Alaskan volcanoes are of the intermediate type as were doubtless the now-extinct volcanoes of the northwestern part of the United States which include: Mt. Shasta, Mt. Rainier, Mt. Hood, Mt. Baker, and others.

The explosive type may be recognized by the steep cone (often seen with the intermediate type as well); the effusive type of volcano with its long lava flows builds a low cone of great areal extent as compared with its height. (E.S.C.S.)



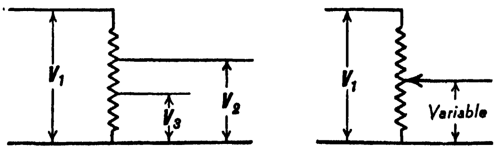
Map showing the distribution of active and recently extinct volcanoes. (*Tarr's New Physical Geography, The Macmillan Co.*)

VOLE. Mammalia, Rodentia. The meadow or field mice, constituting the genus *Microtus*. The genus is limited to the northern hemisphere and in Asia does not extend south of the Himalayas. Voles are characterized by rootless molar teeth formed of two rows of alternating triangular prisms. About 20 species occur in North America. (A.W.L.)

VOLT. The volt, which is the practical unit of **electromotive force** and **electric potential**, may be defined in different ways, some of which are equivalent, while others give rise to slightly different values. Perhaps the simplest definition of the "absolute volt" is that electromotive force or potential difference against which one watt of power is necessary to maintain an electric current of 1 (absolute) **ampere**; or against which one joule of energy is necessary to transfer an electric charge of one (absolute) **coulomb**. The "international volt," on the other hand, is defined in terms of the international ampere and international **ohm** in accordance with **Ohm's law** (one volt maintains a current of 1 ampere through a 1-ohm resistance). The international volt exceeds the absolute volt by about 34 parts in 100,000. (See also **Standard Cell**.) One may get a fair idea of the magnitude of 1 volt by noting that the electromotive force of a 3-cell automobile battery is about 6 volts, and that of the ordinary electric light supply is 110 volts. (L.D.W.)

VOLTAGE DIVIDER. The ordinary three-terminal resistance may be used as a voltage divider. If no current is taken from the intermediate tap the voltages

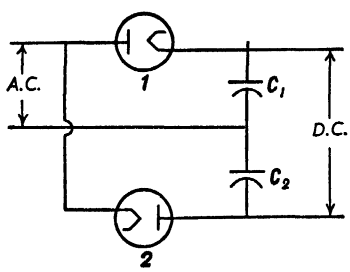
will be in proportion to the resistance included between the taps. In many applications a potentiometer is used as a voltage divider so the voltage may be adjusted by



Voltage divider.

varying the position of the tap. If current is drawn from the tap the exact distribution of the voltage is altered but the total voltage applied across the divider is still divided between the various sections. The figure shows some typical arrangements. (L.R.Q.)

VOLTAGE DOUBLER. This is a connection of condensers and rectifiers across an a-c source which gives a d-c output voltage approximately twice that of the normal connection. The exact value of the output voltage depends upon the load and for very high loads may not even approach the theoretical double value. A circuit is shown in the figure. On one half-cycle C_1 charges



Voltage doubler.

through tube 1 and on the other half-cycle C_2 charges through tube 2, the polarities being as shown on the diagram. It is seen then that the output voltage is the sum of the two condenser voltages. (L.R.Q.)

VOLTAGE REGULATION. Automatic voltage regulators are relied upon for maintenance of constant generator voltage. Alternator-voltage regulators have, for all practical purposes, become limited to four distinct mechanical types, the vibrating, the direct-acting, the rheostatic, and electronic. D-c regulators are usually rheostatic.

In the vibrating voltage regulator system the voltage is maintained by varying the **alternator** field strength indirectly through control of the **exciter** field. The basic idea is the short-circuiting of the exciter shunt field rheostat by rapidly vibrating contacts which open and close the short-circuit path several times per second. The main contacts in this type of regulator are acted on by two sets of control magnets, one connected across the exciter bus and tending to move the main contacts farther apart as the exciter voltage rises, and the other acted upon by a-c potential and current coils. Suitable springs and counterweights allow adjustment to be made. When the main contact closes it energizes the relay magnet, thus closing the relay contact, short-circuiting the exciter rheostat, raising the exciter voltage, and consequently, the alternator voltage. The use of the exciter voltage as one of the main control circuits prevents the alternator voltage "overshooting."

Compensating current winding of the a-c **solenoid** is provided with a dial switch to give any amount of compensation required for the feeder circuit in which the current transformer is located. The vibrating-type regulator may be applied to d-c as well as a-c systems. The **exciters** should be selected with characteristics known to function satisfactorily with the type of regulators used. The regulators may be operated in parallel, also one regulator may control more than one generator through the use of special exciter rheostats. Successful operation of individually regulated exciters in parallel depends upon control of the wattless current which may circulate between the alternators as a result of momentary differences in excitation. Control of this feature is worked out on the basis of alternator power factor.

In direct-acting regulators, an induction motor principle furnishes the actuating impulse. The torque produced is counteracted by a spring (and the exciter field rheostat is an integral part of the regulator). The rheostat arm has pure rolling motion, hence very little effort is required for the voltage regulating motion. A damping mechanism consists of a disk and magnets.

Unlike the first two types, the rheostatic regulator can be used in plants where the excitation is taken normally from a constant-potential bus. The rheostatic regulator does what an operator would do, except that it does it more quickly and provides instantaneous correction to standard voltage. Rheostatic regulators should be used in the case of large slow-speed exciters, the magnitude of whose field current would prove embarrassing to the vibrating-type regulator. It is also applied where exciter field control would give too slow a response to the control impulse.

The electronic regulator employs electron tubes to control the field current of the generator directly or the exciter field. These tubes are controlled by the output voltage so a rise of voltage decreases the current through them and a decrease of voltage increases the current. By proper adjustment of the circuit the control may be made sensitive enough to maintain essentially constant bus voltage. (F.T.M., L.R.Q.)

VOLTAMETER. Coulombmeter.

VOLT-AMPERE. Alternating Currents.

VOLTA'S LAW. Contact Potential Difference.

VOLTMETERS. The usual instruments of this class differ from **ammeters** used on the same type of service in only one essential respect: they are of very high resistance. Therefore, when connected across the terminals between which the voltage is to be measured, they take very little current and cause but a very slight drop in the potential difference. The current through the voltmeter is proportional to the voltage, and the scale may therefore be graduated to read directly in volts. Instruments are made which, with the proper change in connections, serve either as voltmeters or ammeters, the scale having two graduations. For high voltages, the voltmeter is placed in series with a large resistance, called a multiplier, so that the potential difference between its terminals is a known fraction of the voltage under test.

There are electrostatic voltmeters which may be used to measure electrostatic potentials of thousands of volts. A common form resembles a gold-leaf **electrometer** of large size, but with a brass pointer swinging on a scale in place of the gold-leaf. The "sphere gap" (see **Spark**) may also be used for approximate high-voltage measurements. (See **Instruments, Electrical.**) (L.D.W.)

VOLUME EXPANDER. Expander.

VOLUME INTEGRAL. Triple Integral.

VOLUMES BY DOUBLE INTEGRALS. Consider the solid bounded below by a region S in the XY-plane, with boundary $x = a$, $x = b$, the X-axis and a curve $y = \phi(x)$, bounded above by a surface $z = f(x, y)$, and laterally by planes $x = a$, $x = b$, $y = 0$ and the cylindrical surface formed by parallels to the Z-axis through the

points of the curve $y = \phi(x)$. The volume of this solid is given by the double integral

$$V = \int_a^b \left(\int_0^{\phi(x)} z\,dy \right) dx = \int_a^b \left(\int_0^{\phi(x)} f(x, y)\,dy \right) dx.$$

(L.L.S.)

VOLUMES BY PARALLEL SECTIONS. If the plane perpendicular to the X-axis at a distance x from the origin cuts from a given solid a section whose area is $A(x)$, then the volume of that part of the solid between $x = a$ and $x = b$ is given by

$$V = \int_a^b A(x)dx.$$

(L.L.S.)

VOLUMES BY TRIPLE INTEGRALS. A volume in general may be found by the **triple integral**

$$V = \int_{x_1}^{x_2} \left[\int_{y_1}^{y_2} \left(\int_{z_1}^{z_2} dz \right) dy \right] dx,$$

where the limits of the successive integrations are determined by the boundary of the given solid. (L.L.S.)

VOLUMETRIC ANALYSIS. **Analytical Chemistry.**

VOLUMETRIC EFFICIENCY. Volumetric efficiency is a term applicable to a **piston** and **cylinder** mechanism in which an outward stroke of the piston induces a **vacuum** which draws a gas into the cylinder. This efficiency is of special importance in the **internal combustion engine,** and no complete explanation of engine action is possible without invoking it. Volumetric efficiency may be defined as the weight of gas actually drawn in on an induction stroke, divided by the weight which would occupy the piston displacement under standard conditions of atmospheric pressure and 60° F. If an engine revolved very slowly, and the induction passages were large and unobstructed, the cylinder might be filled with a gas at practically atmospheric pressure, but still the volumetric efficiency could be less than 100% by the heating of this fresh charge through contact with warm manifold and cylinder walls. Since internal combustion engines rotate at speeds from 300 to 3000 rpm, a definite pressure decrement must be expected as necessary to overcome inertia and friction in order to get the cylinder filled with gas in so short an interval of time. Of course, the above refers to normal operation, as it is possible to obtain volumetric efficiencies higher than 100% by **supercharging.**

From the above it will be realized that volumetric efficiency has little in common with **thermal efficiency,** but depends on such factors as the rotative speed of the engine, the fraction of the cycle which is given over to induction, the shape of the ports and valves, and the temperature of the gas. The latter is affected by heating in manifolds, carburetor air heaters, or cylinders, though this may be partially offset by some refrigeration obtained in the vaporization action of the carburetor. (F.T.M.)

VOLUTE PUMP. A volute is a spiral or scroll. A volute **centrifugal pump** has a spiral casing surrounding the impeller, so that as water is discharged uniformly around the periphery of the impeller it will be collected in a chamber of increasing cross-sectional area. In this way the discharge from the rim of the rotating impeller is delivered to the discharge outlet without the necessity of the water velocity near the outlet being higher than average. (F.T.M.)

VOMER. A bone of the vertebrate skull. In mammals it is a thin vertical plate in the posterior part of the nasal septum. (A.W.L.)

VOMITING. The expulsion of the stomach contents through the mouth. This is accomplished by reversal of the direction of the normal waves of **peristalsis** in the gastrointestinal tract. Vomiting is caused by irritation of the stomach or bowel by local irritation, or by stimulation of the vomiting center in the brain by **drugs,** pressure (as by a brain tumor or intracranial pressure); or by obstruction in the gastrointestinal tract in the esophagus, stomach, or in the bowel. (D.M.H.)

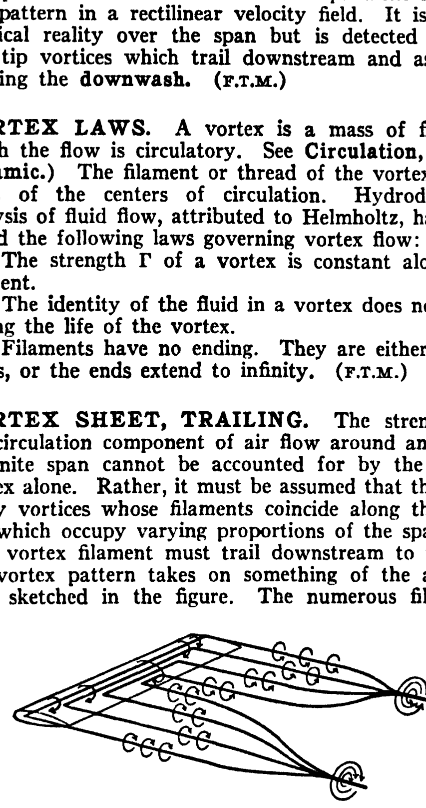
VORTEX. **Aerodynamics.**

VORTEX, BOUND. The assumption of a vortex whose filament coincides with the spanwise axis of an airfoil is a useful expedient in deriving aerodynamic equations for lift and drag. This vortex is considered to replace the airfoil and create an equivalent streamline pattern in a rectilinear velocity field. It is not a physical reality over the span but is detected as the two tip vortices which trail downstream and assist in creating the **downwash.** (F.T.M.)

VORTEX LAWS. A vortex is a mass of fluid in which the flow is circulatory. See **Circulation, Aerodynamic.**) The filament or thread of the vortex is the locus of the centers of circulation. Hydrodynamic analysis of fluid flow, attributed to Helmholtz, has produced the following laws governing vortex flow:

1. The strength Γ of a vortex is constant along the filament.
2. The identity of the fluid in a vortex does not alter during the life of the vortex.
3. Filaments have no ending. They are either closed paths, or the ends extend to infinity. (F.T.M.)

VORTEX SHEET, TRAILING. The strength of the circulation component of air flow around an airfoil of finite span cannot be accounted for by the bound vortex alone. Rather, it must be assumed that there are many vortices whose filaments coincide along the span but which occupy varying proportions of the span. As each vortex filament must trail downstream to infinity the vortex pattern takes on something of the appearance sketched in the figure. The numerous filaments



streaming from the trailing edge create a vortex sheet. Derivations based on this assumption of multiple vortices are verified by experiment. The assumption, moreover, disposes of what was at one time a flaw in the circulation theory of lift. At the airfoil tips where the tip vortices turn downstream the downwash velocity induced by the vortex should be infinity since the radial distance from the vortex filament is zero there. But that the downwash is everywhere of small magnitude was well known. Since the strength of multiple vortices is additive the proximity of numerous other trailing vortices to the tip vortex will minimize the downwash at the tips.

The spanwise halves of the vortex sheet represent a surface of discontinuity which is unstable and each half rolls up into a powerful single vortex at somewhere about a span length behind the airfoil. (F.T.M.)

VUG. A rock cavity lined, but incompletely filled, with mineral matter so that a part of the available space remains empty. (E.S.C.S.)

VULTURE. Aves, Falconiformes. A large flesh-eating bird (**Aves**) with a hooked beak but with claws less strongly developed than those of the eagles, hawks, and owls. They feed largely on carrion, but many species are also known to attack living animals.

Turkey buzzard, *Cathartes aura septentrionales.* Black with brown edging to feathers. Skin of head and neck bare and red.

The Old World vultures belong to a family distinct from the New World species. The latter differ in having the nostrils confluent, so that the beak is perforated transversely. With the exception of the lammergeier, an Old World species, all vultures have the head and neck almost bare of feathers and sometimes brightly colored.

The turkey vultures or turkey buzzards, *Cathartes aura,* of North America are our most widely distributed representatives of the group, and the condor of South America is probably most widely known for its enormous size. It has been recorded with a length of 4′ and a wingspread of 9′. The California vulture or condor, *Gymnogyps californianus,* of the southwestern states and Lower California has also been recorded with a maximum length of 4′ or more, and its wingspread is said to reach almost 11′. Although their habits are repulsive, all of these birds are magnificent fliers, soaring for long periods without flapping a wing. (A.W.L.)

VULVA. The area containing the external genitalia of the female corresponding to the **penis** and scrotum in the male. They comprise the two labia majora and the parts lying between them. They are as follows:

The larger labia are two large fatty folds of skin lying between the thighs. Posteriorly they end at the **anus,** anteriorly they end in the *mons Veneris,* a fatty prominent elevation over the pubic bone. They correspond to the **scrotum** in the male. The lesser labia are two smaller similar folds of skin within the fold of the larger labia. Anteriorly they are prolonged over the **clitoris** to form the foreskin or **prepuce.** Just below the clitoris within the labial folds is the opening of the **urethra,** above the **vagina.** Opening into the area about the vagina are the ducts of several glands whose special purpose is lubrication. (R.S.M.)

W

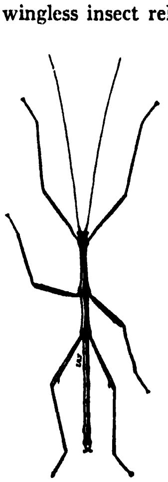
WACKE. An old English term for a dark, greenish-brown clay, a decomposition product of **basalts** and **tuffs.** (R.M.F.)

WAD. The mineral wad, sometimes called bog manganese, occurs in amorphous masses, and consists of mixtures of **manganese** oxides, MnO_2 and MnO and oxides of other metals such as **copper, lead, cobalt, iron,** etc. It is bluish- to brownish-black, usually soft enough to soil the fingers and often porous and light. It is not a distinct mineral species. (E.S.C.S.)

WAGNER BEAM. Tension-Field Theory of Beam Analysis.

WAGTAIL. Aves, Passeriformes. Slender insect-eating birds (**Aves**) of the Old World, related to the larks and pipits. There are numerous species in both hemispheres. (A.W.L.)

WALKING-STICK. Insecta, Orthoptera. A slender wingless insect related to the **grasshoppers.** The walking-sticks are elongate in every part and closely resemble the twigs or stalks of the vegetation on which they live. Together with winged species found in the warmer regions of the world they make up the family Phasmidae. Some of the winged species resemble leaves. (A.W.L.)



Walking-stick.

WALLABY. Mammalia, Marsupialia. A **kangaroo** of the smaller species. The distinction between kangaroos and wallabies is not a scientific one, the large species being called kangaroos and the smaller species wallabies, with a transition in the larger wallabies which are also known as brush kangaroos. Wallabies, like their large relatives, have powerful hind legs and small forelegs, and are bipedal in locomotion. They vary from the hare wallaby, *Lagorchestes,* less than two feet long, to the red-necked wallaby whose body is 3½′ long, exclusive of the tail. The spur-tailed wallabies, *Onychogale,* are peculiar in having the tail tipped with a horny spur. (A.W.L.)

WALLAROO. Mammalia, Marsupialia. A stoutly built **kangaroo,** *Macropus robustus.* It is one of the large species, thickly furred and gray in color. (A.W.L.)

WALNUT. Wood.

WALNUT OIL. Esters.

WALRUS. Mammalia, Carnivora. A giant marine animal related to the seals but constituting a distinct family. Adults reach a length of more than 12′ and a weight of a ton to 3000 lbs. The feet of the walrus are adapted for swimming but they are used for clumsy locomotion on land, as in the seals. In early life the body is covered with thick light brown fur but after middle age this vestiture tends to disappear. The muzzle bears a number of very thick bristles.

Walruses have the canine teeth of the upper jaw prolonged as tusks. The ivory of these tusks is used extensively by the Eskimos.

These animals are confined to the Arctic seas and are commonly regarded as constituting an Atlantic, *Odobaenus rosmarus,* and a Pacific, *O. obesus,* species, the latter with longer tusks. (A.W.L.)

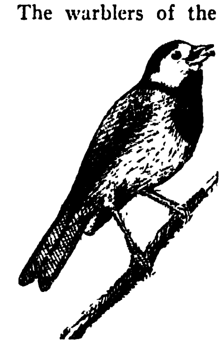
WALSCHAERT GEAR. Valve Gear.

WANDEROO, WANDERU. Mammalia, Primates. The purple-faced monkey of Ceylon, one of the **langurs.** The name has also been applied incorrectly to the lion-tailed monkey of western India, belonging to the **macaques.** (A.W.L.)

WAPITI. Mammalia, Artiodactyla. The American **elk,** *Cervus canadensis,* a member of the red deer group. It is a large species, attaining a height of more than 5′ at the shoulder, with gracefully branched antlers 4–5½′ long. The species once ranged entirely across the continent but is now restricted to the western mountains. (A.W.L.)

WARBLE FLY. Insecta, Diptera. *Hypoderma.* A **bot fly** whose **larva** migrates through the connective tissues of cattle to complete their development in small abscesses called warbles opening through the skin of the animal's back. The adult flies attach their eggs to the hairs of cattle and the newly hatched larva enters the skin by way of the hair follicle. During its development it migrates extensively before reaching its final position under the skin of the back. The perforations leading into the warbles damage the best part of the hide, and the insect is sometimes a source of economic loss as a cause of illness in cattle. The maggots can be pressed out of the warbles when they once become evident or can be destroyed by smearing an ointment over the openings in the skin. A mixture of one ounce of iodoform (see **Iodine**) to five of vaseline has been recommended for this purpose. (A.W.L.)

WARBLER. Aves, Passeriformes. A small bird (**Aves**) related to the thrushes. The warblers of the Old World are an extensive family (Sylviidae) represented in North America only by the kinglets and gnat-catchers. The birds commonly called warblers in America are more accurately distinguished as wood warblers and make up the family Mniotiltidae, more closely related to the vireos.



Hooded warbler, *Wilsonia citrina.* Olive green above, yellow below. The male has a black hood covering the top of the head and running around the neck to the throat, giving the effect of a yellow mask across the face.

Both groups include species whose common names do not indicate their association. Among European examples are the white-throat, the hedge sparrow, the firecrest, and among the American warblers are the **oven bird,** water thrushes, **shats,** and **redstarts.**

Many of these birds are beautiful. Their numerous species are a delight to bird lovers during the spring migration in the United States, and in the fall, due to the great variation of patterns and colors between the sexes and the immature individuals, they are as much a puzzle as a pleasure. (A.W.L.)

WARM FRONTS. Fronts.

WARM SECTOR. That sector of a wave cycle occupied by the warmer air mass is known as the warm sector. A warm sector is always smaller than the cold sector which is occupied by the colder air mass. (P.E.K.)

WARMOUTH. Pisces, Teleostei. A species of **sunfish,** *Chaenobryttus gulosus,* also called the red-eyed bream. It is an olive-green fish, marked with red and blue especially in northern waters. Maximum length ten inches. The species ranges from the Great Lakes to Florida and Texas and is common in quiet waters in the South. (A.W.L.)

WART. Verrucae, or warts, are circumscribed, raised skin **lesions,** gray, tan, brown, or black in color, having a piled up or horny surface. Verruca vulgaris commonly occurs on the hands of children, as multiple, small warts over the fingers and back of the hand. Other forms are plantar warts on the soles of the feet, and venereal warts on the genitalia. Warts are believed to be due to an infectious agent, as yet unidentified.

Treatment consists of removal of the lesions by the application of **salicylic acid, glacial acetic acid,** or trichloracetic acid. Freezing with solid **carbon dioxide,** the application of **radium,** and **x-ray** are also used. In many instances the warts clear spontaneously without treatment. (D.M.H.)

WART-HOG. Mammalia, Artiodactyla. A very ugly pig of Africa. It has a large head bearing excrescences which add the prefix to its name. The broad muzzle also bears strong upturned tusks. Two species are recognized, one, *Phachochoerus africanus,* ranging from Abyssinia southward through eastern Africa and the other, *P. aethiopicus,* confined to the southeastern portion of the continent. (A.W.L.)

WASHBURN AND MOEN. Gauge Number.

WASHER. Screw Fastenings.

WASHING. In photography, washing operations are employed to remove the excess reagents and soluble by-products, which affect later processing or impair the permanency of the photographic image.

Final washing following fixation removes the soluble silver thiosulfate complexes and fixing solution left in emulsion. Normally, the complexes are removed by washing with water or by repeated soaking in fresh-water baths. Under certain conditions, washing times are reduced or residual products are removed with **hypo eliminators.**

Failure to wash out the soluble complexes produces reactions which in time stain both highlight and unexposed areas. Incomplete removal of thiosulfate (hypo) and tetrathionates (oxidation products of thiosulfate) produces gradual sulfurization of image and fading.

Water fit for human consumption is usually satisfactory for washing. Sulfur water should be avoided because of its effect on the silver image. Hard water containing large amounts of calcium, iron, magnesium, sodium and potassium salts has a tendency to leave deposits on negative surfaces that are almost impossible to remove when the negative is dry. Hard water also shows water marks when droplets have dried.

Time of Washing. The rate of washing is dependent on the speed of diffusion of thiosulfate from the emulsion and on its removal from the emulsion surface. Since the diffusion of thiosulfate from the emulsion varies exponentially with time, the quantity of thiosulfate removed from the emulsion at any moment is proportional to that present in the emulsion. The rate of diffusion also depends on the difference between the hypo concentrations in the emulsion and the wash water. The lower the concentration of hypo in water, the faster the rate of diffusion. In practice, the washing time, or removal of hypo from the emulsion surface, depends on the time required for a complete change of water and on the degree of agitation. In ideal conditions of washing, hypo is removed from the surface faster than it diffuses out of the emulsion. The volume of water used should be sufficient to cover the material. The more rapidly the water is renewed, the faster will be the rate of washing. The effect of temperature on hypo elimination is shown in the curve.

At temperatures below 60° F. the rate of washing is retarded, while at temperatures higher than 70° F.

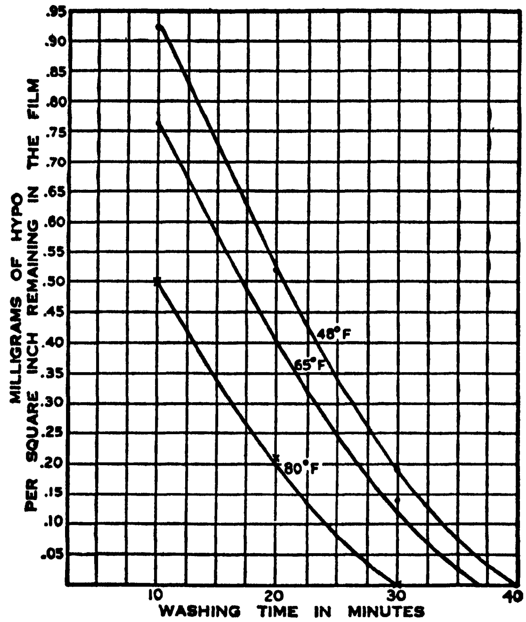


Fig. 1. Curves showing the rate of hypo elimination from a negative material to an ideal stream. (*Neblette's Photography.*)

there is danger of the emulsion becoming swelled and softened. Films fixed in potassium-alum fixing baths require longer washing periods than those fixed in non-hardening and chrom-alum baths.

Washing progresses rapidly at first and then decreases until an equilibrium between the hypo concentrations in the emulsion and water is established. (See Fig. 2.)

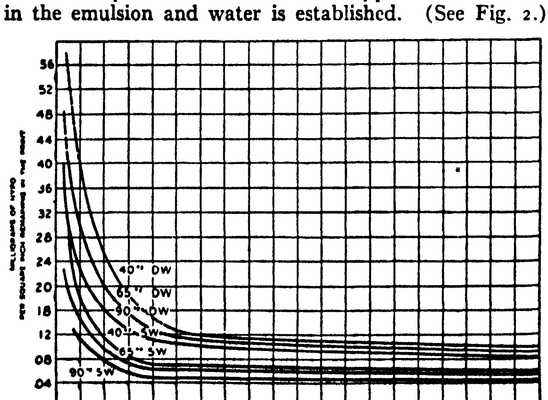

Fig. 2. Curves showing the rate of hypo elimination from papers. (*Neblette's Photography.*)

The average time required for establishment of equilibrium during washing for different photographic materials is:

Film	7 minutes
Single-weight papers	15–60 minutes
Double-weight papers	35–120 minutes

It is impossible to completely wash out the last traces of hypo from prints because of the adsorption of thiosulfate to the paper fiber and the baryta coating. Hypo so retained is termed residual hypo and can only be removed with the aid of hypo eliminators.

The minimum washing time for any material is the sum of the time for a complete water change plus the time for the establishment of equilibrium. The time for a complete water change can be determined by adding a dye or ink solution to the washer and noting the time until the color of the wash water becomes as clear as that from the tap.

Washing Tests. Tests to determine the completeness of washing (hypo tests) may be of two types: those used to detect the presence of hypo diffusing from emulsions and those which determine the presence of residual hypo retained by negative or print. For films, the alkaline permanganate test is widely employed to detect diffusible hypo and determine satisfactory washing. A stock solution is prepared by mixing:

Potassium permanganate	0.5 gram
Sodium hydroxide	1.0 gram
Distilled water to make	1.0 liter

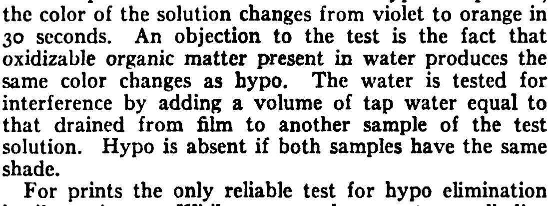
Films thought to be washed are removed from tray or tank and allowed to drain into 10–20 cc. of a test solution prepared by diluting 1 part of the stock solution with 20 parts of water. If traces of hypo are present, the color of the solution changes from violet to orange in 30 seconds. An objection to the test is the fact that oxidizable organic matter present in water produces the same color changes as hypo. The water is tested for interference by adding a volume of tap water equal to that drained from film to another sample of the test solution. Hypo is absent if both samples have the same shade.

For prints the only reliable test for hypo elimination is silver nitrate. While common hypo tests, as alkaline permanganate, sodium azide, and mercuric chloride, show the presence of diffusible hypo in wash water, they do not indicate the amount of hypo retained by the paper base and baryta coating—a quantity sufficient to cause image fading.

Tests for residual hypo are made by taking a strip of undeveloped paper that has been fixed and washed along with a batch of prints, and partially immersing it in a 1% silver nitrate bath for 3 minutes. Any yellow to brown coloration found on the immersed portion after rinsing shows the presence of residual hypo. (S.M.T.)

WASHING SODA. **Sodium.**

WASP. Insecta, Hymenoptera. An **insect** related to the ants and bees. Some species are solitary and some social. Most species have four membranous wings, the front wing much larger than the hinder pair and both



Wasp.

with few veins, joined to form closed cells. Some wasps burrow, some build nests of mud, and some use a coarse paper made by chewing wood from weathered surfaces. The last species are more commonly called hornets. Wasps are well known for their ability to sting; the more commonly known species inflict painful wounds because of their large size.

From the scientific point of view the term wasp is almost without value, since it applies to many different groups of insects. The members of one superfamily, the Vespoidea, include the spider wasps, the cuckoo wasps, the velvet ants, the true ants, the true wasps, and the potter wasps, each making up a different family, while the hornets and yellow-jackets, most familiar of wasps, are only one family of the group. Scientifically another superfamily, Sphecoidea, is made up entirely of insects called wasps according to some writers, but includes the bees according to others. The wasps of this division are represented by the giant cicada-killer, the largest of North American wasps, and the thread-waisted wasps.

Wasps have been extensively studied because of their complex behavior in making and provisioning nests for their young. In the works of the Peckhams and the Raus some remarkable and interesting records are preserved. (A.W.L.)

WASSERMANN REACTION. A serological test used in the diagnosis of **syphilis**. It was described by Wassermann in 1906 and has been of great importance in detecting latent cases as well as active syphilitic disease ever since. The test is performed on blood serum or spinal fluid, and depends upon the presence of **antibodies**. A positive result indicates that antibodies are present, and the individual has been infected with syphilis at some time, even though at the time of the test he may be asymptomatic. The spinal fluid Wassermann may be positive even though the blood is negative; it always indicates central nervous system syphilis. The test on blood or spinal fluid is also a guide as to the effectiveness of treatment, although the early change from a positive to a negative result during therapy does not alter the program of prolonged treatment in the least.

Usually the blood Wassermann does not become positive until several weeks after onset of the infection. Characteristically, at about the time that the chancre begins to heal, a positive blood test is obtained. If treatment is begun before this serological reaction takes place, the prognosis for early cure is better than if the Wassermann reaction is already positive when therapy is undertaken.

The Wassermann reaction is not completely specific. It may be positive in yaws, and occasionally in infectious mononucleosis and leprosy. (D.M.H.)

WATER. Water (H_2O) is a colorless (blue in thick layers), odorless, tasteless liquid, melting point 0° C. (one of the standard temperature points), boiling point 100° C. at 760 mm. pressure (another standard temperature point). At 770.0 mm. pressure, the boiling point is 100.366° C.; at 750.0 mm., 99.360° C.; at 740.0 mm., 99.255° C.; at 730.0 mm., 98.877° C.; at 380 mm., 81.7° C.; at 76 mm., 46.1° C.; at 1520 mm., 120.6° C.; at 7600 mm., 180.5° C. Density, 1.000000 gram per milliliter (or 1.000073 gram per cu. cm.) at 3.98° C. (one of the standard density points). At 0° C., the density is 0.99987 gram per milliliter; at 8° C., 0.99988; at 15° C., 0.99913; at 16° C., 0.99897; at 17.5° C., 0.99871; at 20° C., 0.99823; at 25° C., 0.99707; at 40° C., 0.99224; at 50° C., 0.99807; at 75° C., 0.97489; at 100° C., 0.95838; at 120° C., 0.9434. **Critical temperature** 374° C., **critical pressure** 217.7 atmospheres, **critical density** 0.4 gram per cu. cm. **Viscosity,** 0.01792 poise (dyne-second per sq. cm.) at 0° C. (specific viscosity 1.000). At 20° C., the viscosity is 0.01005 poise (specific viscosity 0.561), at 50° C., 0.00549 (specific viscosity 0.307), at 75° C., 0.00380 (specific viscosity 0.212), at 100° C., 0.00284 (specific viscosity 0.158). **Surface Tension** against air, at 0° C., 75.6 dynes per cm.; at 10° C., 74.22; at 20° C., 72.75; at 30° C., 71.18; at 60° C., 66.18; at 100° C., 58.9. **Specific heat,** 1.00000 at 15° C. (standard of specific heat). At 0° C., the specific heat is 1.00874; at 25° C., 0.99765, at 35° C.,

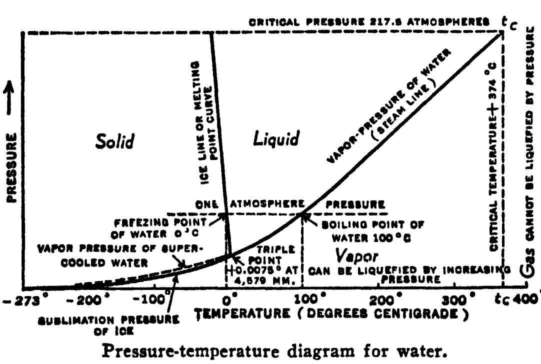
0.99743 (minimum); at 50° C., 0.99829; at 65° C., 1.00001; at 80° C., 1.00239; at 100° C., 1.00645; at 120° C., 1.016; at 180° C., 1.04. Electrical **conductivity** 0.04×10^{-6} reciprocal ohms at 18° C. (Kohlrausch and Heydweiller, 1902), of pure water in **equilibrium** with air 0.8×10^{-6}, of ordinary distilled water about 5×10^{-6}. **Dielectric constant** (specific inductive capacity), 81.07 at 18° C. (compare ethyl alcohol 25.8 at 20° C., carbon disulfide 2.6 at 20° C.).

The chemical composition of water has been the subject of intensive studies from the early years of the science of chemistry. E. W. Morley, of Western Reserve University, Cleveland, Ohio, in 1895, reported the weight ratio of **oxygen** to **hydrogen** in water as 7.9395 to 1.00000, and the volume ratio, 1.00000 to 2.00288. F. P. Burt and E. C. Edgar, of England, in 1916, considered, on the basis of their experiments, 7.9387 to 1.00000 the most exact weight ratio. The present value accepted by the International Union of Chemistry, Committee on Atomic Weights, is 8.0000 to 1.0080. The H_2O molecules in ice and water are associated together by hydrogen bonding. This phenomenon accounts for the abnormally high **heat of vaporization** (and condensation), which is 585 calories (15° C.) per gram of water at 20° C., and 540 at 100° C. (compare butane 88, **ethyl alcohol** 204, **acetone** 125, **acetic acid** 97, **carbon tetrachloride** 46), and high **heat of fusion** (and solidification), which is 80 calories (15° C.) per gram of water (compare **benzene** 30, ethyl alcohol 25, acetone 21, acetic acid 44, carbon tetrachloride 4).

For water as **catalyzer** see **Reactions Involving Water.**

Pure water, especially when free from dissolved gases, may be heated above 100° C., even to 180° C., without boiling, but on further heating boiling with explosive violence may occur. Steam at 100° C. occupies a volume 1700 times greater than water at 100° C. Pure water, when not agitated, may be cooled somewhat below 0° C. without freezing, but on further cooling congeals with increase of volume (density of ice 0.917) exerting great force, when confined, but if in intimate contact with water at atmospheric pressure the temperature is 0° C. Vapor pressure of ice and of water 4.579 mm. at 1 atmosphere pressure, 0° C. Triple point, ice-water-water vapor, +0.007° C. in vacuum. When water is compressed to say 20,000 atmospheres and then cooled, other varieties of ice, all denser than water, are formed (ice II 12% denser than water ice, III 3% denser. Six varieties of ice are known).

Pure water may be obtained (1) by distillation and condensation of water, (2) by partial freezing of water followed by separation of the pure ice and melting, (3) by burning of hydrogen or reduction of heated oxides



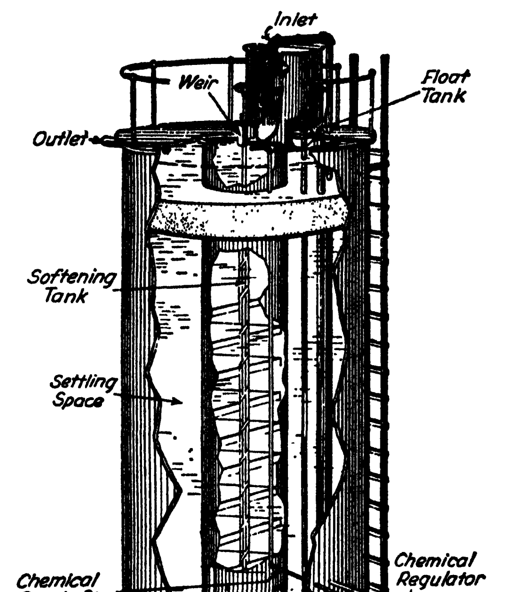
Pressure-temperature diagram for water.

by hydrogen and collecting the product. Hydrogen containing organic substances, e.g., **hydrocarbons**, when burned in air or heated with copper oxide, form water.

"Heavy water," deuterium oxide (D_2O, molecular weight 20, that of ordinary water 18), is concentrated in the residual water of **electrolytic** cells that have been operated a long time, ordinary water being more readily decomposed than heavy water. The physical constants of deuterium oxide are: melting point 3.8° C., boiling point 101.42° C., density at 25° C. 1.1056, temperature of maximum density 11.6° C., solubility of sodium chloride 15% less than in ordinary water.

Water occupies a distinct position among liquids in the matter of dissolving gases, liquids and solids. While there are other liquids that exceed it in solvent power in specific cases, no other shows such a wide range and general intensity of solvent power. Many chemical reactions take place in water as the solvent medium, and many of these occur instantaneously. (See **Solutions and Solubility.**)

Water of the ocean, containing dissolved salts, covers 73% of the surface of the earth; water of lakes (fresh and salt) and rivers forms an important portion of the land surface; water vapor of the atmosphere is a constituent affecting climate and plant growth; snow and ice of mountain tops serve upon melting as regional water supplies, and of the polar regions determine ocean currents and climate; and underground water is an industrial and agricultural source of water supply. The effect of water in changing the earth's surface is mainly due (1) to the disintegration of rocks when ice forms in the interstices, (2) to the mechanical carrying of particles of various sizes from higher to lower levels, (3) to the solution of parts of the rocks, (4) to its beneficial effect on plant growth. Water stands alone in its importance to plant and animal life, and to industry.



Typical lime-soda water softener—continuous type.

Rôle of Water. The rôle of water in our universe is on a par with, if not surpassing, that of any known substance. The scope is briefly as follows:

In nature
- Geochemical
  - The hydrosphere (See below)
  - Water as vapor, liquid, ice and snow
  - Water at rest and in motion

In nature (*Continued*)
- Biochemical
  - Water and plant organisms
  - Water and animal organisms

In industry
- As solvent, and medium of reaction (See **Solutions**)
- Humidity
- Extinguisher of fires by lowering the temperature
- Drying and wetting

In living
- Beverages, foods and their preparation (See **Foods**)
- Washing, cleansing and sanitation

In science
- Standard of reference for many data (See above)
- **Deliquescence and water absorption**
- **Efflorescence and loss of water**
- Drying and desiccation
- **Reactions involving water**
  1. Consumption of water
  2. Production of water
  3. Water as catalyzer

Natural waters may be contaminated with (1) insoluble suspended material. This settles out upon standing, or may be filtered, (2) soluble inorganic matter, (3) soluble organic matter. This may impart color or acidity. The latter may be readily neutralized by addition of a base. The former may be removed by precipitation of gelatinous **aluminum** hydroxide (aluminum sulfate or alum plus sodium carbonate), a process which also removes practically all the bacteria which may be present.

In ocean and salt lake waters the principal content is **sodium** chloride, with small amounts of **calcium, magnesium, potassium,** and **sulfate, carbonate;** in fresh lake, river and underground water the content is variable in amount over a wide range, some surface waters in contact with igneous rocks are practically pure water except for dissolved air, others are notable for their high calcium content in **limestone** regions, usually containing calcium and magnesium as hydrogen carbonate and chloride, respectively ($Ca(HCO_3)_2$, $MgCl_2$). When the hydrogen carbonate is boiled calcium carbonate ($CaCO_3$) is precipitated and can be separated. In order to separate dissolved calcium and magnesium, treatment with calcium hydroxide and sodium carbonate has long been practiced. Other treatments include passage of the water over artificial sodium zeolites or over various ionic resins, addition of trisodium phosphate.

The cycle of water in nature is evaporation from the oceans, then condensation upon cooling by contact with colder bodies of land, e.g., mountains, or cold currents of air from the polar regions. This may fall as rain or snow, which are practically pure water, except for dissolved air. Rain runs off the surface into lakes or rivers or seeps into the earth. Snow and ice form a storage

AVERAGE CONSUMPTION OF WATER IN VARIOUS CITIES

City	Gallons Per Capita Per Day	City	Gallons Per Capita Per Day
London (1924)	43	Tokio (1913)	32
Paris (1913)	38	Sydney (1913)	50
Madrid (1913)	84	Toronto (1913)	118
Rome (1913)	120	New York City	115
Berlin (1913)	35	Chicago	235
Cairo (1913)	25	Baltimore	130
Calcutta (1913)	62	Milwaukee	85

The consumption of water in European cities is usually about 20 to 50 gals. per capita per day, but in the cities of the United States is much larger, from 75 to 150. In the United States, the consumption of water is distributed about 35% domestic, 40% industrial, and the remainder for municipal use plus waste.

source of water which is liberated when and as the temperature rises. Underground water gradually evaporates through porous soil, flows to lower levels, or remains as a storage source. Plants and animals enter the cycle to use such water as is necessary and available, and returning to the atmosphere or the surface of the earth such as is not retained. Animal waste and animal remains furnish a food source for **bacteria** which in some cases are hazardous to animal life. Such water is purified (1) by **filtration** through sand filters, usually accompanied by precipitation of **aluminum** hydroxide, (2) by disinfection, most frequently by chlorine or a hypochlorite, and, in many cases (3) by treatment with activated **carbon** to remove odors. Industry enters the cycle (1) to use the water for power, usually hydroelectric, (2) to generate steam, in which case the purity or impurity of the water used is an important consideration in connection with steam boiler practice, (3) to use the water for cleansing purposes, in cases where soap is used the extent to which **calcium** or **magnesium** ("hardness") is present represents loss of soap, (4) to use the water for dissolving or separating solids, liquids, gases. The effluents from such applications represent a wide range of impurities, e.g., from coal-gas works, wood-pulp mills, tanneries, packing-house plants. These effluents, along with those from domestic sewage, present a serious problem in sanitation. Rivers complete the cycle of water in nature by returning to the oceans the excess of water plus such natural, industrial, and domestic additions of insoluble and soluble materials as are contained.

Volume and Mass of Hydrosphere

Data of Kossinna (1921), accepted by Clarke (1924)

Volume of hydrosphere, including the oceans, the mediterranean seas, the border seas, and the gulfs:

1,370,323,000 cu. kilometers or 327,672,000 cu. miles.

Mass of hydrosphere, described as above:

$1{,}411.4 \times 10^{15}$ metric tons

Density of sea water of normal salinity (35 parts per 1000) at 0° C.:

1.028 (1.03, Clarke)

Mass of salt in hydrosphere:

49.4×10^{15} metric tons

The hydrosphere is estimated to be 7% of the total mass of the earth. (R.K.S.)

WATER BEAR. Bear animalcule. **Tardigrada.** (A.W.L.)

"WATER BLOOM." Algae.

WATER BOATMAN. Insecta, Hemiptera. An aquatic **bug** of the family Corixidae. These insects are flattened, broad at the head and tapering bluntly at the opposite end of the body. The fringed posterior legs project like a pair of oars and are used in swimming. Water boatmen breathe air but they are able to descend to considerable depths, carrying a film of air on the

ventral surface of the body. They feed on ooze containing plant matter and minute animals. (A.W.L.)

WATER BRAKE. Dynamometer.

WATER BUCK. Mammalia, Artiodactyla. *Kobus.* A large **antelope** of southern and eastern Africa. It frequents rocky hills in the vicinity of rivers. The horns are more than 2′ long, slightly curved and ringed almost to the tips. (A.W.L.)

WATER DEER. Mammalia, Artiodactyla. *Hydropotes.* A small **deer** found along the margins of the Yangtse Kiang river in China. The male has long curved tusks in the upper jaw and neither sex has antlers. The species is also remarkable in producing 3–6 young at a time. (A.W.L.)

WATER DOG. Amphibia, Urodela. The **mud puppy.** (A.W.L.)

WATER FLEA. Crustacea, Cladocera. Minute aquatic **crustaceans** of compact form, usually transversely compressed and provided with a bivalve **carapace.** They are superficially like fleas in form. (A.W.L.)

WATER GAP. Gap.

WATER HAMMER. Sudden stoppage of water flow in a long pressure conduit caused by the closing of **valves** can, if the rate of closure be rapid enough, cause the conduit to be subjected to a sharp, hammer-like blow from a steep front pressure **wave.** Water moving in a long pipe-line has considerable mass. To decelerate a mass requires a force equal to the mass times the deceleration (negative **acceleration**). If the rate of deceleration is large, the force will be large. Hence if a valve or gate is suddenly closed, the water has high deceleration, and a large force is set up. Due to the elastic nature of conduit material, this force acts expansively, slightly stretching the pipe. When the **inertia** force has disappeared, the pipe regains its original girth and produces secondary pressure waves. A calculation shows that the power required to decelerate water in a 5-ft. pipe 2000′ long is 1400 hp. This calculation was based on an assumption of 10 ft. per sec. water velocity, and 5 seconds was the time taken to close the valve, and it should acquaint one with the magnitude of power behind the water hammer. To cushion all or parts of the water conduit against the destructive effect of water hammer forces, relief valves, bursting plates, and surge tanks have been used. Water hammer may also be caused by the sudden collapse of steam bubbles upon entering cold water, as when the steam is turned into a cold radiator partly filled with water. (F.T.M.)

WATER HEATING. Feedwater Heating; Heating.

WATER HYACINTH. *Eichhornia crassipes.* Pontederiaceae. This plant occurs widespread in tropical and subtropical regions, where it often becomes a troublesome weed. In Florida it sometimes forms floating masses so dense as to become a serious hindrance to river navigation. Very noticeable are the leaves, the **petioles** of which are swollen in bladder-like enlargements containing many air-spaces. These cause the plant to remain floating at the surface of the water. Because of the broad shining green blades the plants are easily blown about on the surface by the wind. The dark-colored roots form a dense mass beneath the water surface. The root cap at the tip of each rootlet is a very conspicuous structure. The flowers are showy and pale lavender in color. They are trimorphic, there being three different lengths of **styles.** The plant is frequently found in cultivation in northern regions, where, however, it is not hardy. (R.M.W.)

WATER LEVEL REGULATOR. Feedwater Regulator.

WATER MEASURER. Insecta, Hemiptera. A long slender **bug** that creeps slowly on the surface of water. Also called the marsh treaders. These are not the common insects that skate rapidly on the water, although they are closely related. The water measurers make up the family Hydrometridae, and the other insects are water striders of the family Gerridae. (A.W.L.)

WATER MOLDS. Phycomycetes.

WATER PENNY. Insecta, Coleoptera. A small flattened oval **insect** found chiefly on the underside of rocks in running water. Water pennies are the **larvae** of **beetles** of the family Psephenidae. They resemble crustaceans and were originally described as such. (A.W.L.)

WATER PHEASANT. Aves, Charadriiformes. A large and beautiful water bird (**Aves**) of India and Ceylon. Its nest floats on the water or is anchored to water plants. Related to the jacana. (A.W.L.)

WATER PRESSURE. Head.

WATER PROPELLER. A water propeller is a very short section of an endless screw used for propulsion of power-driven vessels. Although when first developed, a short section of an actual endless screw was used, the modern propeller uses only segments of the screw which are arranged radially on a hub, there being usually two, three, or four blades, depending on the type of vessel. The water propeller depends largely upon push exerted on the water by its astern face, and in this respect is unlike the air propeller, in which thrust is developed by vacuum on its forward face. For this reason, also, and because of the greater density of water as compared to air, the water propeller has a relatively small diameter and large blade area. This means that the disk area, i.e., the area of the circle swept by the tips of the blade, is largely occupied by blade. Water propellers are usually made of cast iron or manganese bronze, the latter being more suitable than iron for salt water. The propeller is securely attached to a propeller shaft, which passes through the hull at the stern, and from there is connected to the engine by couplings, and possibly also by universal joints. The propeller shaft is given a slight slant downwards to the rear, and leaves the hull through a stuffing box which reduces water leakage to small value. The pitch of the propeller is the distance it would advance in a complete turn, considering it a screw revolving in a solid medium. In use, it does not actually advance this distance, the difference being **slip.** This slip averages about 15% for a properly selected propeller. In any application of the water propeller, it is important to select the propeller with due regard to the speed and power of the engine. The weight and size of the boat are of much less importance. If a propeller is improperly selected, it will either permit the engine to race, churning the water and producing little thrust, or it will hold the engine speed below rated, and prevent development of its full output. (F.T.M.)

WATER PURIFICATION. Water purification methods may be classified into processes for (1) removing material in solution, (2) removing material in suspension. The former processes are employed principally where the water contains objectionable mineral matter in solution, rendering it unsuitable for domestic or industrial uses. Various objectionable mineral forms in solution may occur but the principal process employed under this heading is that of water-softening which removes the calcium salts typical of hard or limestone water.

The principal problem of water purification is the removal of matter in suspension from the larger particles, which will settle out readily, right on down to the most minute inorganic matter and including bacteria as well.

Plain sedimentation in tanks or basins will remove the larger, readily-settling particles satisfactorily but requires too long a period of detention for a high removal of the finely divided material. Plain sedimentation as a principal or sole means of purifying water is now seldom employed although in earlier days it was often so used.

Certain chemicals such as alum, and certain of the iron salts when added in very small quantities to water naturally hard, or made so by the addition of an alkali, react to produce a sticky, gelatinous precipitate or "floc." This precipitate readily settles, forming larger masses as it settles by agglomeration, and as it passes down through the water it picks up the finer material by surface adhesion and its sticky and gelatinous character. This method of treating water with chemicals, followed by settling, is spoken of as coagulation and sedimentation. By this means clarification by sedimentation is enormously speeded up, especially for the more difficult turbidities caused by finely divided matter in suspension.

Modern sanitary standards, however, usually require that coagulation and sedimentation be followed by filtration for more complete removal of all matter in suspension. In this case the coagulated and settled water is passed through a rapid sand **filter**, the combined treatment processes removing 98–88½% of the matter in suspension, including the bacteria.

As a final process, the effluence from the filters is treated with chlorine to eliminate the remaining bacteria and produce sterile water. The amounts of chlorine so used are small and should not normally affect the taste or odor of the water.

With a high rate of chlorine application, settled water or even unsettled water may be rendered sterile and safe for consumption, but under these conditions so much chlorine has to be used for safety that it commonly produces a distinct taste and odor.

The rapid sand filter, with its auxiliary treatment of coagulation and sedimentation, was especially developed to handle very turbid waters for which, by reason of the very finely divided nature of the matter in suspension, plain sedimentation was ineffective and slow sand filters were unsatisfactory.

Historically, slow sand filters were developed first. They consist of very large enclosed sand beds through which the water passes very slowly. In time, a thin organic coating of bacterial jelly forms on top of the sand bed and acts as a very fine strainer to screen out bacteria or very minute inorganic particles. Slow sand filters will not operate satisfactorily for very turbid waters because the necessarily frequent cleaning of the filter bed, in itself a large job, disturbs and destroys the organic coating on the beds too often for efficient operation. Thus slow sand filters have a field of use limited to the less turbid waters of infrequent occurrence.

In the case of the rapid sand filter, some of the floc passes on into the filter and forms a thin, inorganic, gelatinous coating on top of the sand bed which acts as a fine straining medium to take out the fine material and bacteria. The rapid sand filter is readily washed, as frequently as may be required, by forcing water at a high rate back through the filter and washing off the upper dirty layer on the sand bed. This would be impractical in the case of the slow sand filter because of the large volumes of water required. In the latter case, the dirty layer is skimmed off the top of the sand by means of flat spades, washed, returned to the bed, and re-spread.

Rapid sand filters operate at a daily rate of about 125,000,000 gals. per acre of bed, and slow sand at daily rates of from 3,000,000–10,000,000 gals. per acre. (E.W.S.)

WATER SCORPION. Insecta, Hemiptera. Moderately large water **bugs** of oval or slender and elongate form, with a long breathing tube at the end of the body. The front legs are adapted for catching small prey. (A.W.L.)

WATER SPOUT. Funnel-shaped tornado cloud at sea or over water of lakes or rivers. It is the equivalent of a tornado but does not usually reach the same violence. Sea craft in its path will be damaged and the sea surface only slightly confused. (See **Tornadoes.**) (P.E.K.)

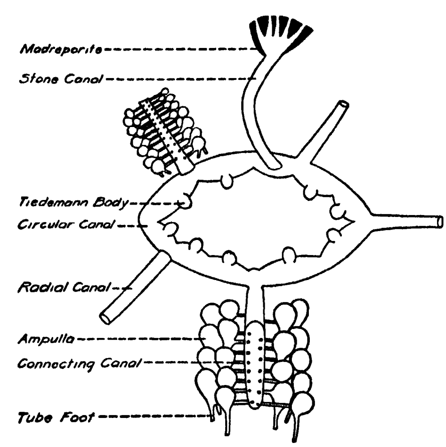
WATER STRIDER. Insecta, Hemiptera. A moderately large **bug** whose two posterior pairs of legs are modified for locomotion on the surface film of water. The claws are set back from the tip of the leg and the hairs of the dense covering are turned under so that the tip of the leg rests on their curved surfaces. These bugs are common on streams and ponds. The members of one genus, *Halobates*, are the only truly marine insects. They are found in tropical waters, often far from land, and their eggs have been found attached to floating feathers. (A.W.L.)

WATER TABLE. Ground Water.

WATER TANK. Tank.

WATER VAPOR. Steam and Vapors.

WATER VASCULAR SYSTEM. A tubular system of **echinoderms** through which sea water is circulated. It is formed from the **coelom** and is associated chiefly with locomotion, respiration, and the securing of food.



Water vascular system of the starfish. (*Drawn by W. J. Moore.*)

In the starfishes (**Asteroidea**) the madreporite on the surface of the disk is a round perforated plate leading into this system of tubes. Directly below it the **stone canal** extends into the disk and joins a ring canal encircling the axis of the body. From the ring canal a radial canal passes out along the axis of each ray, and various appendages arise from all of these canals. The appendages of the ring canal are a series of Polian vesicles and a series of minute Tiedemann's bodies (or vesicles). The former are saccular reservoirs and the latter glandular bodies. The radial canals bear transverse branches with a small vesicular ampulla inwardly and a slender **tube foot**, cupped at the end, extending out through an opening in the hard wall of the animal and projecting in the ambulacral groove on the under surface of the ray. These tube feet grip by suction and adhesion.

The madreporite of sea cucumbers projects into the cavity of the body; several madreporites and stone canals may also occur. The body cavity is in communi-

cation with the exterior by way of the branching respiratory trees that arise from the cloaca. A similar condition exists in the crinoids, which have several stone canals opening by single pores into the cloaca, and other pores from the **cloaca** to the surrounding water. (A.W.L.)

WATER WALL. Water walls are installed on most modern **boilers** that are designed to operate at high rating. They are also often added to old boilers which, by the further installation of high-capacity **combustion** equipment, **economizers,** and **air preheaters,** may be operated at greatly increased capacity. When **pulverized coal** was first used refractory walls were standard, but pulverized coal could be burned by 10 to 20% excess air, whereas 50% was considered good in the existing stoker-fired furnaces. The results of the higher furnace temperatures accompanying pulverized coal were destruction of **refractories** and slagging of walls and tubes. The **furnace** temperature was above the softening point of the ash and particles of it flying about in a sticky or molten state adhered to the first cool surface they touched. Unless the advantages gained from the reduction of flue gas loss were to be sacrificed, furnace designs had to be changed. This led to the introduction of water-cooled furnaces in which the combustion space was partially or completely surrounded by tubes carrying water which, by absorbing radiant heat directly as soon as it was evolved from the combining molecules of fuel and oxygen, prevented the attainment of destructively high furnace temperature. (F.T.M.)

WATER-LILIES. Nymphaeaceae. The water-lilies form a small family of water or marsh plants. The leaves may be submerged or floating or carried well above the surface of the water on stiff petioles, as in the Lotus. The flowers are usually large and solitary. The principal genera are *Cabomba, Nuphar, Nymphaea,* or *Castalia,* and *Nelumbium.*

Cabomba is a genus of tropical American water-lilies having two types of leaves; some are submerged and much-divided into linear segments, while others are entire and floating with the **petiole** centrally attached. The small flowers are borne on long **peduncles,** and have their parts in threes. These plants are frequently used in aquaria, both for ornament and to oxygenate the water.

Nuphar, or *Nymphozanthus,* is a genus of yellow-flowered plants occurring in the northern hemisphere. *Nuphar advena* is the common yellow water-lily or spatterdock of the marshes.

Nymphaea or *Castalia* contains the showy-flowered water-lilies so frequently grown in artificial ponds. Northern hardy forms are white- or sometimes pink-flowered and fragrant. Many tropical species have red, yellow, blue, or pink flowers of great beauty. These flowers float on the surface of the water, as do the large cleft leaves. The fruit is a berry containing many seeds, each enveloped in a spongy **aril.** The fruit ripens under water, the mature seeds floating upward from the fruit and drifting about, by means of the air bubbles contained in the aril. Eventually each seed sinks to the bottom.

Nelumbium is a genus which contains but two species, *N. lutea,* a native of the southern half of North America, and *N. Nelumbo,* of Asia and the East Indian Islands. The American species is pale yellow-flowered, the flowers and also the large peltate leaves standing well above the surface of the water. The Asiatic species is the Sacred Lotus, which has showy fragrant pink flowers of great beauty. The fruit of the lotus is a curious obconical receptacle in the top of which are embedded the many carpels. At maturity the receptacle is very light and dry, so that when broken from its stalk it floats on the water, carrying the seeds about until it breaks apart. The seeds of the lotus are used as food by many peoples, especially in Asia.

Victoria regia, the giant water-lily of the Amazon, is related to *Nymphaea.* It is a plant of tremendous size, the floating leaf with its upturned rim often having a diameter of six feet or more. The flowers are likewise very large. The seeds are used as food in the Amazon valley, where the plant is native. (R.M.W.)

WATERMELON. *Citrullus Vulgaris;* **Gourd Family.**

WATERSHED. The area which supplies water to a stream and its tributaries by direct runoff and by **ground water** runoff is the drainage area or watershed for the stream. The yield of the watershed is the direct runoff plus the ground water runoff for a given period of time. That part of yield which is used for industrial or domestic purposes is called the draft. When the draft approaches the yield, the latter may be adjusted by the construction of an **impounding reservoir.** (C.W.C.)

WATKINS-FACTOR. Factorial Development.

WATT. A metric unit of **power.** The absolute watt is equivalent to 10^7 **ergs** (one **joule**) of work per sec. The watt is especially convenient in electrodynamics, because the practical electrical units are so chosen that the product of the current (**amperes**) by the electromotive force (**volts**) at any instant equals the power in watts. The international watt is so defined in terms of the international ampere and the international volt, and thus differ slightly from the absolute watt. One **horsepower** is equal to about 746 watts, so that the **kilowatt** (1000 watts) is approximately 1.34 hp. (L.D.W.)

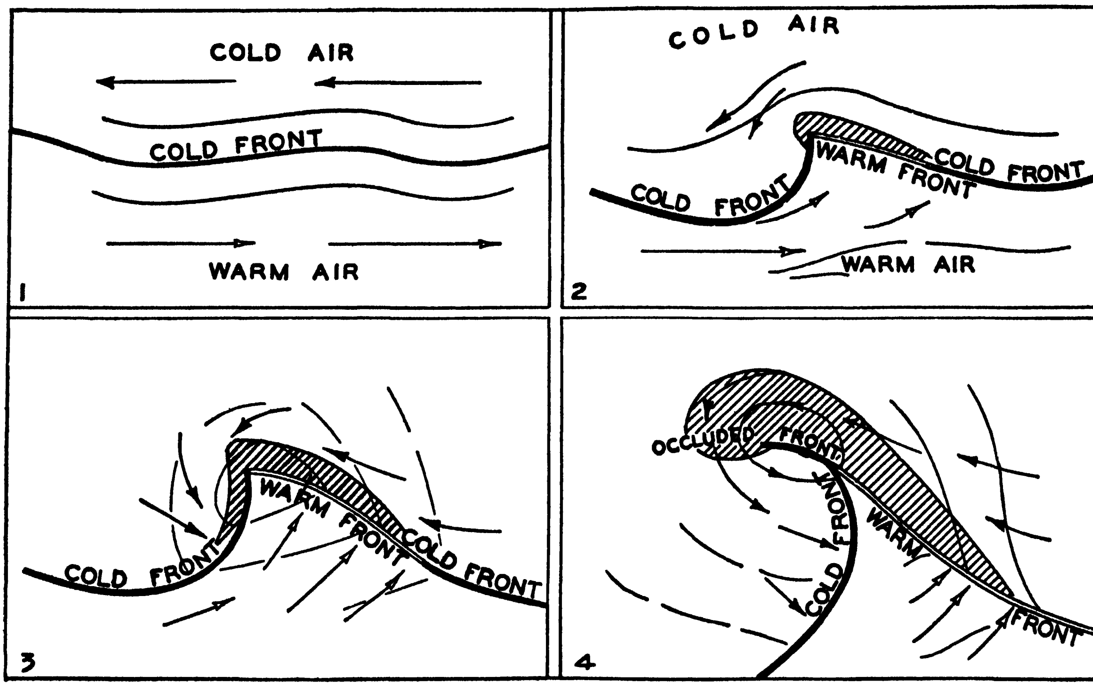
WATT-HOUR METER. Integrating Meters.

WATTMETERS. A wattmeter has two coils, one fixed, the other capable of turning in the field of the first, both coils being without iron cores. The fixed coil is connected in series with the main circuit, so as to carry the whole current (or, with d-c instruments, a known fraction of it, as determined by a shunt). The movable coil, which is of high resistance, is connected across the terminals of the "load," that is, that portion of the circuit in which the power is to be measured, and the small current in the coil is therefore proportional to the voltage between these terminals. This coil turns against a hairspring, and since the torque is proportional to the product of the currents in the two coils, it is proportional to the product of the main current by the terminal voltage, that is, to the required power. The scale may therefore be graduated directly in watts. The wattmeter may be replaced by an ammeter (in series with the load) together with a voltmeter (across the load terminals). To obtain the power it is merely necessary to multiply their readings together; except that in the case of **alternating currents** with reactance in the load, this product must also be multiplied by a "power factor" equal to the cosine of the phase angle. (L.D.W.)

WAVE CYCLONES. Cyclones which develop in the temperate zone are waves on frontal surfaces in contrast with tropical cyclones in which fronts are not prominent features. Cyclones develop more frequently along a Polar front than any other place, but they also appear on the inter-tropical front and on other minor fronts. It is on the Polar front, however, that wave cyclones develop into major storms and climax their lives as large-scale vortices. Wave cyclone development occurs in the following sequence of events.

1. A fairly prominent front exists between two air masses of some density contrast. The frontal slope is approximately in equilibrium.

2. A perturbation of wave form with the major motion nearly horizontal, rather than vertical (as in gravity



History and development of an extra-tropical cyclone. (Forming occlusion.) (*Gillmer and Nietsch, Clouds, Weather and Flight.*)

waves), develops on the frontal surface. One part of the front is bent toward the cold air as a warm front and an adjacent part is bent from equilibrium toward the warm air as a cold front. A deep indentation into the cold sector (cold air mass) occurs with the crest of the wave at the maximum point of indentation.

3. The wave moves along the frontal zone, but while it moves it also begins to occlude, i.e., the warm sector begins to close because the cold front moves more rapidly than the warm front. Pressure falls about the center but most rapidly in the direction toward which the crest of the wave is moving.

4. As the cold front overtakes the warm front, occlusion continues and the warm-sector air is squeezed aloft between the frontal surfaces.

After the fronts have occluded and the warm sector is gone, only an approximate vortex remains which slowly loses intensity. Typical warm and cold frontal weather are associated with both fronts respectively. In the fall, winter, and spring months of the year, most of the rain and snow falling over the United States and Canada is due to wave cyclones. Movement of the cyclones is generally easterly with a north or south component but it should be remembered that wave cyclones tend to move along the frontal zone in which they developed. Rate of movement varies from less than 100 miles per day to as much as 1000 miles; on the average, about 400–500 miles in summer and 600–700 miles in the winter. Velocity of the wave crest (center of the cyclone) is greatest during the early stages of the storm and normally decreases as it approaches maturity. Wave cyclones often occur in a series with a definite wavelength, thus have a uniform spacing. Under the influence of a well-established major circulation pattern the paths of cyclones can be predicted and the general aspect of weather estimated for several days. With transient general circulation patterns, however, the paths of cyclones become quite variable and accurate prediction from one group of cyclones to the next becomes next to impossible. (P.E.K.)

WAVE FILTER. **Electric Oscillations and Electric Waves.**

WAVE GUIDE. While it is ordinarily considered necessary to have a conductor surrounded by an insulating medium to conduct electrical energy from one point to another, it can be done in the reverse fashion, i.e., the insulating medium conducts the energy and is surrounded by a conductor which guides the energy flow. This is the wave-guide principle. Since the success of the method depends upon the correct dimensions of the guide and these vary as an inverse function of frequency the method is not feasible except at ultra high and higher frequencies, but at these ranges it is the standard means of conducting the energy. The guide may be considered a coaxial line without a center conductor or may be regarded as a pipe or tube down which the energy flows. Electrically the energy is carried by a radio wave which is reflected from the guide surfaces so the result is guided transmission along the tube. These guides have a variety of uses at the higher frequencies, being used to form resonant cavities, to conduct radio-frequency power from point to point, to serve as radiators or collectors by shaping them as open-ended horns, etc. (L.R.Q.)

WAVE MECHANICS. Wave mechanics is a more or less direct outgrowth of the **quantum theory**, and an integral part of **quantum mechanics**. The fact that radiant **energy** (light, x-rays, etc.) is certainly emitted by atoms or molecules and is as certainly done up in parcels, called quanta, the magnitude of each of which is definitely associated with a vibration or wave frequency of some kind (see **Planck's Law**), leads one to inquire what there is about an atom or the electrons in it that has to do with vibrations or waves. The now classic **Davisson-Germer experiment** gave most conclusive evidence that electrons actually do have wave characteristics even when flying freely through space (or at least when they strike and rebound from something like a crystal), and that, again, the energy of their motion is expressible in terms of a wave or vibration frequency. Even whole atoms are reflected by crystals as if they were waves, as shown by the experiments of Ellett, Olson, and Zahl.

Such facts have given rise to the idea that perhaps all physical processes are, in the last analysis, wave

processes, with frequencies or wavelengths appropriate to the quanta into which the energy divides itself. Indeed it seems not impossible that the very atoms of which matter is composed are complex wave patterns, and that when an atom changes from one "quantum state" to another, it is because this wave pattern changes to one of different frequency. (A useful analogy is found in a metal plate clamped at the center and covered with sand; when stroked with a violin bow it shows one or another of a variety of possible complex wave patterns.) Instead of being particles which revolve in orbits like planets, the electrons in the atom, according to this conception, become wave trains reverberating like sound in a closed room, and setting up stationary **interference** patterns corresponding to the stationary quantum states. It is of such boldly revolutionary concepts that the new wave mechanics is built. The mathematical formulation of the theory has been developed largely by de Broglie and by Schroedinger. (L.D.W.)

WAVE PROPAGATION. In the propagation of a train of waves, each particle of the medium undergoes some sort of periodic variation, represented by the departure of some periodic variable from a neutral or zero value. This variable may be a position (geometrical coordinate), a pressure or other stress, a magnetic intensity, an electric intensity, a temperature, etc. Let the departure of the variable from its zero or equilibrium value at any instant be represented by d. If the variation is harmonic, it may, for any one particle of the medium, be represented by the equation $d = a \cos 2\pi\nu t$; in which a is the amplitude and ν the frequency of the periodic variation, and t is the time reckoned from an instant when d is at its maximum value. (See **Harmonic Motion.**) But if we consider different particles, we must also provide for differences in phase, by adding an adjustable phase term Δ:

$$d = a \cos (2\pi\nu t + \Delta). \qquad (1)$$

Now if a train of waves is moving in a homogeneous medium in the direction, let us say, of the X-axis, this phase term Δ is a linear function of x; so that, if we could arrest the process for a moment and examine conditions along the X-axis, the phase of d would be found to differ by equal amounts at equal intervals of distance. This linear function has the form

$$\Delta = \Delta_0 - \frac{2\pi\nu}{V} x;$$

in which Δ_0 is the value of Δ at the origin, and V is the speed of the wave propagation. Also, the amplitude a is in general some function of x, called a "wave function"; let it be represented by $\psi(x)$. Substituting these expressions in (1), we obtain the simple harmonic "wave equation":

$$d = \psi(x) \cdot \cos \left[2\pi\nu \left(t - \frac{x}{V} \right) + \Delta_0 \right]. \qquad (2)$$

According to Fourier's theorem of **harmonic analysis**, any periodic variable can be expressed as the sum of a number of simple harmonic variables, so that any wave equation in one dimension (x) may be written by equating d to a series of terms similar to (2) but with different values of $\psi(x)$, ν, Δ_0, and sometimes also of V. (See **Group Velocity** and **Vibrations and Waves.**) (L.D.W.)

WAVELENGTH CONSTANT. Propagation Constant.

WAVELLITE. The mineral wavellite is a hydrous phosphate of **aluminum**, formula $(Al \cdot OH)_3(PO)_4 \cdot 5H_2O$. It is **orthorhombic** but crystals are of rare occurrence as it is ordinarily found in crusts or radial aggregates, sometimes fibrous. Its hardness is 3.5–4; specific gravity, 2.3–2.4; may be of various colors, gray, blue, green, yellow, black, or colorless. It has a vitreous luster, and is translucent. This mineral is of secondary origin, probably formed by waters bearing phosphoric acid which have acted on aluminum minerals. Wavellite is found in Saxony, Bavaria, Devonshire, from whence it was originally described; and in the United States in Chester and Cumberland Counties, Pennsylvania; and Montgomery and Garland Counties, Arkansas. It was named after its discoverer, Dr. Wavel. (E.S.C.S.)

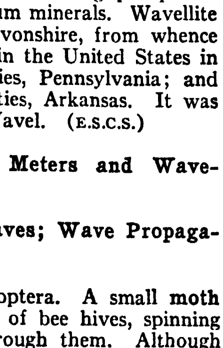
WAVEMETER. Frequency Meters and Wavemeters.

WAVES. Vibrations and Waves; Wave Propagation.

WAX MOTH. Insecta, Lepidoptera. A small **moth** whose **larva** lives in the combs of bee hives, spinning silken tunnels as it burrows through them. Although it eats the wax of which the combs are built and will attack the pure wax in stored comb foundation, careful studies have shown that it does not thrive on a pure wax diet. The other materials in old combs are a necessary source of nitrogen, without which the **caterpillar** may live but cannot grow and develop normally.

The moth does not become a serious pest in strong colonies of bees but it is sometimes a cause of serious damage in weak colonies and stored combs. It may be killed by fumigating stored supplies with **carbon disulfide.** This fumigant is highly explosive and must be used with due precautions to prevent ignition. The vapor is heavier than air and may collect in dangerous quantities in low places, but fortunately its disagreeable odor makes it easy to detect. (A.W.L.)

WAXES. Esters.



Cedar waxwing, *Ampelis cedrorum.* Soft cinnamon-brown. A yellow band across the end of the tail. A crest on the head. The end of each secondary feather in the wing has a red tip like a drop of sealing-wax, whence the name of the bird.

WAXWING. Aves, Passeriformes. A bird (**Aves**) of the northern hemisphere, smoothly gray and brown, with limited yellow shading and black marks, and red tips of horny material on some of the wing feathers. The name waxwing refers to these tips. The head bears a sharp crest. One species, the cedar waxwing or cedar bird, *Bombycilla cedrorum,* is peculiar to the United States. The Bohemian waxwing, *B. garrula,* nests in northern latitudes in Europe and North America and is occasional through the northern half of the states. A third species, the Japanese waxwing, *B. japonica,* breeds in eastern Asia. (A.W.L.)

WEAKFISH. Pisces, Teleostei. A food fish, *Cynoscion regalis,* belonging to the **drum** family. It attains a length of 2½′ and is found from Cape Cod to Florida. Also called the squeteague. Two related species of more southern distribution are the white and the spotted weakfish. (A.W.L.)

WEASEL. Mammalia, Carnivora. A small carnivorous animal, slim and short-legged, related to the minks, ferrets, and martens. Several species of weasels occur in Eurasia and a dozen North American species have been described. The common or long-tailed weasel, *Mustela noveboracensis,* ranges from Illinois to Carolina and northward into Canada. It is brown above and yellowish below in the summer, becoming white in winter, with a black-tipped tail, in the northern part of its range. The winter phase has also been called **ermine.**

The name long-tailed weasel applies also to another species, *M. longicauda,* found only on the plains from Kansas northward. The short-tailed weasel, *M. cicognanii,* resembles the common species but is white below in summer; it ranges from the northern states to Alaska. Other species are of limited distribution or are not commonly known. (A.W.L.)

WEATHER. All the atmospheric phenomena occurring for short periods such as hourly or daily. Thus, existing phenomena constitute weather while the average weather over long periods of time constitutes climate. (P.E.K.)

WEATHER ANALYSIS. Synoptic weather reports received from a relatively large area, i.e., part of a continent, or part of the world, are plotted on a weather chart in a systematic manner. The chart is then analyzed in such a manner that fronts, isobars, isallobars, isotherms, precipitation areas, clouded areas, and air masses are indicated. Also, forecast movements of prominent features are usually indicated. This is an analysis of current weather. It is a "moon-view" of the weather of the area of interest on a single chart or map. (P.E.K.)

WEATHER FORECASTING. Anticipation of the next hour's, the next day's, or the next week's weather is the work of a weather forecaster. Forecasts may be divided into several categories.

1. Micro-forecasts or highly detailed forecasts for small regions.
2. Macro-forecasts or general forecasts for large areas.
3. Short-period forecasts covering generally 24 hours or less, but sometimes 48 hours.
4. Long-period forecasts covering more than 48 hours and up to and including a week.
5. Seasonal forecasts.

An example of a micro-forecast is one issued for aircraft operation for one flight in which the period will be only a few hours. Cloud bases and tops are described to within a few hundred feet, depth and degree of roughness of air are outlined, temperature and winds within very small limits of variation are given the pilot for computation of a flight time and drift. Location of thunderstorms and icing conditions also are cited when necessary.

An example of a macro-forecast is found in one issued for farming operations covering a few days, i.e., for cutting and curing a crop of hay in a state or several states. In this forecast the amount of cloudiness, the general drying characteristics of the atmosphere, and the probability of dew or rain are outlined. Forest-fire hazard forecasts also are macro-forecasts covering humidity conditions in general for a large area for several days.

Forecast accuracy depends on two factors, (1) the required detail of the forecast, (2) the length of the forecast period. Micro-forecasts are usually inaccurate for more than 24 hours and often at the end of a 12-hour period some adjustments must be made. Macro-forecasts can be fairly accurate for several days. Forecasts for periods of more than a few days must be very generalized. The reason for failing accuracy as the forecast period grows longer lies in the fact that accelerations in atmospheric activities are ever-present in varying quantity and, as such, are not capable of being analyzed. Varying accelerations alter considerably the velocity of atmospheric phenomena until computed or estimated velocities on which a forecast is based are no longer valid. Forecasts then go off schedule. Another factor is introduced in the unknown quantity of vertical wind currents. Such currents are known to exist but there is no direct method of computing or estimating them. These currents alter considerably the wind structure of the atmosphere, which in turn changes circumstances on which a forecast is based.

A short-period forecaster works with many synoptic charts. He uses a surface map as the basic chart. Also available are maps of 5000, 10,000, 15,000, and 20,000′, cross-sections of the atmosphere, temperature and humidity soundings up to the stratosphere, temperature difference between selected level maps, moisture pattern maps, streamline and temperature maps, as well as a variety of innovations he has found useful. Each one of these charts contains some pertinent data taken from synoptic observations. The forecaster transposes the current synoptic charts into charts as they are expected to appear at some future time. These are called prognostic charts. Features of the futuristic charts are then interpreted in terms of atmospheric phenomena which is the forecast for that future time.

A long-period forecaster uses other charts which are ordinarily mean-value fields of atmospheric properties, synoptic patterns of a generalized nature, and the mean wind blowing at some chosen altitudes such as 10,000′. Long-period forecasts must, of necessity, be stated in broad and general terms. Such forecasts are useful for some activities which are seriously affected by abnormal or large-scale changes in the weather. (P.E.K.)

WEATHER MAPS. Synoptic Reports and Charts.

WEATHER OBSERVATIONS. Throughout the world, at pre-selected sites on continents, on ships at sea, on aircraft in flight, certain properties and features of the atmosphere are observed at regular intervals of 3, 6, 12, or 24 hours. Also, along airways throughout the world properties and features of the atmosphere useful in aircraft operation are observed hourly. Usually included in these synoptic observations are: form of low, middle, and high clouds; state of weather, i.e., snow, rain, thunderstorms; visibility; height of lower clouds; total sky cover; direction and velocity of the wind; atmospheric pressure, temperature and dew point; relative humidity; tendency of the barometric pressure; total change in pressure in previous 3 hours; past state of the weather. Several other items, such as maximum or minimum temperature, time of onset or ending of rain, total snow on ground also are included in some reports. (P.E.K.)

WEATHER SYMBOLS. Observations of atmospheric conditions are stated in numerical values or in terms of symbols. Transmission of a weather observation always is partly in code, with symbols or numbers representing specific values, and partly in direct numerical values. Temperature and dew point and velocity of the wind are values that can be observed and transmitted directly. Type, amount, and direction of movement of clouds usually must be coded with a symbol or a number representing a certain value of each. Many meteorological quantities also are plotted in symbol form on a synoptic chart. Weather-symbol systems in use in the United States and Canada are two in number, (1) the airways' system, used for hourly reports, which consists of symbols and numbers, (2) the international system which consists of numbers only and is used for 6- and 12-hourly observations. (P.E.K.)

WEATHERING. The processes by which the atmospheric agencies, commonly associated with the weather, mechanically disintegrate or chemically decompose the rocks at or near the earth's surface. Mechanical weathering includes the effects produced by changes of temperature, the action of frost, etc.; chemical weathering includes the solvent action of water, the union of atmospheric oxygen with rock materials—oxidation, union with atmospheric carbon dioxide—carbonation, and the chemical combination of substances with water—hydration. (E.S.C.S.)

WEAVER. Pisces, Teleostei. Marine fishes (Pisces) with poisonous spines on the dorsal fins and opercula. They are found in European and South American

waters. The greater weaver, *Trachinus draco,* or sting-bull of British seas, is an excellent food fish. (A.W.L.)

WEAVER BIRD. Aves, Passeriformes. A bird (**Aves**) of a large group found in Africa, Australia, and tropical Asia. They build remarkable nests, weaving their materials intricately and sometimes in complex forms. Some species are gregarious, building large nests for the entire colony. Many species of weavers are brilliantly colored. The group includes the ox birds, whydah birds, bishop birds, munias, and weaver finches. (A.W.L.)

WEB MEMBER. **Bridge, Truss.**

WEB PLATE. **Bridge, Girder.**

WEBWORM. Insecta, Lepidoptera. A **caterpillar** that surrounds the site of its work on plants with a mixture of silk and debris. Several insects belonging to different families are known as webworms. The burrowing webworms (Acrolophidae) eat the roots of **grass** and may damage **corn** when planted on sod ground. The sod webworms work at the base of the stem and damage **grasses, cereals,** and other plants. They belong to the subfamily Crambinae of the family Pyralidae, which also contains the cabbage and garden webworms, members of a different subfamily, Pyraustinae. The former affects cabbage and related plants and the latter attacks corn, cotton, and various species of garden plants. The European corn borer is closely related to the last two species.

Cultural methods are the most important in controlling these pests. They vary according to the species, the crop, and the conditions. (A.W.L.)

WEDGE. **Machines.**

WEDGE LINE. A line drawn symmetrically in a wedge of pressure along which the isobars are curved anticyclonically and symmetrically. Wedge lines or wedges of pressure are elongated anticyclones and are always U-shaped in contrast to trough lines which often are V-shaped. (P.E.K.)

WEDGE PHOTOMETER. In the many forms of **bench photometer,** the illuminations or luminous flux densities from the two sources to be compared are made equal by regulating the relative distances. In photometers of the wedge type, the same object is accomplished by pushing into the beam from the brighter source a graduated wedge of absorbing material until its intensity is cut down to equality with that from the other source. The scale reading on the wedge indicates the ratio in which the flux density has been reduced, and hence the luminous intensity ratio of the two sources. It is highly important that the absorbing wedge shall be "neutral," that is, not selective as to wavelength, in its absorption; otherwise there will be an alteration of color as well as of total intensity.

This same principle may be applied to **stellar photometry.** By means of a complicated system of diaphragms, lenses, and color screens, an "artificial star" image may be formed and reflected into the eyepiece of a telescope close beside the image of a star whose **stellar magnitude** is desired. The source of light for this artificial star is usually a small incandescent lamp whose brightness is maintained as nearly constant as is possible by using a storage battery of large capacity. In the path of the light from this lamp is placed the neutral optical wedge so that the brightness of the artificial star may be varied, with the amount of variation proportional to the position of the wedge. In determining magnitude with this instrument the observer sets the telescope on a star whose brightness is desired and adjusts the wedge until the artificial star and the star image formed by the telescope have the same apparent brightness. The telescope is then turned to a star of known magnitude, e.g., a star of the north polar sequence, and the wedge readjusted. The difference in wedge positions on the two stars may be converted into the difference of magnitude between the stars by means of a calibration curve previously obtained for the instruments and the observer. (L.D.W., W.K.G.)

WEEDS. Any plant growing where it is not wanted and seeming to have no usefulness may be called a weed. Many plants become weeds when introduced to new regions, where they can grow rapidly. Cultivated land, in which competition with other plants is very much reduced, is such a region. Here small plants such as purslane, which would be choked out in competition with other plants, can spread rapidly. Attempted eradication by hoeing often fails to remove such plants, because of the ease with which they put out branching stems which root at the nodes and become reestablished. Other plants become weeds when introduced into countries in which they do not naturally occur and where they meet with little competition from native plants. The common white daisy, introduced into America in colonial times as a garden flower, grows rapidly in hay fields and by its presence greatly reduces the value of the crop. Another weed causing even greater loss in such situations is the common hawkweed or devil's paintbrush. The prickly-pear cactus, introduced into Australia and into Mediterranean countries, has become a troublesome weed. In the western plains the Russian thistle, *Salsola Kali,* becomes a pest which, however, may be of value at times because of its great drought-resisting ability. When young the plants are fairly good forage. When mature they are utterly worthless, breaking loose from their roots and rolling about as tumbleweeds, scattering seeds far and wide. Other plants such as dandelion and plantain, because of the coarse unsightly habit of their leaves, become weeds when they get into lawns.

Various means are used to control weeds. Whenever possible they may be kept down or eliminated by thorough hoeing, which prevents them from getting established. In other cases the tops may be prevented from forming, thus gradually starving the plants by preventing **photosynthesis.** Sometimes they may be prevented by covering the ground with paper or other materials. This method is successfully used in the pineapple fields of the Hawaiian Islands. Recently some success has been obtained by using certain lethal sprays, such as iron sulfate solution, which sticks to the broad leaves of such plants as kale or mustard, but does not materially harm the grain among which the weeds are growing. The plant hormones themselves have also been used to kill broad-leaf weeds, which is accomplished by accelerating the normal life cycle. The plant hormone widely used for this purpose is the so-called 2,4-D, which is the chemical compound 2,4-dichloro-phenoxyacetic acid. Weed killers have also been used to spray poison ivy, where the latter has become an obnoxious and unwanted weed. The ingredients of these sprays are selected for their capacity to produce ultimate death by interfering with the metabolism of the weed. (R.M.W.)

WEEVIL. Insecta, Coleoptera. A **snout beetle,** member of a large division of the order known as the Rhynchophora. These insects, with some exceptions, have the head prolonged into a snout which bears the small mandibles at its tip. The snout is most conspicuous in the nut weevils, where it exceeds the length of the body and is very slender. Some of the weevils are important pests, notably the cotton boll weevil and the granary weevil. The former lives as a **larva** in the squares and bolls of the cotton plant, preventing the normal development of seeds and lint, and the latter is found chiefly in stored grains. (A.W.L.)

WEIGHING METHODS. The use of a **balance** for measuring masses is something more than the mere placing of equal weights on the two pans. The chief reasons are that the refinement required often goes beyond the smallest weights in any set, and that the arms of a balance are never exactly equal in length.

The former condition is commonly met by the use of a "rider," a small weight (usually 1 milligram) sliding along a scale on the beam. The most approved procedure, however, makes use of the known sensibility of the balance, expressed in divisions of the pointer scale per unit excess weight on one pan. The arm inequality may be allowed for by the substitution method, in which the object to be weighed is first counterpoised, or nearly so, and then replaced by known weights on the same pan, the small difference in pointer reading being noted and the difference in weight computed from it.

Both difficulties can be met at once by the method of "double weighing." The object is first placed on the left pan and weights nearly equal to it on the right, the resulting pointer reading being r_1. The object and weights are now interchanged, with pointer reading r_2. Then if the sensibility of the balance is s, and if the weights used total a value w, the weight of the object is given by

$$W = w + \frac{r_1 - r_2}{2s}.$$

The sensibility is, in general, a function of the load, and before precise weighing is attempted, a table or a graph should be prepared from which s can be obtained from the value of w. When the pointer is used, it should not be allowed to come to rest, but its equilibrium position should be deduced from the extremes of its small oscillation (see **Damping**).

It is of course presumed in any case that the errors of the weights themselves have been accurately determined. Due allowance must also be made in precise weighing, for the buoyancy of the air, or rather for the difference of the buoyant force on the object to be weighed and that on the weights in the opposite pan. If the weights are mainly of brass (density 8.4 g./cm.^{3}), the corrected or "vacuum" weight of an object of volume V (cm.^{3}), weighed in air of density ρ (g./cm.^{3}), is

$$W_0 = \left(1 - \frac{\rho}{8.4}\right) W + V\rho,$$

where W is the uncorrected result of the weighing. Under ordinary laboratory conditions, the value of ρ is approximately 0.00119 g./cm.^{3}, giving 0.99986 as the coefficient of W in the above formula. (L.D.W.)

WEIGHT. Gravitation and Gravity; Weighing Methods; Errors.

WEIGHT, AIRPLANE. Airplane weight is the total weight of an airplane and its contents. As number of passengers, fuel, and baggage are variables, airplane weight actually is a variable, ranging between minimum and maximum values. The minimum weight employed for commercial designing in the United States is the weight empty with standard equipment, plus crew, plus full capacity of lubricating oil, plus 0.25 lb. of fuel per hp. maximum continuous engine rating. The maximum weight of an airplane is the gross weight which can be lifted from the longest available runway or water surface at sea level and raised to a safe flying altitude. Conservative aeronautic practice does not sanction flight with this maximum weight except in emergencies. Safety allowances are provided by specifying airworthiness requirements for commercial design. Then the maximum practical weight becomes that for which the airplane is certificated as complying with all the officially promulgated airworthiness requirements for normal operations.

The (empty) weight of an airplane is a matter of far greater importance to aeronautics than dead structural weights are in almost any other field. Insufficient structure is a hazard that is not countenanced, but unnecessary weight represents a continuous loss of pay load during the operating life of a commercial airplane. Therefore **weight control** is given great emphasis in airplane design and construction. (F.T.M.)

WEIGHT CONTROL, AIRPLANE. Adequacy of an airplane structure for the loads imposed on it and ability of the airplane to carry the maximum weight of fuel, passengers, and cargo at high speeds are of the greatest importance to aviation—to the designer, the builder, and the user of airplanes. Unfortunately any unnecessary margin of structural weight employed in meeting the first requirement will penalize the second, and vice versa.

Airplane weight affects the tactical performance of military airplanes. Commercial airlines are interested primarily in pay load, so weight control in design and construction is imperative for the airliner. The airplane of superior performance (speed, range, etc.), and which maintains adequate structural safety will be more attractive to the private owner. Here again, weight control is important.

After an airplane is built, and while it is in use, weight control continues to demand attention. If accessories such as flares or radio are added, there must be a corresponding reduction of freight or baggage capacity. Also, the effect on center of gravity needs investigation in order to maintain predetermined stability limits Weight control must be practiced by every scheduled airline. Cargo compartments are provided fore and aft and cargo suitably apportioned to each in order to maintain trim.

All phases of aviation are "weight conscious," but none more so than manufacturing. In this field the specialized service of "weight control engineering" is becoming more and more essential to manufacturing as airplane sizes increase. The ultimate object is to establish the methods and control, both in design and production, whereby the lightest weight possible is achieved in a structure of adequate strength. The weight-control engineer alone cannot hope to control the final airplane weight closely. Designers, fabricators, and many others must be weight-conscious, with the weight-control engineer in continuous touch with all phases of construction and continuously cognizant of the weight being incorporated into the structure. Subassemblies are weighed and tested for center of gravity so that the practical weight control is not delayed until the airplane is finished. However, the actual weight and center of gravity of the completed airplane is the final test of successful weight control.

Enough has been said to point out the importance of technical weight control in aviation. Weight must be closely watched and controlled from the inception of design, through construction, and during the life of the craft. A carefully compiled record of weight and balance must accompany an airplane throughout its commercially airworthy life. (F.T.M.)

WEIL'S DISEASE (Spirochetal jaundice). An acute infectious disease caused by a spirochete (*Spirochaeta icterohaemorrhagiae*). This spirochete is present in rats, and is excreted in their urine. Such urine, contaminating water supplies, is a major source of infection. The agent is also found in dogs, cats, mice, pigs, and horses.

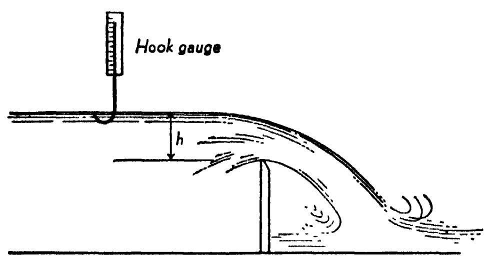
The disease is characterized by a sudden onset after an incubation period of 10 days, of fever, chills, gastrointestinal symptoms, **jaundice**, enlargement of the spleen, and a tendency to hemorrhage into the skin and mucous membranes.

Immune serum and bismuth have been used in the

treatment with some success, although the main treatment is still supportive. (D.M.H.)

WEIR. A weir is any **dam** or **bulkhead** over which water flows, or it may be a bulkhead containing a notch through which water flows, the notch at no time becoming completely submerged. A weir is usually employed to measure the volume in a flow of water. This it accomplishes through the fact that a discharge through a weir bears a certain definite relationship to the **head** of water over its crest, and this head is comparatively easy to measure. Uses of a weir, then, are for the precise measurement of a large flow of water, or of one where peculiar conditions eliminate other methods of volume measurement. The weir is frequently used for measuring the flow of small streams, and the discharge from all sorts of hydraulic apparatus. It also is used for measuring hot water. When used with water which is not at atmospheric pressure and temperature, the general weir formulae do not apply, and the weir must be calibrated by a primary meter.

There are many different forms of weirs, such as sharp-crested and flat-crested, rectangular and V-notch, trapezoidal, broad-crested and submerged. Also the distance from the crest to the bottom of the channel and from the edge of the weir to the side of the channel



Sharp-crested weir.

distinguishes a weir. If the edge of the channel is also the edge of the weir, it is said to have no end contraction, and this type is recommended, since no corrections for end contraction need be made. The crest, however, should be high enough over the bottom that a standard crest contraction exists. The figure shows a cross-section through a trapezoidal weir, with sharp-edged crest. This type is better than the flat crest, as results may be duplicated with greater accuracy. The height of water over the crest should be measured at least 2½ crest heads upstream, so that the water surface contraction will not be included in the reading of head. The head is measured by a hook gauge, which is a hook submerged in the water and raised until the point just touches the surface. To the stem of the hook is attached a scale, so that the head may be read. Where it is possible to flood the weir, and then shut off the water supply, the hook gauge can be used to give a zero reading, since the water will stand back of the weir at exactly the crest elevation. Where this is not possible, a surveyor's level can be employed to give the elevation of the crest in comparison with some reference point on the hook-gauge support.

If the flow is highly variable, it is better to use a triangular-notch weir than rectangular, because at small discharges the head does not become so minute. Both 90° and 60° V-notch weirs are used. A trapezoidal-shaped notch whose sides slope four on one theoretically gives the discharge without "end contraction" corrections, because the decrease of flow resulting from end contractions is compensated for by the flow through the small triangles on either side of the weir. The bottom width is used as crest length in the regular rectangular weir formula. This is known as the Cipolletti weir.

Weirs having flat or rounded crests can be used to measure discharge of water, and often the overflow section of a dam can be used in this way. The discharge is proportional to the length of crest, and to the $\frac{3}{2}$ power of the head over the crest, but the factor of proportionality must be established by experiments with models which duplicate hydrodynamically the proposed weir.

The most common formula for the discharge of water through a suppressed rectangular weir is the Francis formula:

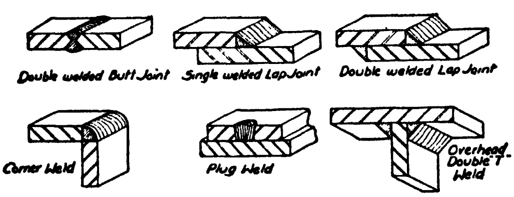
$$Q = 3.33Lh^{3/2}.$$

Q is the discharge, cu. ft. per sec., L is the crest length in ft., and h the crest head in ft. Specific weir installations may call for corrections to this formula for end contractions or velocity of approach, or both. Furthermore, if the crest is very close to the bottom of the channel of approach, a correction for suppression of crest contraction is used. The discharge through V-notch weirs is given by the following formula:

$$Q = Ch^{5/2}.$$

Q and h have the meanings given above, and C is a constant depending upon the angle of the notch. It is approximately 2.5 for a 90° notch. (F.T.M.)

WELDED JOINTS. Fig. 1 shows various types of welded joints. Double-welded butt joints are those welded from both sides of the plate; single-welded butt



(*Hesse's Engineering Tools and Processes*)

joints are welded from one side only. In **pressure vessel** design, double-welded butt joints are considered to have a joint efficiency of 80%; single-welded butt joints 70%; double-welded fillet lap joints and single-welded fillet lap joints with plug welds have a joint efficiency of 65%. In structural practice, butt welds may be stressed to 13,000 lbs. per sq. in. in tension and 11,300 lbs. per sq. in. in shear. The allowable shearing stress in full-fillet lap joints is 1000 lbs. per lineal in. of length per ⅛" of fillet leg for ordinary strength welds; that is, a ½" weld has a strength of 4000 lbs. per in. of length; a ⅞" weld a strength of 7000 lbs. per in. of length. For welds made with coated rods, the strength is about 20% greater. (H.C.H.)

WELDING. Welding is a method of joining metals by means of fusion or by interdiffusion in the solid state under the influence of high temperature and pressure as in forge welding. Metals having similar composition may be united in one homogeneous piece by fusing together the edges in contact, or by additional molten metal of the proper characteristics deposited where it will form a fused joint with each piece. In any machine or structure there are numerous cases where permanent junctions between the component parts are required. Before the advent of fusion welding, these were made by riveting or bolting and forge welding.

In a number of instances within comparatively recent years, structures have been built with welded joints at a lower cost than was possible formerly. Typical of such practice might be mentioned the welding of joints in pipe lines, eliminating flanges, couplings, and cumbersome fittings. Bridges and buildings of structural steel have been fabricated by arc welding, replacing the older riveted connections. Modern shipbuilding practice is

turning to welding as the principal means of fabrication. Where weight saving is as important as strength, welding is especially suitable because of the elimination of the weight of rivets and bolts, and often of the flanges in which they are seated. Many complicated machine parts, which at one time could be produced only by casting, are now built up from structural steel shapes by welding. To the above illustrations may be added the aircraft structures, where, especially in the fuselage tubing, welding has become standard practice. Machinery frames and bases, tanks, and steel frames are welded. Even high-temperature and pressure vessels, such as boiler drums, are now accepted if welded in conformance with standard procedures.

Welding can be practiced on castings, on rolled and forged metals, and on thin sheet metals, using techniques appropriate for the thickness of section being welded. Steel, iron, copper, nickel, aluminum, duraluminum, and even magnesium may be welded. The principal methods of welding are gas welding, arc welding, resistance welding, pressure welding, and combination methods such as atomic-hydrogen welding.

Gas welding is usually accomplished by the oxyhydrogen or oxyacetylene methods, the latter being the most common, with oxyhydrogen welding being used primarily on aluminum. High pressure oxygen and acetylene are led through reducer valves to reduce the pressure to a torch where they are mixed and burned at the tip. The flame, either oxidizing, reducing, or neutral, is adjusted to the proper size and brought into contact with the work which has been previously prepared and clamped into position. The temperature of the work is raised until it melts and flows together. Additional metal necessary to accomplish the formation of a sound joint may be added as wire or rod as the welding progresses. In some cases fluxes must be added to insure a sound weld, particularly with stainless steel or aluminum.

Arc welding is accomplished by utilizing the heat generated by an electric arc, either a.c. or d.c., to fuse the metals together. A common method is to use a motor-generator set to supply d.c. at relatively low voltage. One electrode is fastened to the work, and the welding rod, usually coated with a flux, is made the other electrode, the arc being struck between the rod and the work. Metal from the rod melts off and is fused into the joint. Automatic machines for arc welding use coils of wire to feed into the arc, flux being supplied from a hopper as the work travels under the arc. This process is also known as submerged arc welding. Another method of arc welding is the carbon arc in which one electrode is a rod of carbon. It is generally used on automatic machines. The wandering of the arc is minimized by placing a magnetic field near the arc to stabilize it. Extra filler material is fed into the arc if needed, and it is often shielded by gas generated from a chemically treated string or cord.

Atomic-hydrogen arc welding is a combination of gas welding and arc welding. In this case heat is supplied to the work by a stream of hydrogen passing through an arc struck between two tungsten electrodes. As the hydrogen passes through the arc, it is dissociated into its atomic form. When it recombines to form molecular hydrogen, a large amount of heat is generated in a small space, making an intensely hot flame. The hydrogen blankets the weld as it is made and largely prevents loss of alloying materials. This method also has been applied to automatic machines, no flux being necessary. A large variety of alloy steels for exacting specifications are welded by this method.

Heliarc welding is a modification of the atomic hydrogen method for the welding of magnesium; here helium gas is blown along a single tungsten electrode, the work being the other terminal as in ordinary electric arc welding. The helium serves to protect the highly reactive magnesium from burning.

Electric-resistance welds may be divided into a number of different categories but all have the common characteristic, that the metal is heated by its own resistance to a semi-fused or fused state by the passage of very heavy currents for very short lengths of time and then welded by the application of pressure.

Spot welding is accomplished by clamping the lapped edges of the work between two water-cooled copper electrodes usually having a small tip area. Pressures up to 50,000 lbs. per sq. in. are applied and currents up to 60,000 amperes. The heavy current which is applied for a fraction of a second melts the metal at the interface of the lapped pieces of the work, resulting in complete welding of the two pieces under the contact area of the electrodes.

Projection welding is a modification of spot welding and is much used in mass-produced articles. Small projections are stamped into the work at the desired positions. The electrodes are applied opposite this projection and thus many welds may be made simultaneously.

Seam welds are another type of resistance weld. Here the electrodes are in the form of rollers which oppose each other on opposite sides of the work. Current is passed usually intermittently between the electrodes as the work moves along. The current may operate, for example, 12 times per sec., the frequency depending on the speed of travel of the work through the rolls. Spot, projection, and seam welding have wide application in the joining of sheet metals, particularly steel and stainless steel

Butt welds are a form of resistance welding in which the two butted surfaces are heated by resistance to a fusing temperature with simultaneous application of pressure. In slow butt welds the pressure is increased to forge the joints together. These welds are characterized by a large upset or swelling in the fused section.

Flash welds are similar to butt welds except that high pressures are applied suddenly after the metal is quite hot, resulting in a small upset or swelling in the heated area.

Pressure welding is also quite similar to butt welding except that the heat is usually applied by some source other than resistance to electric current. The parts to be welded are cleaned and carefully fitted together to exclude as much air as possible. Pressure is applied and the parts heated to a forging temperature where upsetting and welding occur. This method has been used extensively in the joining of pipe in the field. It is of interest to note that such an operation is a mechanized form of forge welding as practiced by the blacksmith long before fusion welding methods were known. Some of the most modern welding techniques make use of the principle of interdiffusion in the solid state under pressure without melting or fusion of any part of the joint. (F.T.M and C. R. TAYLOR)

WELS. Pisces, Teleostei. A **catfish,** *Siluris glanis,* found in European rivers east of the Rhine. It is a large fish, attaining commonly a length of 6′, and a maximum of twice that figure. (A.W.L.)

WELSBACH MANTLE. This is a gauze made out of **thorium** and **cerium oxides** which is used for gas mantles. The heat derived in the combustion of the gas is converted by this mantle into light energy. (R.K.S.)

WENTLETRAP. Mollusca, Gasteropoda. A marine **mollusk** with a white shell of elongated conical form, with many convex whorls bearing prominent ribs. Also called spiral staircases. The 200 species are widely distributed. (A.W.L.)

WERNERITE. The mineral wernerite is a **silicate** of **calcium** and **aluminum** which contains also some **soda** and **chlorine.** It can be considered as an **isomorphous**

mixture of two molecules corresponding to the following compositions:

$CaCO_3 \cdot 3CaAl_2Si_2O_8$, called meionite, and
$NaCl \cdot 3NaAlSi_3O_8$, called marialite.

Its **tetragonal** crystals are coarse and thick, often very large. It occurs also in massive forms. It has a distinct prismatic **cleavage;** subconchoidal fracture; is brittle; hardness, 5–6; specific gravity, 2.66–2.73; luster, vitreous to rather dull; color, white to gray, red, green, or blue; translucent to nearly opaque. Wernerite is found in the **metamorphic rocks,** particularly those rich in calcium, also in contact metamorphic deposits in limestones. It has been found in **basic** igneous rocks, probably as a secondary mineral. Notable localities are Lake Baikal, Siberia, Arendal, Norway, and Madagascar. In the United States it is found in Massachusetts, New York, and New Jersey. Grenville, in the Province of Quebec, Canada, is an important locality. Wernerite is named in honor of A. G. Werner, a famous German mineralogist (1749–1817). (E.S.C.S.)

WESTON CELL. Standard Cell.

WET-AND-DRY-BULB THERMOMETER. Hygrometers.

WET-BULB TEMPERATURE. Humidity.

WETTING AGENTS. Surface-Acting Compounds.

WHALE. Mammalia, Odontoceti and Mystacoceti. A marine animal of completely aquatic habits. The whales vary to a considerable degree in structure, as is indicated by their classification in two orders. Whales 20′ long are among the smaller species. Individuals 60 to 80 or 90′ long have been recorded among several of the large kinds.

The whalebone whales (**Mystacoceti**) live on small marine animals which are separated from the water by the sievelike whalebone fringes of the jaws. The toothed whales (**Odontoceti**) include some actively predacious species. Species of both orders were once widely sought for their oil and whalebone, but the latter has long been supplanted by manufactured products and the oil has given way for many uses to petroleum oils. Sperm oil is still valued as a fine lubricant and sperm whales are killed also for a waxy material, spermaceti, used in the manufacture of cosmetics. The peculiar substance called ambergris is formed in the intestine of the whale and is used to make the odor of **perfumes** more persistent.

Whales are specialized for life in the ocean by the formation of the pectoral appendages into paddlelike flippers and by the complete loss of hind limbs. The tail is expanded horizontally into a pair of broad lobes, the flukes, which serve as a powerful swimming organ. The **respiratory system** is also highly specialized. The lung capacity is great and the nostrils are located high on the head, so that very little of the animal need be exposed to enable it to breathe. In some species they are combined to form a single opening. The whales are without hair, which would be useless to animals living always in the water, but they have a thick layer of fat, the blubber, as an insulation against the cold of the surrounding water. Much of the oil secured from their bodies is from the blubber, but the sperm whale also has an enormous cavity in the head filled with oil.

The various kinds of whales are briefly mentioned under the two orders. (See **Esters.**) (A.W.L.)

WHEAT. *Triticum sativum* and other species. Gramineae. Wheat is an annual plant producing the most valuable of cereal grains used by the white race. The plants grow either as summer annuals, seed being planted in the spring and the harvest gathered in the fall of the same year, or winter annuals, the seed then being planted in the fall and growing until stopped by cold weather, developing during that time an abundant root system which insures rapid growth in the springtime, the mature crop being ready for harvest in early summer. (See **Vernalization.**)

When wheat seeds germinate a small primary root system is formed by the development of the radicle or seed root. This primary root system lasts but a short time, being soon replaced by a system of **adventitious roots** arising from the lowermost nodes of the stem and extending outward and downward to fill the soil with an extensive fibrous root system. The stem of the wheat plant is 2–4′ tall and usually hollow, although some species have solid stems. The dried stems form wheat straw, frequently used in the manufacture of straw board. The leaves are of the ordinary grass type. The **inflorescence** is composed of very short-stemmed **spikelets** attached alternately on opposite sides of a zigzag axis. Each spikelet has 2–8 flowers. In certain varieties known as bearded wheats the **lemma** of the flower bears a long bristle or **awn.** Most species of wheat, particularly those grown in temperate climates, are close-pollinated. Durum wheat and primitive species are cross-pollinated. Evidence indicates, also, that wheats grown in hot dry climates are cross-pollinated. The fruit or grain of cultivated wheat varies somewhat according to the species. In many kinds of wheat the fruit separates readily from the surrounding floral **bracts,** while in a few kinds the lemma and **palea** tightly enwrap the grain. The grain bears at its apex a tuft of short hairs called the brush and has a distinct groove along the side which was against the palea. In section, a wheat grain shows several very distinct parts. Externally there is a layer several cells thick called the **pericarp,** or **ovary** wall. Within this is a layer two cells thick, the tegmen, which is formed from the inner integument. The outer integument was absorbed during the development of the grain. Next is the **nucellus,** a single cell in thickness. These three layers constitute some 8% of the grain, and make up the substance which is called bran. Within these is the **endosperm,** which forms the bulk of the grain; the outermost layer of cells of the endosperm is the aleurone layer. In the basal portion of the seed next to the endosperm is the so-called germ, or embryo, from which the new plant may develop.

There are several ways of classifying wheats. Botanically they are separated according to the structure of the spikelet, the number of **florets** and the nature of the parts of the flower. Among the kinds of wheat recognized in this classification are einkorn, spelt, emmer, durum, and common wheat. Again, if the palea and lemma adhere to the grain, the wheat is classified as spelt wheat, while if the grain readily separates from these two parts it is naked wheat. If one turns to the grain itself there are hard wheats, in which the grain is horny and has a high **protein** content, and soft wheats with starchy grains. The nature of the soil in which the wheat is grown and the climate have considerable effect on the nature of the grain. Hard wheats are separated into hard spring wheat, hard winter wheat, and durum, the latter being especially rich in protein content.

While a considerable quantity of wheat is used directly as food for domestic animals, the greater part is ground into flour. This milling of wheat is a very carefully controlled process. The first step is the thorough cleaning of the grain, removing therefrom any other substance. During this process the brush of the grain is removed. The cleaned grain is then moistened slightly in order to soften the outer layers so that they may be more easily removed subsequently. The moistened grain is then passed between iron rollers. The first of these are corrugated and break up the grains Each successive pair of rollers grind the grain into finer and finer particles. Early in this grinding the coarse flakes of bran

and the germ are removed. These are disposed of as such or ground up separately. The ground grain is passed through fine bolting silks which insure a very even grade of fineness of the flour particles. Every precaution is taken in flour mills to prevent the accumulation of dust particles in the atmosphere, since these may form very dangerous explosive mixtures.

Flour is classified according to the amount of the grain included in the final product, into Graham flour, which contains the entire grain; whole wheat flour, which contains all the grain except about half of the bran; and straight bread flour, which results when all the bran is removed early in the grinding process. Wheat flour is used extensively in making breads, crackers, and pastries. Because it is so highly glutinous that pastes made from it will support their own weight, durum wheat is used in making spaghetti and macaroni. In making this product a thick viscous paste or dough is prepared. This is forced, under great pressure, through holes in metal dies. Metal pins may project into the hole in the die, causing the dough which is forced through to emerge as a hollow tube. This is macaroni. As they emerge, the tubes or strings are cut into suitable lengths and hung up to dry. Durum wheat alone has the necessary properties for making macaroni and similar substances. If any other wheat were used the product would break apart from its own weight. In addition to flour and macaroni, much wheat is used in making breakfast foods. The familiar puffed wheat results from heating wheat grains under pressure and suddenly releasing the pressure; the grain expands rapidly. Some wheat is used for making whiskey and certain varieties of beer. (R.M.W.)

WHEAT MIDGE. Insecta, Diptera. A minute fly whose **larva** develops in the growing kernel of wheat. Introduced from Europe into Canada early in the nineteenth century, the species was troublesome in New York about the middle of the century but has not been serious since. Cultural methods are an adequate protection. They include crop rotation, fall plowing to bury and destroy the larvae, and the destruction of all debris from infested fields. (A.W.L.)

WHEATEAR. Aves, Passeriformes. A bird (**Aves**), *Oenanthe oenanthe*, related to the thrushes and bluebirds. It nests in the northern part of Europe and in Alaska, and is widely distributed in the Old World and occasionally in the United States during its southern migrations. (A.W.L.)

WHEATSTONE BRIDGE. One of the simplest and best-known **bridge** networks for measuring electrical **resistances.** Referring to Fig. 1, let R_1 be the unknown resistance and R_2 a known resistance, preferably not very different from R_1, in terms of which R_1 is to be measured. R_3 and R_4, called the ratio arms, are two other resistances which may be varied continuously or by very small stages and the values of which are known, either in ohms or relatively to each other. From C to D

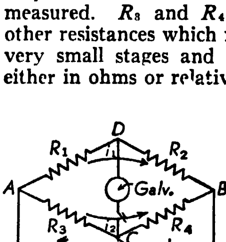


Fig. 1.

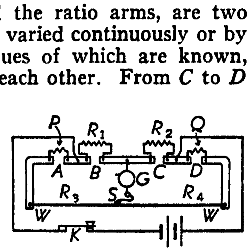

Fig. 2.

Sketches of simple and four-gap Wheatstone bridge circuits.

is the bridge proper, containing a **galvanometer.** To measure R_1, the resistances R_3 and R_4 are adjusted until the galvanometer shows no current, which means that C and D are at the same potential. It then readily follows from the **law of potential drop** that $R_1 : R_2 = R_3 : R_4$, and hence $R_1 = R_2R_3/R_4$. Fig. 2 shows a "slide-wire" form having a graduated resistance wire and four gaps. The **Carey-Foster bridge** is a special type of Wheatstone bridge. (L.D.W.)

WHEEL-AND-AXLE. Machines.

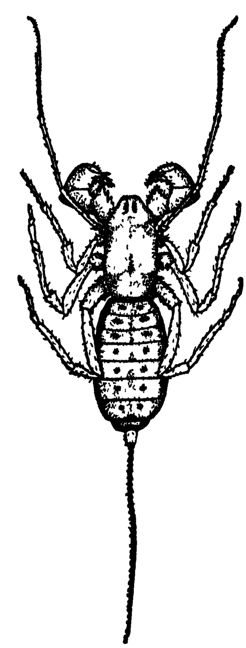
WHELK. Mollusca, Gasteropoda. A moderately large marine **mollusk** with a spirally coiled shell. It is used as a bait in the cod fisheries and in Europe is eaten. (A.W.L.)

Fulgur, the whelk. (*U.S.B.F. Report, 1897.*)

WHIMBREL. Aves, Charadriiformes. Northern shore birds (**Aves**) with long legs and a long curved beak. Related to the curlews and plovers. The name is European; the species that occur in North America are called here the Eskimo, *Phaeopus borealis,* and Hudsonian, *P. hudsonicus,* curlews. (A.W.L.)

WHINCHAT. Aves, Passeriformes. A small European bird (**Aves**) related to the bluebirds and thrushes. It nests in the far north and winters in Africa. (A.W.L.)

WHINSTONE. A popular British term for **basic,** fine-grained **igneous rocks** belonging to the basaltic group and including **diabase, dolorite, spidiorite,** also **greenstone** and the **lamprophyres.** Synonym for **trap** or trap rock. (R.M.F.)

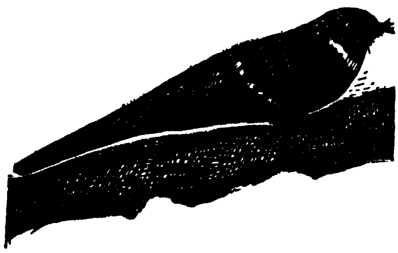


Whip scorpion.

WHIP SCORPION. Arachnida, Pedipalpi. A large **arthropod** whose abdomen bears a whiplike posterior portion, although some species of the same order lack this terminal filament. The **pedipalps** are large and strong, either chelate or simple. The first pair of legs are modified as slender many-jointed sensory appendages. They are tropical animals, only a few species entering the southern part of the United States.

In the Southwest many fears and superstitions are associated with these unpleasant looking animals, which are called vinegarones (also spelled vinegar roan and vinegaroon). They discharge a disagreeable, sour-smelling secretion, but are entirely harmless to man. (A.W.L.)

WHIPPOORWILL. Aves, Caprimulgiformes. A nocturnal bird, *Anthrostomus vociferus,* with a short beak and wide mouth, adapted for taking insects in flight.



Whippoorwill, *Antrostomus vociferous.* Mottled grayish, reddish, and white. Long wings, conspicuous bristles around the mouth.

Its call has been likened to the words used in its name. Often the three syllables are repeated over and over scores of times without cessation. One of the **nightjars.** (A.W.L.)

WHIRLWIND. Small cyclonic whirls of air usually not more than a few hundred feet high and several tens of feet in diameter. If the whirls pick up dust they are more commonly known as dust-devils. A few whirlwinds grow larger than the average and do some damage, particularly to grain fields during harvest. Whirlwinds originate in a shallow layer of very unstable air lying immediately above the ground and are therefore primarily afternoon phenomena. (P.E.K.)

WHISTLER. Mammalia, Rodentia. An animal related to the woodchuck. A **marmot.** Its range extends from Alaska to Montana and Washington. (A.W.L.)

WHITE ANT. **Isoptera.**

WHITE DWARFS. In the article on **giant and dwarf stars** it was shown that more than 99% of the observed stars may be classified either as super giants, giants, or main sequence stars. A few stars do not fit into this general scheme at all and form a unique and little understood class known as the white dwarfs. The first star of this class to be discovered was the companion star to **Sirius.** The orbit of the pair has been computed, and from it the mass of the companion was computed and found to be about the same as that of the sun. Its **absolute magnitude** was known and the **luminosity** found to be about 1/360 that of the sun. On the ordinary giant and dwarf hypothesis such a star should be in the dwarf M-type **spectral class** having low brightness per unit area. However, when its spectral class was finally determined it was found to be of class F and hence hotter than the sun and brighter per unit area. From the brightness per unit area and the intrinsic brightness, the diameter can be computed, and it is found to be about 30,000 miles, or of planetary dimensions. This means that we have an object of stellar mass and planetary dimensions, and an unbelievably great density, of the order of magnitude of 30,000 times the density of water. At such a density a cu. ft. of this stellar material would weigh 935 tons.

This star is one of the general class known as white dwarfs, all with spectral classes between A and F. The total number of such stars is not known, for they are all apparently very faint and cannot be detected as white dwarfs except by spectrographic analysis, which is difficult for faint objects. Furthermore, their intrinsic brightness is so small that only the closer ones would be observed at all (the few known at present are all within 15 **light years** of the sun).

The problem of the internal constitution of objects of such great density is as yet far from completely solved. The best hypothesis is that the material consists of atomic nuclei stripped of all external **electrons** and tightly packed together by gravitational compression. Such matter would be in a state much like a single huge molecule, or crystal. (W.K.G.)

WHITE FLY. Insecta, Homoptera. A minute sucking **insect** related to the phylloxerans and scale insects. The adult has four wings and is mealy white. In spite of their small size these insects are important pests. One species, *Asterochiton packardi,* attacks strawberry plants, one, *Dialeurodes citri,* is a pest of citrus fruits in Florida, and two attack both flowers and vegetables in greenhouses.

Cyanide fumigation is recommended for the control of the greenhouse species, while spraying with oil emulsions is effective against others. In Florida an ingenious method of spraying with an infusion of the spores of fungi has been devised. Three species of fungi live on the immature insects and destroy them in large numbers when the colonies are once inoculated. (A.W.L.)

WHITE LEAD. **Lead** (Carbonates).

WHITE LIGHT. **Color.**

WHITE WHALE. Mammalia, Odontoceti. A small species related to the **narwhal.** The **beluga.** (A.W.L.)

WHITEFISH. Pisces, Teleostei. A lake fish of the **salmon** family, genus *Coregonus.* The several species are excellent food fishes and the common whitefish of the Great Lakes is among the most important in the inland fisheries of the United States. Several species are known by various distinctive names, among them pilot-fish, whiting, cisco, bluefin, and tullibee. (A.W.L.)

WHITENOSE. Pisces, Teleostei. A common fish (**Pisces**), *Moxostoma anisurum,* of the Great Lakes and Ohio River basins, related to the redhorse. It reaches a length of seventeen inches and is a good but not an important food fish. (A.W.L.)

WHITETHROAT. Aves, Passeriformes. A European **warbler.** The common species, *Sylvia cinerea,* is gray-brown above and whitish below, and the lesser whitethroat, *S. curruca,* is gray above with dark brown ear coverts and tinged with pinkish on the breast. (A.W.L.)

WHITING. Pisces, Teleostei. 1. Marine fishes, *Menticirrhus,* of the **drum** family. One occurs on the Atlantic coast from Maryland to Brazil and another, called the silver or surf whiting, is found from Virginia to Texas. 2. A member of the **cod** family found on the Atlantic coast of North America. Also called the silver **hake** and stock-fish. (A.W.L.)

WHITWORTH. **Screw Thread.**

WHOOPING COUGH (Pertussis). An acute contagious disease of childhood, caused by a small bacillus, *Hemophilus pertussis,* first identified by Bordet and Gengou in 1906. Nearly 50% of the cases occur during the first two years of life and most of the deaths are in this age group. During the first year of life the mortality rate is at least 25%. In children over 5, the disease is rarely fatal.

The incubation period of whooping cough is from 5–15 days. The disease may run a mild brief course, or it may be a severe illness, especially in the very young child, lasting 6 weeks or more.

The symptoms of the first week and a half are mild and are those of **bronchitis.** Although the disease is most contagious at this stage, diagnosis is difficult unless there is a history of exposure. Instead of subsiding

the coughing becomes more frequent, occurring in paroxysms, terminating in the characteristic whoop. Several exhausting paroxysms may occur together until a small amount of mucus is coughed up, giving immediate relief. Vomiting may occur after these paroxysms. **Convulsions** are not uncommon in infancy. Nose bleeds and hemorrhages beneath the **conjunctivae** of the eye appear when the coughing is very severe. Hemorrhages in the lungs and brain may also occur. This active stage of the disease averages between 3 and 6 weeks, the intensity and severity of attacks slowly diminishing.

The most important complication of whooping cough is bronchopneumonia, which causes most of the deaths from the disease. **Atelectasis** and **bronchiectasis** may occur. **Otitis media** due to secondary invading organisms is frequently encountered.

The prevention of whooping cough by immunization with **vaccine** has been very successful. It should be carried out in all children between the ages of 6 and 12 months. If an infant has been exposed to the disease, he should be given immune or convalescent **serum** immediately, to protect him against the disease and modify the severity of its course should it develop.

Treatment of the active case is general and supportive. Bed rest, sedation, and medication to control the cough are useful. (D.M.H.)

WHYDAH BIRD. Aves, Passeriformes. A brilliantly colored and long-tailed **weaver bird** of Africa. The several species constitute the genus *Vidua*. (A.W.L.)

WICHERT TRUSS. **Bridge.**

WIDE FLANGE BEAM. **I-Beam.**

WIDGEON, WIGEON. Aves, Anseriformes. A **duck** with a relatively small beak, widest at the base. The European species is occasionally taken in the United States, in addition to a native species called the baldpate and sometimes the American widgeon. A third species occurs in South America. All belong to the genus *Mareca*. (A.W.L.)

WIDMANSTAETTEN STRUCTURE. A microstructure often observed in steels and certain other alloys. It is a duplex structure in which one phase forms sets of parallel plates embedded in the matrix. (See **Metallography.**) Typical examples are found in medium carbon cast steels and in meteoric iron. (R.H.H.)

WIEDEMANN-FRANZ LAW. The most casual observation reveals that at ordinary temperatures the metals which are the best electrical conductors are also the best conductors of heat. (See **Thermal Conduction.**) In fact, if we calculate the ratio of the thermal conductivity (in calories per cm. per sec. per degree) to the electrical conductivity (in reciprocal ohms-centimeters) for a number of metals at 0° C., we get results like the following: copper, 0.00000156; platinum, 0.00000143; lead, 0.00000169; etc.; all in calorie-ohms per degree per sec. The ratio appears to be nearly constant.

The Wiedemann-Franz law states that the ratio of the thermal to the electrical conductivity for all metals is proportional to the absolute temperature T, and in the above units equal to $6.11 \times 10^{-9}\ T$. For 0° C. (273° absolute) this gives 0.00000147 calorie-ohm per sec. per degree, which is very close to the observed value for platinum. The Wiedemann-Franz formula is theoretical and its coefficient involves both the **Boltzmann constant** and the electronic charge. For most metals the ratio as observed is a little higher than that given by the formula, doubtless because of thermal conduction due to other causes than electronic activity. (L.D.W.)

WIEN'S LAWS. From a study of the **spectral energy distribution** of **thermal radiation**, W. Wien, in 1896, arrived at three laws relating to the radiation from a **black body.**

1. The wavelength λ_m of the spectral distribution, for which the radiation has greatest intensity, is inversely proportional to the absolute temperature T of the black body:

$$\lambda_m T = c_1.$$

Thus as the temperature rises, the "peak" of the distribution curve is displaced or shifted toward the short-wavelength end of the spectrum. This is commonly called Wien's "displacement law." The value of the "displacement constant" c_1 is about 0.2897 centimeter-degree.

2. The emissive power of the black body within the maximum-intensity wavelength interval $d\lambda$ is proportional to the fifth power of the absolute temperature:

$$dE_m = c_2 T^5 d\lambda.$$

Subsequent work by Planck and others gives the value of the constant c_2 as about 1.288×10^{-4} erg/cm.^{3} sec. deg.^{5}

3. Wien's third law is an attempt to express the spectral energy distribution of the radiation from the black body at temperature T, as follows:

$$dE_\lambda = A\lambda^{-5}e^{-B/\lambda T}d\lambda,$$

in which dE_λ is the emissive power within the wavelength interval $d\lambda$ and A and B are constants to be empirically determined.

The first and second laws are in accord with thermodynamic theory and with **Planck's equation,** and also agree very accurately with experiment. The third law is empirical, but is almost identical in form with **Planck's equation** and agrees with it closely except for short wavelengths. (L.D.W.)

WILD RICE. **Rice.**

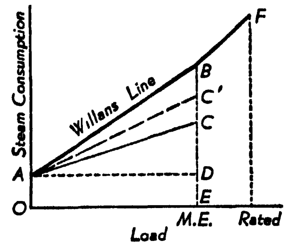
WILDCAT. Mammalia, Carnivora. *Lynx*. Any of five species of **cats** found in North America, related to the Canada lynx but of slightly smaller size. One species, also called the bobcat, is found in forested regions throughout the United States and southern Canada, and extends into Mexico. It is now confined to wilder areas. (A.W.L.)

WILDEBEEST. **Gnu.**

WILLANS LINE. A characteristic curve for the **steam turbine** is that of steam consumption per kilowatt-hour versus load in kilowatts. From this curve the Willans line, conveying information of great value, can be plotted. The Willans line shows total steam consumption at each load. In conjunction with the load curve it can be used to find total **steam** required per day or any other period of time. The steam-rate curve for all turbines will exhibit a node corresponding to the most efficient load. This point will be observed on the Willans line as a break on the nearly straight slopes on each side of it. This is the load point at which the first overload valve opens. The slope of the Willans line is a result of the combined effect of the various losses in the steam turbine.

For the sake of comparison with the ideal turbine, the Willans line of an ideal turbine is shown in line OC in the figure. The line OC', parallel to AB, would be the Willans line of a turbine having stage efficiencies less than those of the ideal turbine (100%) but, at the same time, having no no-load losses. The **steam rate** of such a turbine would be constant at all loads up to the most economical. The line AB represents the steam consumption of an actual turbine under specified operating conditions Practically all steam consumption curves are straight lines between the no-load and most economical loac

points. Above the most economical load performance varies. In general computers assume that the steam rate at full rated load is 5% greater than at the most



Willans line.

economical lqad, when the latter is about 80% of the rated load. The end point of the Willans line, F, is usually joined to B by a straight line unless the overload characteristics of the particular turbine are known. (F.T.M.)

WILLEMITE. The mineral willemite is an **ortho-silicate of zinc**, Zn_2SiO_4, occurring in **hexagonal** prisms, as masses or scattered grain. It has a good basal **cleavage**; conchoidal fracture; is brittle; hardness, 5.5; specific gravity, 3.9–4.2; subvitreous luster; usually some shade of yellow, yellowish-green, green, or reddish-brown, but may be colorless, white, or blue to nearly black; transparent to opaque. Much willemite is strongly fluorescent in yellow or yellowish-green hues. Willemite occurs associated with other zinc materials in Belgium, Algeria, the French Congo, South West Africa, and Greenland. In the United States, except for three occurrences, one in Colorado, one in New Mexico, and one in Utah, Sussex County, New Jersey, is the only locality in this country for willemite and is the only one in which that mineral is found in quantity. Here it is found associated with **zincite** and **franklinite**, forming an important ore of zinc. It was named by the French mineralogist, Michel Lévy, in honor of King William the First of the Netherlands. (E.S.C.S.)

WILLET. Aves, Charadriiformes. A North American wading bird, *Catoptrophorus semipalmatus*, long legged and with a long straight beak. They are mottled grayish above and white below. Closely related to the sandpipers. (A.W.L.)

WILLIOT DIAGRAM. A Williot diagram is a graphical representation (drawn to any convenient scale) of the relative movements of the **panel points** of a loaded planar **truss**. Longitudinal **deformation** of the truss members produces horizontal and vertical **deflections** of all **joints** except the end panel points which are restrained against movement in one or both of these directions. These longitudinal deformations are given by the formula:

$$e = \frac{PL}{AE}$$

in which e = Total deformation.
P = Total **stress**.
L = Length.
A = Cross-sectional area.
E = **Modulus of elasticity.**

If it were possible to draw a diagram of the deflected truss itself to scale, the relative position of the panel points could be found by plotting the truss as a series of connected triangles, using the deformed length of the members. Since the longitudinal deformations are small compared with the theoretical length of the unstressed members, such a diagram is not practical.

However, it is possible to represent the longitudinal deformations to scale in a diagram which will give the correct relative movement of the panel points. In this case one of the joints is assumed to be fixed in position and one of the members at the joint fixed in direction.

The undeformed shape of a symmetrical truss, symmetrically loaded, is shown in Fig. 1. The tension and

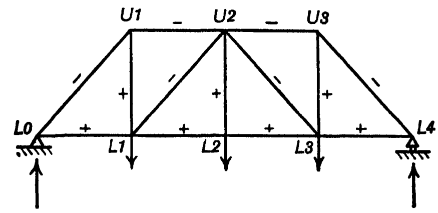


Fig. 1. Undeformed shape of a symmetrical truss, symmetrically loaded.

compression members are indicated by + and − signs respectively.

Fig. 2 shows a Williot diagram for this truss which is based on the correct assumption that U_2L_2 is vertical before and after loading. As a basis for plotting the deformations it is also assumed that one end of this member, L_2, is fixed with relation to the movement of all other panel points. Tensile deformations should be shown as acting away from the joint and compressive deformations toward the joint. The plotting is begun by establishing the joint L_2 at L_2'. The relative position U_2 is found by laying off the deformation of U_2L_2 to scale away from the joint in the assumed fixed direction of this member. The relative position of the third joint of the triangle $L_1L_2U_2$ is obtained by drawing the deformations of the members L_1U_2 and L_1L_2 from the points U_2' and L_2' respectively in the correct direction and parallel to these members in the unloaded truss. The intersection of perpendiculars from the end of these deformations locates the position of L_1 relative to U_2 and L_2 because joint L_1 in the loaded truss lies at the intersection of the deformed lengths of L_1U_2 and L_1L_2. The relative positions of the other joints are located in a similar manner. Since the truss is symmetrical in all respects, U_2L_2 will be vertical in the loaded truss and the diagram will give the correct relative and actual displacements. The relative displacement of any two joints is obtained by connecting the corresponding points with a straight line. The dash-dot line $L_0'L_1'$ indicates that joint L_1 has moved downward and to the right with respect to L_0. The vertical deflection of L_1 is the vertical projection of this line which is marked V_1 on the diagram. The horizontal movement of L_4, which is restrained against downward movement by the support, is the distance H_4. Because of symmetry it is not necessary to actually plot points U_3', L_3', and L_4'.

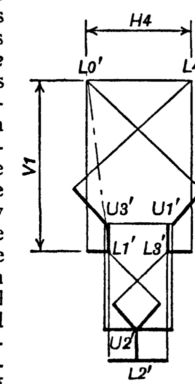

Fig. 2. Williot diagram for truss in Fig. 1.

The full lines of Fig. 3 show a Williot diagram based on the incorrect assumption that L_0L_1 is horizontal in the loaded structure. L_0 is the joint which was assumed to be fixed in position. Since L_1 does not lie on a horizontal line through L_0, it is necessary to apply a correction diagram called a Mohr correction diagram. The points U_1', L_1', etc., of Fig. 3 represent the position of the panel points of the loaded structure relative to the unloaded structure assuming L_0L_1 to be horizontal. To correct for the fact that L_4 is at the same elevation as L_0, the truss must be rotated. In rotating, each joint moves vertically a distance proportional to its horizontal distance from the fixed joint and horizontally

proportional to its vertical distance from this joint. Plotting these distances with their signs changed produces the truss shown by dash lines in Fig. 3. It should be noted that the correction diagram is similar

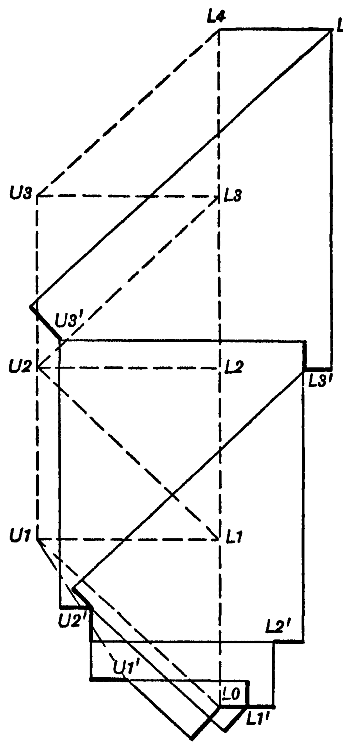

Fig. 3. Mohr correction diagram.

to the truss of Fig. 1 and the corresponding members are perpendicular. This similarity forms the practical basis for constructing the diagram. The vertical displacement of joint $L4$ in the Williot diagram is divided into as many parts as the lower chord of the real truss; then the remainder of the diagram can be constructed from similarity. The actual movement of any joint such as $U1$ is shown in direction and magnitude on the combined Williot-Mohr diagram by a dash-dot line joining $U1$ and $U1'$. In this case the diagram indicates that $U1$ has deflected downward and to the right. A Mohr correction diagram will always be necessary for any unsymmetrical truss with or without symmetrical loading. (C.W.C.)

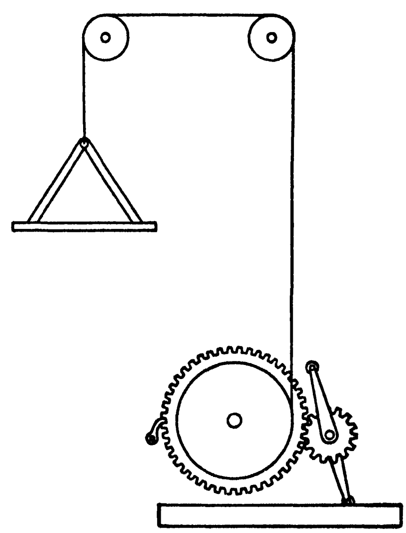
WILSON CHAMBER. Cloud Track.

WILSON EXPERIMENT. The theory of the electromagnetic field in dielectrics requires that if a dielectric move across a magnetic field, an electric polarization should be produced in it at right angles to the field and to the motion; just as in a conductor, likewise moved, electric induction is set up. The question was tested by H. A. Wilson in an experiment which has become classic. A hollow cylinder of dielectric material, coated on its inner and outer cylindrical surfaces with metal, was rotated about its axis in a magnetic field whose lines of force were parallel to the axis. The metal coatings were connected to a sensitive electrometer, which registered a charge, reversing with the reversal of the field, and having both the sign and the magnitude required by the theory. (L.D.W.)

WILTING. This phenomenon, observed most commonly in leaves, results from a complete or nearly complete loss of turgor by the cells. Drooping, rolling, or folding are the common external manifestations of the wilting of leaves. During hot summer days plants often wilt during the daylight hours only to regain their turgidity during the following night. This type of wilting is called *temporary wilting* and results from a daytime excess of the rate of transpiration over the rate of absorption of water from the soil. Even when the soil water supply is adequate the absorption rate often lags behind the transpiration rate if the latter is high, resulting in a gradual reduction in the water content of the plant and the accompanying phenomenon of wilting. During the night hours the absorption rate exceeds the usually low transpiration rate and the turgidity of the plant tissues is gradually restored. The other type of wilting is called *permanent wilting* and occurs only when the available soil water supply has been exhausted. Plants can recover from permanent wilting only when the soil water supply is replenished. Permanent wilting is of common occurrence in most kinds of plants whenever prolonged drought conditions prevail. Some kinds of plants can endure this condition for long periods without lethal effects, others will die within a few days or a few weeks if subjected to continuous permanent wilting. (B.S.M.)

WIMSHURST MACHINE. Static Machines.

WINCH. A mechanism arranged to hoist by manual or mechanical power through the medium of a rope, cable, etc., winding on a drum is a winch. The winch is provided with means for stepping up the torque obtainable and a brake for lowering the load. However, the brake is sometimes omitted in the simplest winches. The setup of a winch used for hoisting is shown in the accompanying figure. The hoisting rope passes up and



Winch.

over two sheaves, so that a load may be hoisted from a position adjacent to the winch. The hand power is applied at a crank or cranks, which are attached to a shaft bearing a pinion gear. This pinion engages with a large gear attached to the winding drum. On the winding drum there is a brake, generally of the band type, which is brought into play when a load is to be lowered. A high-capacity winch may have a double reduction gear, instead of the single gear illustrated. Winches are necessarily slow-moving, and they are not ordinarily economical for other than intermittent hoisting jobs. (F.T.M.)

WIND CORRECTION ANGLE. The angle between the **heading** of a plane and the **course** made good is known as the wind correction angle. The angle is always measured from the heading to the course and is named right (+) or left (−) to indicate the direction of drift. The signs permit of immediate algebraic addition of the wind correction angle to the heading to obtain the course being made good.

The wind correction angle must always be determined if a plane is to make good a specified course whenever there is a wind blowing. The method of determination is always graphical, either by actual drawing or by use of any one of the numerous types of **dead-reckoning computers**. The **vector** diagram constructed is similar to that used in graphical methods of **dead reckoning** and from the diagram not only the wind correction angle (WCA), but also the predicted ground speed (PGS) of the plane can be determined.

The procedure may best be described by consideration of a specific situation. A plane is to proceed to a point on rhumb-line bearing 105° distant 180 miles. The plane is to cruise at 130 knots and the wind is from 345° speed 25 knots. The pilot wishes to know the wind correction angle, the heading of the plane, and the estimated time of arrival (ETA). The velocity-vector diagram is shown in Fig. 1, which is constructed and

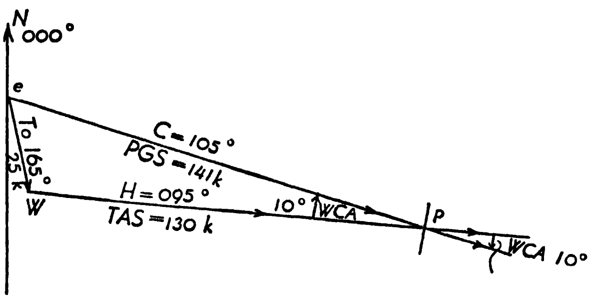


Fig. 1. Velocity-vector diagram for determining wind correction angle and predicted ground speed.

labelled in accordance with the standard procedure of U. S. Naval Aviation. From a point e a vector ew is drawn representing the velocity in which the wind is moving the plane. From e a line is drawn in the direction of the course to be made good. Then from w an arc is struck, using either dividers or a scale, with length equal to the true air speed of the plane (TAS). This arc cuts the course direction line in the point p. This completes the velocity-vector diagram with ep representing course to be made good and PGS, wp the heading and TAS, and the angle at p, measured from wp toward ep, representing WCA. Measurement with scale and protractor on the completed diagram gives PGS = 141 knots and WCA = 10° Right. Since, by definition H + WCA = C we have in this case H + 10° = 105° or H = 095°. Finally with PGS = 141 knots and distance to be made good 180 miles, we have an expected elapsed time of 1hr 17m for the flight. This interval added to the time of departure will give the ETA.

Throughout flight the navigator must keep careful watch with the **driftmeter** and if the drift is not equal to the predetermined wind correction angle, the wind must be determined and a new heading computed to make good the desired course. This procedure is illustrated under **Air Plot**. (W.K.G.)

WIND EQUATIONS. Many factors influence the movement of air in any quasi-horizontal plane at or above the surface of the earth. In the friction layer, frictional forces play an important role. Convergence and divergence also play their part in determining air flow. Isallobaric fields have some influence. But, in general, three major forces play the main roles in establishing the winds. They are:

1. The Coriolis or Deflective Force due to the earth's rotation which is given by $2\omega V\rho \sin\phi$.

2. The pressure gradient of the atmosphere which is given by $\frac{dp}{dx}$.

3. Centrifugal force due to curvature of path of air parcel, which is given by $\frac{V^2\rho}{r}$.

If air movement is unaccelerated, these three forces are the only factors involved in determining the wind. When other forces are active, accelerations and decelerations alter equilibrium conditions among the three principal forces. However, equilibrium conditions hold, except under the excessive influence of one or more of the minor forces, and winds are generally determined by the balance among the three main forces.

There are several cases possible for establishing a balance of forces among the three. The following are for the northern hemisphere.

Case 1. If the parcel of air is moving in a field of pressure which is higher at the center of the field than at the exterior, the pressure gradient is directed outward from the center. In this case, the flow is clockwise and the deflective or Coriolis Force balances the pressure gradient and the centrifugal force.

$$\underset{\left(\substack{\text{pressure}\\ \text{gradient}}\right)}{\frac{dp}{dx}} + \underset{\left(\substack{\text{centrifugal}\\ \text{force}}\right)}{\frac{V^2\rho}{r}} = \underset{\left(\substack{\text{Coriolis}\\ \text{force}}\right)}{2\omega\rho V \sin\phi}$$

where dp/dx = The pressure gradient.
V = The velocity of the parcel.
ρ (rho) = The density of the air.
ω (omega) = The angular velocity of the earth.
r = The radius of curvature of the parcel's path.
ϕ (phi) = The latitude.

Solving for this equation we obtain:

$$V = r\omega \sin\phi \pm \sqrt{(r\omega \sin\phi)^2 - \frac{r}{\rho}\frac{dp}{dx}}.$$

But $v = 0$ when $\frac{dp}{dx} = 0$, and we have

$$V = r\omega \sin\phi - \sqrt{(r\omega \sin\phi)^2 - \frac{r}{\rho}\frac{dp}{dx}}.$$

It is not possible to give meaning in this case to a negative value for the radical, therefore, the quantity under the radical must always be positive. This places a limiting value in wind velocity in a clockwise or anticyclonic system of winds which is given by the value of zero for the quantity under the radical.

We then have

$$V_{\max} = r\omega \sin\phi.$$

For a given latitude the quantity $\omega \sin\phi$ becomes fixed and $V_{\max}/r$ is constant. At the equator the quantity ($\sin\phi$) becomes zero and the velocity also becomes zero. Anticyclonic winds at the equator, therefore, are not possible.

For a given pressure gradient, the velocity of an anticyclonic wind increases toward the center of the system until the critical value of velocity is reached.

Case 2. If the parcel of air is moving in a field of pressure such that the pressure is less at the center than the exterior, the pressure gradient is directed inward toward the center. In this case, the flow is counterclockwise and the pressure gradient balances the deflective force and the centrifugal force.

$$\frac{dp}{dx} = \frac{V^2\rho}{r} + 2\omega\rho V \sin\phi.$$

The solution to this equation is

$$V = \pm\sqrt{(r\omega \sin\phi)^2 + \frac{r}{\rho}\frac{dp}{dx}} - r\omega \sin\phi.$$

Again, when $\frac{dp}{dx} = 0$, $V = 0$ and the + sign before the radical is necessary.

$$V = \sqrt{(r\omega \sin \phi)^2 + \frac{r}{\rho}\frac{dp}{dx}} - r\omega \sin \phi.$$

The quantity under the radical is always positive so there can be no limiting value on the velocity. At the equator, where sin ϕ is zero, the pressure gradient is still present under the radical to give the velocity a positive value. Winds blowing under these conditions are known as cyclonic winds and include both tropical and wave cyclones as the main types.

Case 3. If the flow of air is in a straight line, the centrifugal-force term drops out and the balance of forces is between the pressure gradient and the deflective force only.

$$\frac{dp}{dx} = 2\,\omega\rho V \sin \phi.$$

$$V = \frac{dp/dx}{2\,\omega\rho \sin \phi}.$$

This wind is known as the geostrophic wind in contrast to Cases 1 and 2, which are gradient wind cases. Geostrophic winds increase southward for a given pressure gradient and theoretically become infinitely great at the equator where the denominator becomes zero. They are directly proportional to the pressure gradient at any given latitude.

Case 4. At the equator where the deflective force drops out entirely, a balance between the pressure gradient and centrifugal force is possible.

$$\frac{\rho V^2}{r} = \frac{dp}{dx}.$$

$$V = \sqrt{\frac{r}{\rho}\frac{dp}{dx}}.$$

Winds of this type are cyclostrophic winds and blow cyclonically or counterclockwise about a center of low pressure. Hurricanes are the best example of cyclostrophic winds and, even though they develop and migrate from the equatorial zone, the deflective force plays no significant role until the center is considerably removed from low latitudes.

In the southern hemisphere, wind relations are the mirror image of the northern hemisphere, i.e., they blow counterclockwise about centers of high pressure, clockwise about centers of low pressure, and with high pressure to the left. (P.E.K.)

WIND GAP. Gap.

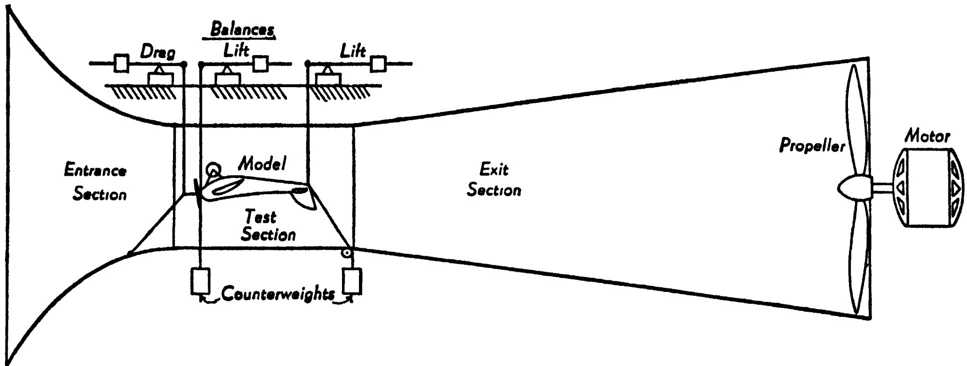
WIND INDICATOR. A device that indicates direction and/or velocity of the surface wind. Examples: Wind "sock," swivelling wind tee, smoke pot, weather vane, anemometer. The wind sock, or cone, is a tapered fabric sleeve pivoted on a standard. When exposed to a wind stream it "weathervanes" to point the wind direction. Being large and bright colored, it is easily observed from aircraft, and gives needed information to the pilot planning a landing in the vicinity. The small end is usually unsupported, other than by the wind, hence a rough indication of the magnitude as well as direction of the wind, is afforded by the cone, since it will be limp in calm air, and partially so in light winds. (F.T.M.)

WIND ROSE. Any diagram showing features of wind direction and velocity in the form of a hub, with spokes of a wheel representing direction or velocity values or both. The most common wind rose is one in which the length of the spokes of the wheel extending into the cardinal directions represents the frequency of winds from that direction. Wind roses are used primarily in climatology to show the wind features of a particular area. (P.E.K.)

WIND TUNNEL. Aerodynamic data upon which are founded the rational design of heavier-than-air craft, are obtained in large measure from tests made by blowing air past a stationary model which is supported so that the air forces acting on it may be measured. The conduit which contains and directs the air across the model, together with the auxiliaries required for its operation, is known as a wind tunnel. The auxiliaries mentioned are a **blower** or **propeller,** a return duct, a honeycomb, and corner vanes. Besides heavier-than-air research, the wind tunnel is used to obtain data on **airship** hulls, automobile shapes, and other cases where air reactions are important. Theoretically, the reaction of air upon any shape or object is the same, whether the object be moving through still air, or whether the object is at rest, and the air moving past it. Actually, however, there are some differences, arising largely from the fact that the air in a wind tunnel has a certain degree of **turbulence** not present in a calm atmosphere. Furthermore, model tests may not be applied directly to full-scale designs without certain corrections. Chief among these is the scale correction. The relative size of a molecule of air and a wind tunnel model is much different than the relative size of a molecule of air and the actual airplane. The fact that molecular density against the airfoil is not in proportion in the model introduces the scale effect. If a model test were to yield lift and drag coefficients which could be used directly in airplane design, the scale effect would have to be absent. Scale is usually measured by **Reynolds number.** This criterion shows that either the velocity in the wind tunnel must be vastly increased, or the model must be as large as the actual airplane, in order to get the same scale. If the model is one-tenth actual size, the velocity would have to be ten times actual flying velocity. As this is impracticable, models have been tested at lower scales than **airplanes** operate, and corrections for scale have had to be applied. Considerable knowledge as to the magnitude of scale effect, and means for correcting it, have been devised from tests in a variable density wind tunnel. This special type is arranged so that compressed air having pressure of several atmospheres, and a corresponding high density, can be blown over the model. The advantage here is that by increasing the density of air sufficiently, a small model may be tested at reasonable tunnel velocities, and yet have the Reynolds number of a magnitude comparable to that of a full-sized airplane. Besides scale and turbulence, corrections must be made for shape of the wind tunnel walls, tunnel wall interference, and aspect ratio.

The wind tunnel is used to measure the drag of all sorts of objects, particularly components of aircraft, and to measure the drag and lift forces of complete model aircraft. It is also employed to test for stability and balance of the same. The principal classifications of tunnels are once-through and return-circuit types. Another classification is open or closed test section. The air is usually blown by a propeller driven by a variable speed electric motor. The models most frequently tested are those having a wing span varying from 2–3′. This means that the tunnel must have a 30–50″ width at the test section. However, tunnels are built in a variety of sizes, ranging anywhere from 6″ to 60′ at the throat.

Ordinarily, a tunnel has a nozzle to give something like constant acceleration to the air, and direct it into the test section, which is a constant area section in which the models are mounted. Passing the test section, the tunnel is slowly enlarged in order to recover the pressure head. In a once-through tunnel, the propeller is mounted at the end of the diverging section. In a return-circuit tunnel it may be mounted there or in the



Simple wind tunnel.

return circuit. The materials from which tunnels have been constructed are wood, plaster, concrete, and steel. The sections employed have been circular, octagonal, hexagonal, square, and rectangular. The models are supported from a balance, which can be of a suspension wire type (Goettingen), or a rigid post-like support (National Physical Laboratory). In either case the purpose of the balance is to maintain the model in a predetermined attitude with respect to the wind stream, and quantitatively measure the air forces which arise therefrom.

The "atmospheric" wind tunnel illustrates most of the foregoing remarks. Varied tests of great value are performed in tunnels of this character upon solid models held by the balances in a horizontal airstream. Unfortunately this fails to cover all the needed testing and research and other designs of tunnels are required.

Pressure Tunnels. Closed-throat tunnels when made air-tight and structurally strong enough to contain air above atmospheric pressure are used in research when Reynolds number and viscosity effects are important since the increase of mass density accentuates the viscosity effects.

Vertical Tunnels. Generally these are atmospheric but having upwardly directed air jets. They are most frequently employed to test airplane spinning characteristics. The model is a replica of the prototype, being similar not only in shape but also in mass disposal. It is launched into the vertical jet and spins freely if a light-weight flying model is used, or it is mounted free to spin on a post if the model is heavy. The light-weight models are effective in discovering the spin recovery properties produced by the control surfaces.

Other special purpose tunnels are (a) smoke tunnels for visualizing air flows at low speeds, (b) supersonic tunnels for compressibility effects, (c) refrigerated and altitude tunnels for test work on engines and aircraft auxiliaries.

With the increasing size and speed of the modern airplane, two tendencies have appeared in wind tunnel construction. One has been the tendency to increase of the working section, with a maximum width of 80′, so that full-scale airplanes can be tested in the aerodynamic laboratory. The other has been in the increase of working speeds, with speeds running as high as 600 m.p.h. so that compressibility effects can be adequately investigated. The Mach number, which is the ratio of the tunnel speed to the speed of sound, is now as important as the Reynolds number. (F.T.M.)

WIND VANE. Meteorological Instruments.

WINDHOVER. Falcon.

WINDMILL. Any arrangement of sails or blades which will turn the shaft to which they are attached when exposed to a wind may be called a windmill. The practical use of the windmill is to obtain for local use some of the energy represented by atmospheric motion.

Power from the winds has served man for many centuries, but the total amount of energy generated in this manner is small. While the expense of installation and the uncertainty of operation have prevented serious consideration of the windmill for other than such intermittent services as pumping, there has been considerable experimentation relative to the generation of electrical energy by moderate-sized wheels for charging storage batteries. 35-volt third-brush generators which may be set to produce maximum charge at the best wheel speed have been proposed for farm lighting plants. A 15-ft. American type wheel has, under test, produced an average of 2.5 kw-hr. per day.

There are four well-differentiated types of windmills, viz.:

1. The multi-bladed turbine wheel, or American type.
2. The Dutch type.
3. The propeller-type high-speed wheel.
4. The rotor.

The American type was given its name in Europe to distinguish it from the Dutch type. Its wheel is kept into the wind by a tail or rudder. The regulation in high winds is usually accomplished by automatic devices which swing the wheel out of the wind when it becomes excessive.

Although its large 4-sailed wheel is efficient, the Dutch type, being difficult to regulate and operate, and having a higher first cost, has been used mainly in its place of origin, the Low Countries of Europe. The rpm is lower than the American wheel, but the tip speed is relatively higher because of the length of the sails. Regulation is accomplished by turning the movable top of the tower into the wind.

Developed during World War I, for aircraft generator drive, the propeller type of windmill has possibilities of development into a convenient source of motive power for farm electric systems. It is inherently a high-speed wheel enabling the generator to be coupled directly to its shaft. Regulation can be accomplished by adjusting the pitch of the blades.

The most recently perfected mechanism for obtaining energy from the winds is the rotor. The phenomenon which causes a rapidly rotating baseball or tennis ball to take a curved path was first investigated by Professor Magnus and has been named the Magnus effect. The industrial application of this was successfully accomplished by Flettner in his rotorship.

The characteristics of the rotor windmill are:

1. Ability to start in very low winds.
2. With constant rotor rpm the wheel is automatically regulated, since an increase in wind speed above the designed condition leaves the rotative force on the rotor unchanged unless the rpm of the rotor also increases.
3. After the designed value of wind velocity is exceeded, the delivered power remains a constant.

4. The rotor remains, along its entire length, in the most favorable position relative to the direction of the wind.

Turbine windmills for pumping have become more or less standardized in form and design and are usually rated in terms of the gallons per hour they will lift through various heights. The design of the wind wheel for electric generation is susceptible of much greater perfection since the starting torque is small and the running torque is uniform throughout the revolution, resulting in constant wheel velocity in a wind of constant velocity.

The kinetic energy in a mass M' of air moving at a velocity V is $\frac{1}{2}M'V^2$. For a wheel of diameter D, $M' = kD^2V$, in which k is a constant. The power represented in a wind of velocity V flowing through an area included by a wheel of diameter D is:

$$P = kD^2V^3.$$

This equation shows that the power of a windmill is proportional to the cube of the wind velocity and the square of the wheel diameter. Using 0.0763 lb. as the weight of 1 cu. ft. of air, it can be shown that the theoretical wind hp. is:

$$\text{Hp.} = 5.36 \times 10^{-6}D^2V^3$$

Hp. = the theoretical wind hp.
D = the wheel diameter in ft.
V = the wind velocity in m.p.h.

The power actually developed will be but a fraction of this wind hp.—about 10% for the American type wheel, and 20% for the Dutch type. The ability of a wheel to start in light winds is an unquestioned advantage.

The starting torque, and therefore the wind speed at which the wheel will start, is largely determined by the blade angle; the greater its pitch, the greater the starting torque, but the lower the running speed. This means a heavier wheel for the same hp. than one designed to start at a higher value of wind velocity. An adjustment must be made between cost of construction and percentage of time in service. The velocity duration for a station 100′ above ground is very little higher in value than that for the 50-ft. point; however, it must be remembered that the wind hp. increases as the cube of the velocity and an increase from 10 to 12 m.p.h. is equivalent to a 73% increase in power. (F.T.M.)

WINDOW PANE. **Turbot.**

WINDPIPE. The **trachea,** in the **respiratory system** of air-breathing vertebrates. (A.W.L.)

WINDS. Since only slight horizontal variations in the density of the air can occur ordinarily, and the total volume of the atmosphere is substantially constant, it is evident that a wind is necessarily a circulation; that is, any movement of the air in one direction must be offset by a return current elsewhere. All such movements are the result of **thermal convection** due to the heat of the sun.

The winds may be roughly classified into three types: 1. Winds which are in a sense permanent, including the easterly trade winds of the tropics and the westerly winds prevailing in the temperature zones. 2. Seasonal winds, such as the monsoons of the Indian ocean, which blow northward toward the warm Asiatic continent in summer, bringing heavy rainfall to India, and which pour southward over the Himalayas from the cold plateaus in winter. (To such may be added the diurnal land and sea breezes, which have similar origin but on a much smaller scale.) 3. Local winds and storms, which temporarily interrupt the more general air movements prevailing at the time. Among these are the great **cyclones** and **anticyclones** characteristic of North American climate, ocean cyclones (including hurricanes or typhoons), **thunderstorms, tornadoes,** waterspouts or ocean tornadoes, chinooks, and the very cold mistrals and blizzards. These local winds are all of the vortex type. The cyclone, for example, is generated over a large, heated land area, where the air is warmed to lower than average density. Air accordingly moves inward along the ground, rises in the central region, and returns outward at high altitudes; the movement being given at the same time a rotary character because of the deflection of the air masses by the rotation of the earth (producing a counter-clockwise whirl in the northern hemisphere, clockwise in the southern). The cyclones of the United States are carried in a northeasterly direction by the prevailing north-temperate westerlies, so that weather conditions experienced, say, in Iowa one day may be looked for in Wisconsin the next. The same is true of the anticyclones formed over cold areas, but with high pressure and with the direction of the local air currents reversed. Hurricanes, tornadoes, waterspouts, etc., are similarly formed but in varying circumstances and on different scales.

The winds are practically all confined to a very few miles vertically above the earth's surface. Above this lies the **stratosphere,** believed to be a region of almost perpetual calm. (See **Atmosphere.**) Air currents at high altitudes are commonly studied by means of small pilot balloons, released for the purpose and watched through telescopes. (L.D.W.)

WING. For the use of this term in aeronautics, see **Wing, Airplane.** In zoology, a wing is a broad thin appendage used to support the animal in the air, either through its resistance to air currents or by muscular movement against the air. The support may be accompanied by the progress called **flight** or may sustain the animal in one spot. The latter action is called hovering.

Wings and flight have been developed in only four groups of animals: the extinct pterosaurs, a group of **reptiles;** the **insects;** the **birds;** and the **bats,** an order of mammals. Other animals progress through the air to a limited extent, but they merely coast, supported by extended surfaces of various kinds; this form of locomotion is known as gliding and is considered with flight.

Only the insects have developed wings independent of their other appendages. In this class there are two pairs at the maximum, attached dorsolaterally to the second and third segments of the thorax. They are developed as saclike outgrowths of the body wall whose upper and lower walls become closely apposed and relatively very thin to form a light membrane. Some rigidity is conferred by the cuticula of the wing membrane and additional support is provided by thick-walled tubes called veins or nervures running through the structure. The principal veins follow the courses of tracheae which are functional during the developmental stages, but others of a supplementary nature may be present. The number and arrangement of the veins have been of the greatest importance in the classification of the insects.

Insect wings are modified in some orders beyond the changes of shape, venation, texture, and vestiture which do not interfere with their use in flight. Examples are the **elytra** of beetles, the **tegmina** of grasshoppers, and the **halteres** of flies.

The wings of bats are thin folds of skin extending between elongated digits of the front legs, along the sides of the body to the hind legs, and in some species thence to the tail. They are admirably adapted to flight but they have the one great weakness of presenting a greatly extended surface from which the radiation of heat may take place, hence the activities of bats are limited to warmer climates and warmer seasons of temperate regions. The **pterodactyls** had similar wings, but the problem of radiation was not the same to them since they were presumably cold-blooded.

The wings of birds, like those of bats and pterodactyls, are supported by the skeleton of the pectoral appendages. In this group, however, they are no more

than modified pectoral appendages. The extended surface of the bird's wing is made up of large stiff feathers and the supporting skeleton is reduced in size and complexity. The resulting advantage in the lightness of the wings and in their presenting no radiating surface greatly extends the radius of activity of birds. No climate is too cold for them, and no season too severe. They are among the most widely distributed of all living things.

The wings of bats retain short clawed appendages on the anterior margin, but those of birds are wholly transformed into organs of flight except in the young **hoatzin,** which uses similar clawed digits in climbing. The only other noteworthy modification of birds' wings is found in the **penguins,** where they are small paddles with greatly reduced feathers, useless for flight but effectively developed for swimming. Reduction to a vestigial state has also occurred in various flightless species, such as the **ostrich** and the **kiwis.** (A.W.L.)

WING, AIRPLANE. Wing is a general term applied to the airfoil, or one of the airfoils, designed to develop a major part of the lift of an airplane. An airfoil is an aerodynamic shape which yields useful lift for the price of relatively small drag. An airplane wing is an airfoil whose lifting power is utilized to make flight possible. The reader is referred to **airfoil** for wing aerodynamics.

The most common wing arrangements are biplane and monoplane. The biplane was once the principal type, but now airplanes usually have monoplane wings.

The wing is composed of a surface, of members supporting that surface in the external shape of the desired airfoil, and of an underlying structural framework which receives the air reactions from the above-mentioned components and transmits the lift to the fuselage, nacelle, etc. Typical construction of a light airplane wing is shown in Fig. 1. The load-carrying structure consists of two

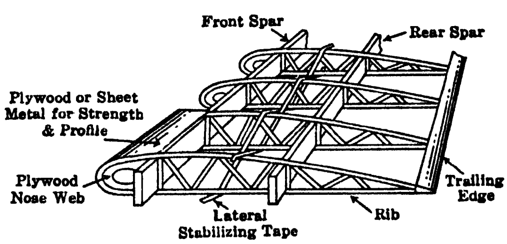


Fig. 1. Simple wing structure.

spars to which ribs are fastened at intervals of about 1′. The ribs form the profile of the airfoil desired. In stressed metal skin types, the ribs and attached skin and the stiffeners (see Fig. 3) provide for stiffness and rigidity, while the spars, webs, and stiffeners take the bending load.

The forward edge or "nose" section of a fabric-covered wing is usually strengthened with sheet metal or plywood because here the unit air forces are greatest; also here it is most necessary to maintain the true airfoil profile. The fabric is stretched over the ribs and sewed firmly to each. Upon application of the fabric finish (airplane "dope") the fabric shrinks to a taut, smooth wing-covering. Air reactions on this surface are transmitted to the numerous ribs, and from the ribs to the spars. This structure requires internal support against drag forces in the plane of the spars. If the spars are not cantelevered from rigid root fittings, external struts or wires must support the spars. The **wing truss** therefore must be duplex in character, carrying both normal and chord loads.

Spars are constructed of wood and of metal. Usually wood is preferred for small and medium airplanes, while aluminum alloy in the form of drawn shapes, tubes, corrugations, etc., is used for the built-up spars of the larger airplanes. Some typical spar cross-sections are shown in Fig. 2. Ribs are (1) built up from spruce strips by gluing and nailing, (2) stamped one-piece from metal sheet, (3) built up of metal shapes by riveting

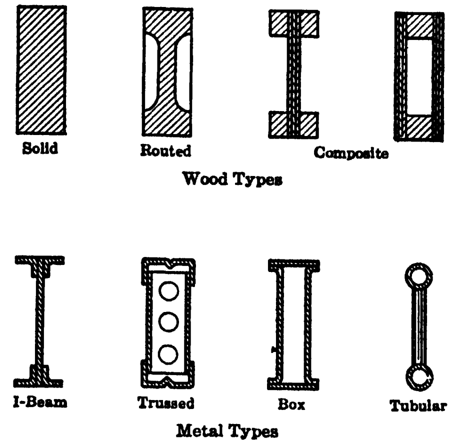

Fig. 2. Typical wing spar sections.

or welding. Fabric covering is limited to smaller airplanes. Aluminum alloy sheet such as 24ST, or plywood, is preferred for covering large wings. Although fabric does nothing except provide an airfoil profile, a plywood or sheet metal skin may be counted on to carry tensile, compressive and shear loads. The "stressed-skin" construction is lighter than flexible two-spar construction for large wings. A stressed-skin wing may employ the skin to resist torsion and the internal structure consisting of spars, shear webs, corrugated sheet, etc., to resist bending and shear.

The light-plane wing is occasionally a simple structure, similar to Fig. 1, with constant chord and profile, containing, internally, only wing structure and aileron controls. In contrast, the wing of the large multi-engined airplane is not only structurally more complex, but may also be required to provide space and fittings for some or all of the following:

1. Power cell assembly, consisting of engine mount, nacelle, cowling, controls, fuel, and oil supply.
2. Landing gear, retraction mechanism, wheel wells.
3. Flaps and control.
4. De-icer inflation air tubing.
5. Fuel tanks and piping.
6. Fire-extinguishing equipment.
7. Emergency "ditching" equipment (life rafts, etc.) and automatic release for same.
8. Electrical equipment. Position and landing lights, flap and wheel position indicators, etc.
9. Military equipment—guns, bomb and rocket racks.
10. Miscellaneous equipment such as Venturis, engine and propeller control and instrument leads, air scoops and ducts.

These large wings are tapered to secure aerodynamic advantage and the **airfoil classification** is frequently

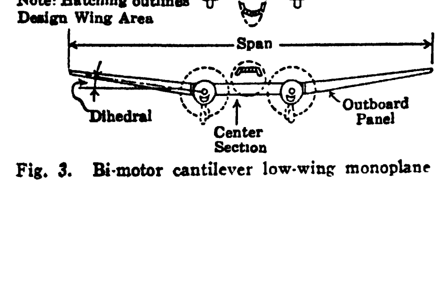

Fig. 3. Bi-motor cantilever low-wing monoplane

different at the root and tip because the taper in thickness is not the same as the taper in chord. The wing is often built with allowance for twist due to torsion load, so that in flight all sections will be at the angle of attack for maximum efficiency (or for maximum lift) at the same time. It is apparent from the materials and construction of a wing that it is an elastic structure. Wing flutter may occur and build up to hazardous magnitude if torsional rigidity is insufficient. While this might occur in the tip overhang of an externally braced wing, it is more common in the all-metal cantilever wing. The wing may flutter in bending as a result of the inertia moment of the aileron about its hinge and the play or elasticity of the aileron control system, or it may flutter torsionally.

Wing oscillations in torsion are far more serious than in bending since torsional deformation increases the angle of attack, the lift, and hence the torsional moment. Ailerons are purposely built as light as possible to prevent bending flutter, often being fabric-covered, whereas the remainder of the wing is all metal. Stressed-skin construction has the advantage of high torsional rigidity, and this is, indeed, an outstanding virtue of the all-metal wing. (See **Wing Truss, Wing Stress Analysis, Wing Area, Airfoil, Airplane, Aspect Ratio, Chord, Controls, Airplane Flight, Dihedral, Equivalent Monoplane, Flap, Monoplane, Tab.**) (F.T.M.)

WING AREA. The only area of an airplane wing to have been officially specified is the "design wing area." This is the area enclosed by the projection of the wing outline, including ailerons and flaps, but ignoring fairings and fillets, on a surface containing the wing chords. The outline is assumed to extend through nacelles and through the fuselage to the plane of symmetry. (See **Wing, Airplane.**) (F.T.M.)

WING SPAN. Maximum distance measured parallel to lateral axis from tip to tip of airfoil of an airplane wing inclusive of ailerons, or of a stabilizer inclusive of elevator.

Effective. True span of wing less corrections for tip loss. (F.T.M.)

WING STRESS ANALYSIS. Of all structural designs, none presents more difficult problems of analysis, nor requires as perfect a design, as that of the airplane structure. In that structure the *wing* analysis involves the greatest variety of problems. The nature of aviation causes an airplane structure to receive large increments of dynamic load, sometimes attaining two or three times the static loading. Intentional acrobatics may extend the dynamic load even more. The reader is referred to **load factor** for description of dynamic load determination. When the load on and size of the wing have been fixed by aerodynamics, structural design must follow with a wing design that has adequate strength to meet the contemplated load factor, but which has no surplus strength or unnecessary weight.

Air loads received from the ribs are conveyed at close intervals to the spars. The rib spacing is small and the air load is usually assumed to be a running load on the spars, being first resolved into *beam* and *chord* components. Structural analysis must be made for all or parts of the airplane for each of several critical flight conditions, each of which results in the imposition on the wing of a different air reaction and center of pressure. Typical of these critical load conditions are: (1) encountering vertical air gusts while flying horizontally at maximum speed (see **Bump**), (2) inverted flight, (3) maneuvering at gliding speeds in excess of maximum level speed. The following discussion will outline the problems involved without entering into detailed structural theories.

Trussed Wing. A 2-spar wing supported by a lift truss and made rigid by a drag truss offers the least complication in design since, mostly, it is solvable by the methods of statical mechanics and simple structural theory. The wing truss has axial compression or tension in all members except the spars themselves.

The beam component of air reaction is apportioned between front and rear spar by decomposition from the center of pressure position. The spar is considered to receive a distributed air load, the spanwise variation of which must have been determined by airfoil aerodynamics. As is shown in Fig. 1, this results in reactions at

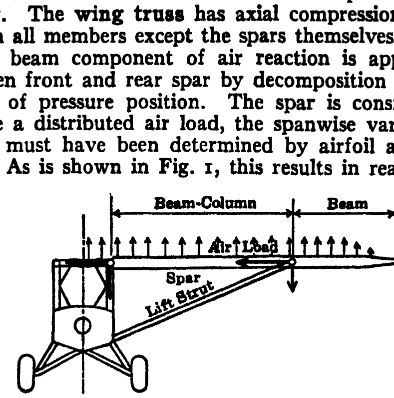

Fig. 1. Loads in the lift truss.

the root fitting and outboard strut fitting. Since the strut is inclined to the spar, it not only supports the beam reactions, but places the spar under compression. Therefore, although the other members of the lift truss have axial loads only, the spar is a **beam-column** and must be analyzed by methods too complicated to admit of inclusion here. Basic formulae were worked out for beam-columns by Müller-Breslau and Berry.

The chord component loads the drag truss which consists of the spars, compression struts, and wire braces arranged in the form of a Warren truss with the spars for chords. If the lift truss strut is not in the plane of the beam component, it will produce a chordwise component to load the drag truss. The average spar compression produced by the drag truss must be included with compression introduced by the lift strut in the beam-column analysis.

Stressed Skin Wing. Wing structures which stress the skin are found in a variety of forms, with different analytical approaches indicated for different wing types. A fairly common design is the box beam shown in Fig. 2

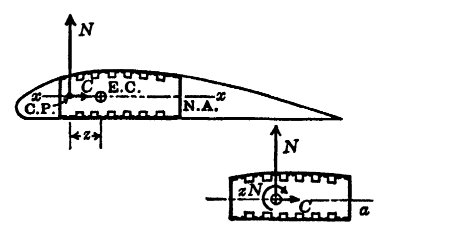

Fig. 2. Box beam with stressed-skin flanges. Bending and torsion loading separated.

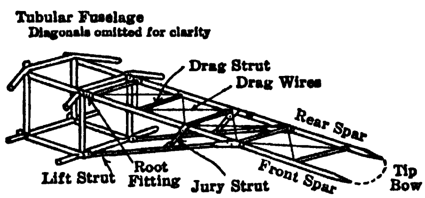
Here the wing is shown to be composed of a skin reinforced laterally with "hat section" stiffeners. Ribs stiffen transversely and establish the airfoil profile. Two (several in some wings) shear webs extend from upper to lower surfaces and, together with the reinforced skin between them, form a box beam of considerable torsional rigidity. This beam is considered to resist bending caused by the components of air reaction N (normal or beam component) and C (chord component). Since N acts through an aerodynamic center of pressure, it introduces a twist. To separate bending and torsion, N is moved to the elastic center $E.\ C.$ of the beam by introducing a torsional moment or torque zN. The elastic center is that point on the neutral axis about which the sum of the first moments of elementary moments of inertia of the beam material is zero, i.e., where $\Sigma x I_{ee} = 0$. The principal axes of bending through $E.\ C.$ may not coincide with the direction of N and C, but usually are near enough to be so considered. However, in cases of considerable unbalance of distribution of flange material

horizontally it may be necessary to find the angle of the principal axes to XX, and resolve the bending moments normal to these new axes before computing the bending stress. The torsion produces a shearing stress which can be analyzed by treating the box beam as a shell in torsion from torque zN. The nose section of the wing may contribute appreciably to torsional rigidity and, if so, the torsional analysis is that of connected shells, treatment of which is beyond the present scope, but may be found in texts devoted to aircraft structural design. The flange material of the box beam is thus seen to be in combined shear (from torsion) and compression or tension (from bending). The resulting stress must be determined by some of the analytical or graphical methods of combining stresses, such as the Culmann Circle of Stress. (F.T.M.)

WING TRUSS. A wing which obtains rigidity by truss action is said to be trussed. The resultant air reaction on an **airfoil** is inclined to the plane of the chord, hence two truss systems are necessary—a lift truss and a drag truss. The lift truss is composed of the spar and external bracing in a plane normal to the wing chord, or approximately so. The drag truss is in the plane of the spars. The high-wing monoplane used for illustration has a lift strut connecting an outboard point on the spar



Diagrammatic view of trussed wing.

with the lower fuselage longeron. During flight this strut is in tension. The stress changes to compression when air lift ceases and dead weight of the wing is supported by the truss. The strut is a long slender column and hard landings may impose critical compression stresses on it. It is strengthened by a jury strut which serves to reduce the unsupported length. The spar is in combined compression and bending.

The drag truss system consists of compression struts (sometimes extra heavy "bulkhead" ribs are used) which divide the plane of the spars into "bays." Each bay is crossed with drag wires and counter wires which absorb the shear of the chord component of air reaction. At high angle of attack the character of this shear may reverse, hence the need for counter-diagonals. In stressed-skin designs, no drag truss is needed. (F.T.M.)

WING WALL. **Abutment.**

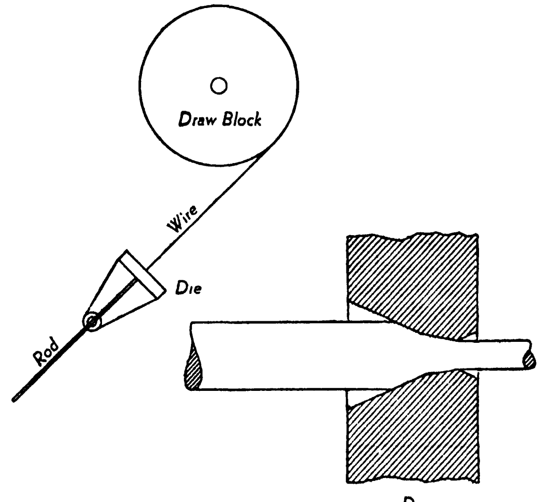
WINTER EGG. A form of egg produced by some invertebrates, usually in the fall. It has a thick protective shell and in species with a complex life cycle, such as the **aphids**, it is produced by the sexual generation. Such eggs usually pass through the winter before hatching, but similar eggs may be produced at the beginning of other unfavorable seasons, as periods of drought. (A.W.L.)

WINTERGREEN. **Heath Family.**

WIRE. A wire is defined as a slender rod or filament of drawn metal. If covered with electrical **insulation**, it is called insulated wire. There are manifold uses of wire in the present day and time. Among the more important uses are fencing, woven and barbed type; binding of extra strong nature for heavy packages; spring stock; ropes and hawsers; electrical **conductors** or **resistors**; and stock for forming various small light-weight parts, such as mouse traps, egg beaters, triggers, latches, etc. The materials from which wires are drawn are wrought iron, steel, annealed copper, aluminum, and phosphor bronze. Wires are sized by the areas in circular mills or American wire gauge. (See **Gauge.**) Despite the arguments in favor of one system using the diameters in mills as the size numbers, the American wire gauge is commonly used in gauge numbers from 40 to 0000. Descending gauge numbers indicate increasing wire sizes. Electrical conductor is usually annealed copper wire, although aluminum is used for transmission lines, and iron for resistance wires. Most low-voltage electrical conductors are insulated. Rubber compound and varnished cambric are the principal materials for insulating wires. The standardizing agency in the field of electric wiring is the National Electric Code. (F.T.M.)

WIRE DRAWING. The term "wire drawing" has two separate and distinct meanings. First, it is descriptive of the action whereby a rod is reduced to a wire by being pulled forcibly through a round die which reduces its diameter and increases its length (see figure). Secondly, wire drawing refers to a similar action occurring in fluid flow through a small aperture. The usage in the second case is derived from the first. Wire drawing as applied to a **fluid** is usually employed in discussions of the flow of **steam** or **gas** through the **valves** of engines. When the valves are partially open, the small area through which a fluid flows causes a reduction of pressure which is known as wire drawing. The description below refers entirely to the production of wires.

To make a wire, the metal is first prepared as a rod by rolling. It is then treated to give it a surface coating



Wire drawing.

which will act as a lubricant during its passage through the die. The method of applying the lubricant gives rise to the wet and dry process of wire drawing. In the dry process the wire is dipped in an emulsion of hydrated lime (see **Calcium**), and dried in baking ovens Then just before it is passed into the die it passes through a greasing operation. The combination of lime film and grease provides the lubricant between the rod and the die during the drawing process. In the wet process the rod is first dipped in a solution of copper sulfate, which results in a thin coating of copper in the wire. It is then dipped in a vat containing a fermented mixture made from meal and yeast. Upon being withdrawn from this vat, it is fed wet to the die. The liquor, together with the thin copper deposited in the salt bath, lubricates the rod in the wet drawing process.

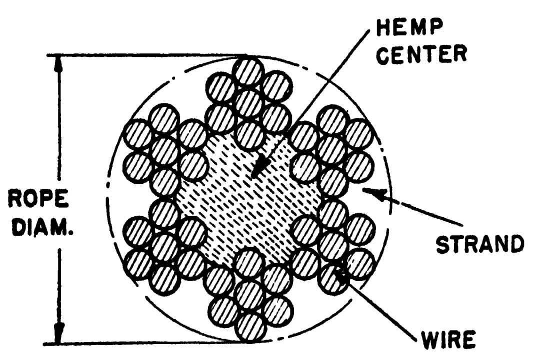
Drawing consists of pointing the rod and threading it through the die. It is then gripped by pinchers and drawn a short distance by hand power applied through

a draw bar. Then the end is clamped in a vise on a revolving drum called the drawblock. This drum is revolved slowly by power applied through a geared shaft, and in so revolving continues to pull the wire through the die until the rod has been completely reduced. When the stock is passed through the die it is elongated and reduced in cross-section. The elongation is known as draft, and may amount to from 10 to 40 times the length of the original rod. Sometimes more than one draft is necessary to finish the wire. In such cases it is removed from the block and started through another smaller die.

The dies are the most essential part of wire drawing. They are made of chilled cast iron, steel, cemented carbides, or diamond. The hard cemented carbide type dies are widely used. Diamond dies are used only for fine wire. A typical cross-section of a die is shown in the figure. The hole through the die is tapered, and the part where the reduction in wire size occurs is reamed to a very smooth finish. Two tapers are employed, one in which most of the reduction takes place, the other one of smaller taper, in order to ease the wire down to the exact size at exit from the die. The initial part of the tapered hole is not machined, as it serves only as a region for application of the lubricant to the rod. A plan of a draw bench which is the production unit in wire drawing, is also given. (F.T.M.)

WIRE ROPE. Wire rope is in wide use for hoisting and haulage, and for static loads, such as guy and supporting wires for stacks, masts, and towers. Wire rope consists of cold-drawn steel wires wrapped into strands and twisted around a hemp center or core saturated with lubricant. Commercial wire rope is obtainable in several grades of steel, referred to as cast steel, plow steel, and extra-high-strength steel. Rope made of aluminum, bronze, and stainless steel wire is also available. Rope with wires fabricated from cast steel is used for ordinary service; plow steel, high-strength or improved plow steel, or extra-high-strength steel ropes are used for high degrees of security and severe service conditions. In preformed wire rope, the strands are given their helical shape in the process of manufacture, which serves to reduce metallic fatigue and friction between the parts, and increases the load capacity.

The type and construction of wire rope is indicated by two figures, the first giving the number of strands, and the second the number of individual wires per strand. A 2-in., 6 x 7 rope has a maximum diameter of 2″, as illustrated in the figure, and has six strands of seven



Cross-section of 2-in., 6 x 7 rope.

wires each. For a given diameter, ropes made up of many wires are more flexible than those with few wires, and may therefore be used on sheaves of smaller diameter. The common rope types are 6 x 7 coarse, 6 x 19 flexible, and 6 x 37 and 8 x 19, extra-flexible. The 6 x 7 rope is used for mine and yard haulage and guy wires; 6 x 19 is the standard hoisting rope, and is used for mine and ore hoists, car pullers, cranes, and elevators. Extra-flexible rope is used for small diameter sheave applications, and for steel mill ladles, cranes, and high-speed elevators.

A wire rope under load is subjected to stresses caused by the load lifted (which includes the weight of the carrier and the rope length between the carrier and the drum), to stresses caused by sudden starting and stopping and taking up slack in the rope, and to stresses caused by bending the rope around the sheave. If the load is lifted suddenly, the force F, induced by acceleration, is given by

$$F = Wa/32.2$$

where W is the total load and a the acceleration in ft. per sec. per sec. Impact loads, caused by taking up rope slack suddenly, are difficult to evaluate but may cause an increase in the actual stress in the rope by as much as 100%. Impact stresses are usually accounted for by a reasonable increase in the factor of safety used for rope selection. When a wire rope is bent around a sheave, the outer wires tend to increase in length. This action induces a tensile stress in the wires, over and above that caused by the direct load, and is dependent upon the wire size and rope construction. The total tensile force induced by bending varies with the cube of the diameter of the rope and inversely as the diameter of the sheave.

The factor of safety of a wire rope is the ratio of the breaking strength to the sum of the stresses induced in the rope. The factor varies from 8 to 12 for elevator service, from 2½ to 5 for mine hoists, derrick service, and hand-operated cranes, and from 4 to 6 for power-actuated cranes. Wire rope which is joined by splicing should not be used for severe or important service. Spliced rope is considered to have about 75% of the breaking strength of unspliced rope.

Various types of attachments are used for fastening wire rope to crane hooks and other devices; details and necessary dimensions may be found in suppliers' and manufacturers' catalogs. The rope socket attachment is the only one that will develop 100% of the full rope strength. It is made of forged steel with a tapered socket into which the separated wires of the rope are anchored by means of high-grade zinc poured into the socket in molten state. Another attachment uses a steel thimble for the loop or eye of the rope; the rope itself is fastened by clips, clamps, or by splicing. Rope connections made with clips or clamps are not recommended as permanent fastenings since they develop only 50 to 75% of the strength of the rope. (H.C.H.)

WIRELESS TELEGRAPHY. **Radio Telegraphy.**

WIREWORM. Insecta, Coleoptera. Slender hard-bodied **larvae** of the **click-beetles.** They live under bark and in logs or in the ground. Among the latter species are some important crop pests which damage the roots of **grass** and **grains,** and a few other crops including **potatoes** and **cotton.** The corn wireworm is one of the most widely known, often destroying entire fields.

The hard bodies of these worms render them immune from repellent substances that can be used in the soil, but crop rotation including clover, **soy beans, buckwheat,** flax, or some other species not subject to attack, is an effective method of avoiding serious loss. (A.W.L.)

WIRING, ELECTRIC. Wiring consists of running the necessary electrical **conductors** from distribution panels to such lamps, plug-in sockets, motors, ovens, etc., as may be served from the distribution center. The interpretation given here to wiring includes the field of interior wiring, only. Wiring must meet so widely differing service conditions that different types have been developed. The conditions which may vary in different installations are: average quantity of current flowing, light or heavy

power service, need for finished appearance or concealment of wiring, presence of moisture or fumes, different structural types of buildings in which wiring is installed, and time of installation, i.e., during construction or in old buildings. Other factors which bear on the development and use of different types of wiring are the money which can be expended on wiring, and the possible loss which might result from electrical fires. These factors have brought about the creation of the following methods of wiring:

1. Exposed knob and cleat wiring (mill type).
2. Concealed knob and tube wiring.
3. Raceway wiring.
4. Armored conductor wiring (BX).
5. Rigid iron conduit wiring.
6. Non-metallic protected cable.

The first two of these methods involve suspension of the conductors a certain distance apart (minimum 5″), or their enclosure in flexible loom when, as at switches and fixtures, they must converge. However, knob wiring, wherein the insulators are supported on porcelain knobs or cleats, or in tubes where they pass through holes in beams and walls, very definitely insulates the conductors from one another, and eliminates contact with anything but the porcelain insulation. Of course, when poorly installed, and not taut, the conductors may sag between insulators and may create a very definite fire hazard. Even when installed perfectly, little can be said for the decorative appearance of open wiring, so that it is limited to industrial buildings, garages, sheds, and other places where appearance is not a primary consideration. Knob and tube wiring installed in residences is inexpensive, although it must be done during construction of the building. If well installed, it is as good as any method of wiring, except possibly the rigid iron conduit.

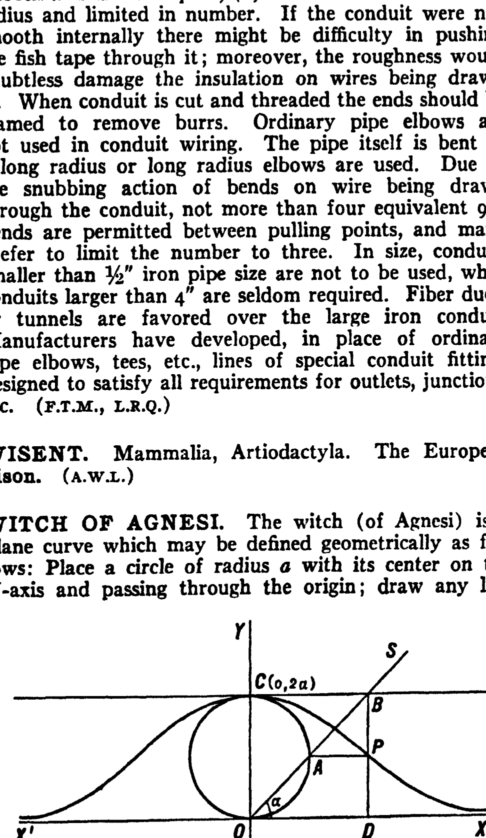
Raceway wiring is to be thought of as a type whose maximum usefulness is in the field of wiring installation subsequent to construction, where the opening of partitions or ceilings for the purpose of introducing concealed wiring is impossible or undesirable. Raceway wiring is surface wiring, with the wires concealed in wooden or metal raceway which is attached to the surface of walls or ceilings. A wooden raceway is provided with a molded decorative cover which may be worked into a semblance of decoration in a room. The same cannot be said for a metal raceway, but it is of small size as compared to the wooden raceway, less conspicuous, and is frequently used for surface wiring of offices and mercantile establishments. In raceway wiring, the base is installed and the wires laid therein, complete from outlet to outlet, then the cover is applied.

Flexible armored conductor is probably used more nowadays for residence wiring than any other type. The armored conductor consists of two rubber-covered wires (three-conductor cable is also commercially produced) covered with a spiral serving of craft paper over which is laid a double spiral steel sheath. The flexibility of the latter permits the armored cable to be bent, although if too small a radius of bending is attempted, the sheath will be damaged. Armored cable is not moisture-proof unless it is of a special type having a lead sheath between armor and the conductor. However, it is approved for wiring in dry locations, such as residences. The cable must be continuous from outlet to outlet, and is generally employed in connection with iron outlet boxes, to which it is attached by special clamping connectors. It does not need to be held by **insulators**, and may be passed through holes bored in beams or joists without the aid of insulating bushings. The non-metallic protected cable is very similar to this, the major difference being in the protective sheath which is woven.

Rigid iron conduit is the best method of wiring; also the most expensive. It is superior in durability, is moisture-proof, and fireproof, reliable, safe, and mechanically strong. While it is not the intention here to give details of conduit wiring (there are standard handbooks treating that subject), some of the general principles are stated. Although the conduit is an ordinary water pipe smoothed on the inside, there is little in common between the installation of conduit and of water pipe, unless it be that junction of adjacent lengths is made by screwed couplings in both cases. To understand the differences let it first be noted how wires are installed in a conduit. A run of conduit having been installed complete and unbroken between the terminal points, the wire is drawn in as follows. A fish tape or wire, a tempered steel wire of rectangular cross-section, is pushed through the conduit until its end appears at the farther end. A draw line is then attached to it and by withdrawing the fish tape, the line is drawn through the conduit. The wires are in turn attached to the draw line and drawn into position. This method of installation requires (1) that the conduit interior be smooth and uninterrupted, (2) that the bends be of long radius and limited in number. If the conduit were not smooth internally there might be difficulty in pushing the fish tape through it; moreover, the roughness would doubtless damage the insulation on wires being drawn in. When conduit is cut and threaded the ends should be reamed to remove burrs. Ordinary pipe elbows are not used in conduit wiring. The pipe itself is bent to a long radius or long radius elbows are used. Due to the snubbing action of bends on wire being drawn through the conduit, not more than four equivalent 90° bends are permitted between pulling points, and many prefer to limit the number to three. In size, conduits smaller than ½″ iron pipe size are not to be used, while conduits larger than 4″ are seldom required. Fiber ducts or tunnels are favored over the large iron conduit. Manufacturers have developed, in place of ordinary pipe elbows, tees, etc., lines of special conduit fittings designed to satisfy all requirements for outlets, junctions, etc. (F.T.M., L.R.Q.)

WISENT. Mammalia, Artiodactyla. The European bison. (A.W.L.)

WITCH OF AGNESI. The witch (of Agnesi) is a plane curve which may be defined geometrically as follows: Place a circle of radius a with its center on the Y-axis and passing through the origin; draw any line



Witch of Agnesi.

OS cutting the circle at A and cutting the tangent at C at B; draw BD perpendicular to the X-axis and AP parallel to the X-axis, and let BD and AP intersect at P. As OA rotates about O, the point P describes the witch.

The **parametric equations** of the witch are

$$x = 2a \cot \alpha, \quad y = 2a \sin^2 \alpha$$

The equation in **rectangular coordinates** is:

$$x^2y + 4a^2y - 8a^3 = 0,$$

or

$$y = \frac{8a^3}{4a^2 + x^2}.$$

(L.L.S.)

WITCHES' BROOMS. The malformations known as witches' brooms are formed in many different kinds of woody plants. Many of them are caused by the presence of *Exoascus*, an **ascomycete**, which grows parasitically in the tissues of the plant. A bud infected by *Exoascus* is stimulated to rapid growth. So are the lateral buds of this shoot. The result is a bush-like mass of branches. The leaves of these infected branches are commonly dwarfed and fall earlier than the other leaves of the plant. The stems contain a much greater amount of **parenchymatous** tissue than is found in the normal branches. No reproductive parts are found on the brooms.

Witches' brooms are formed on fir trees; here they are caused by *Aecidium elatinum*, one of **the rusts**. A rust, *Gymnosporangium*, also causes the formation of witches' brooms on white cedars. Hackberry trees are often conspicuously covered with witches' brooms. In this plant they are caused by a mite, *Phytoptus*, which attacks the plant. (R.M.W.)

WITHERITE. The mineral witherite is **barium** carbonate, $BaCO_3$, crystallizing in the **orthorhombic** system. It is interesting to note that at 811° C. it changes to the **hexagonal** system, and at 982° C. it appears to become **isometric**. It has a rather imperfect prismatic **cleavage**; uneven fracture; hardness 3–3.7; specific gravity, 4.2–4.35; luster, vitreous to resinous; color, white to yellowish or grayish; streak, white; transparent to translucent. Witherite is not a common mineral, being found in veins, and often associated with **galena** as at Alston Moor, Cumberland, England. Associated with barite at Freiberg, Saxony, and at Lexington, Kentucky. Named in honor of Dr. William Withering, an English botanist. (E.S.C.S.)

WOLF. Mammalia, Carnivora. A large dog-like animal belonging to the family Canidae, containing the jackals and domestic dogs, the various wild dogs, and the foxes. The wolves are closely related to the domestic dogs and are supposed to be the ancestral stock of the latter. The relatively few species are found in Europe, Asia and North America, with the one exception of the Antarctic wolf of the Falkland Islands, a species somewhat smaller than the coyote, with a less bushy tail, black at the middle and tipped with white. The kaberu, also called the Abyssinian wolf, is related to the jackals.

Of the true wolves of the genus *Canis*, the **coyote** or prairie wolf of North America is the smallest form. Seven species ranging over various limited areas from Canada to Texas and from Iowa to California are known indiscriminately as coyotes. They are more cowardly animals than the larger wolves and in settled areas often persist as annoying predators, robbing poultry roosts and catching small game.

Wolves are now common only in the wilder parts of the continent and are entirely exterminated in well settled regions. The North American species are the gray, *Canis lycaon*, southern, *C. floridanus*, lobo or timber, *C. nubilis*, and Texas red, *C. rufus*, wolves, and the American jackal, *C. frustron*, of Texas and Oklahoma. (A.W.L.)

WOLFFIAN DUCT. Urogenital System.

WOLFRAM. Tungsten.

WOLFRAMITE. The mineral wolframite, **tungstate of iron and manganese**, is an **isomorphous** mixture of tungstate of iron, $FeWO_4$, and tungstate of manganese, $MnWO_4$, the amounts being variable. The pure iron tungstate is called ferberite and the manganese tungstate, hübnerite. It has been proposed that the name ferberite be applied to mixtures of not less than 80% $FeWO_4$ and not more than 20% $MnWO_4$, and that the term hübnerite be given to mixtures of not less than 80% $MnWO_4$ but not more than 20% $FeWO_4$. Wolframite would thus include the minerals of intermediate composition, and its formula would be written $(Fe,Mn)WO_4$. Wolframite is **monoclinic**, usually appearing in tabular, columnar or bladed crystals, sometimes quite large; also may be massive. Its hardness is 5–5.5; specific gravity, 7.1–7.5; color, gray, reddish-brown, brown or black; streak, reddish-brown to black; luster, submetallic; opaque, occasionally magnetic. Wolframite is found associated with **apatite, cassiterite, quartz, fluorite**, etc.; in **granites** and **pegmatites**. Often with **scheelite**, $CaWO_4$, and sometimes as a **pseudomorph** after that mineral. Wolframite is found in Czechoslovakia, Rumania, Saxony, Cornwall in England, New South Wales, Bolivia; and in the United States at Trumbull, Connecticut; Luna and Lincoln Counties, New Mexico. It also occurs in small quantities in Nevada and Utah.

Ferberite, which has monoclinic tabular crystals, sometimes massive, resembles wolframite, and occurs in Spain and in Boulder County, Colorado.

Hübnerite crystals are monoclinic, often long fibrous or bladed, may be massive; resembles wolframite and is found in Peru, the Black Hills, South Dakota; San Juan County, Colorado; White Pine County, Nevada, and Lemhi County, Idaho. (E.S.C.S.)

WOLLASTONITE. The mineral wollastonite is **calcium** metasilicate, $CaSiO_3$, which is found as tabular or short prismatic **monoclinic** crystals. This mineral has a hardness of 4–5; specific gravity, 2.8–2.9; color, yellowish, reddish or brownish, to gray, white or colorless; luster, vitreous to pearly; transparent to translucent. Wollastonite in the main is formed by the action of contact **metamorphic** processes on limestones at relatively high temperatures (600° C.+). Its common associates, **diopside, vesuvianite, garnet** and **epidote**, suggest this origin. Some of the more important foreign localities are in the copper mines of Rumania, in the lavas of Monte Somma and Vesuvius, in Finland and Mexico. In the United States it is found in Essex and Lewis Counties, New York; Keweenaw County, Michigan; and Riverside County, California. Wollastonite was named in honor of the English chemist, William Hyde Wollaston. (E.S.C.S.)

WOLVERINE. Mammalia, Carnivora. A stoutly built short-legged animal, *Gulo luscus*, of northern North America, ranging from the mountain forests of Colorado and Pennsylvania to the Arctic. It is over 3′ long, with large feet, a short bushy tail, and shaggy fur. Also known as the glutton, and by the Canadian French name carcajou.

The wolverine is noted as a vicious killer and as a despoiler of camps. It not only damages foods that it cannot eat but steals objects that it cannot use and so makes itself a general nuisance to campers and trappers in the northern woods. Since it climbs, gnaws, and digs with great facility, protection of supplies against its attacks is difficult. Wolverines eat dead animals as well as prey that they kill, and often rob trap lines.

A second species of wolverine, *G. luteus*, of slightly smaller size and different proportions, has been recognized, extending southward in the Sierra Nevada of California. (A.W.L.)

WOMB. The mammalian **uterus. Reproductive System.** (A.W.L.)

WOMBAT. Mammalia, Marsupialia. *Phascolomys*. Stoutly built pouched animals of Australia and Tasmania, broad of body and with short thick legs. They have a pair of chisel-like incisor teeth in each jaw, like the rodents, and have similar food habits. They live in burrows or in crevices among rocks. Several species are known. (A.W.L.)

WOOD. (TIMBER. LUMBER.) The word wood is frequently applied to fuel, which in this case means forest products cut to a size suitable for burning in stoves. Again, especially in the plural form, the word refers to a stand of growing trees, especially if the stand covers a considerable area. The word may also apply to finished products such as boards, joists, and beams, all called wood. In botanical language, the word wood means that part of the stem, trunk, or branches, which is composed of the water-conducting **xylem** and associated fibers, especially in perennial plants in which these cells form a considerable mass, as in trees, shrubs and vines.

The word timber is also applied to standing trees, especially in the phrase standing timber, meaning trees large enough to be commercially valuable. Another common phrase is timber-land. Timber also means prepared forest products, especially any large beams, or coarse products. **Lumber** has a similar meaning, but is used in a rather broader sense, applying generally to any forest products such as boards, planks, beams, etc.

Practically all plants yielding wood of any value are **gymnosperms** or **dicotyledonous angiosperms.** Among **monocotyledons** only certain **bamboos** and **palms** have any appreciable use, and that largely restricted to the regions in which these plants grow.

It is worthy of note that forests have a very great value to man in addition to their yields of wood. For a forest is a very important factor in conserving water, preventing it from rapid running-off, and so tending greatly to reduce the possibility of disastrous floods. This retention of water is due to several factors; one because the roots themselves tend to form hollows in which water stands and settles, to move slowly through the ground, another because the increased supply of **humus** accumulating in the ground under the trees acts as a sponge, absorbing and retaining water. Vast amounts of water are absorbed by trees and given off to the air by transpiration.

In North America there are several types of forests, distinguished mainly by the kinds of trees which are most numerous in any kind. In eastern North America three main regions are recognized. There is the Northern Forest, occupying the northernmost tier of states from Minnesota east, and reaching downward in the mountains to Virginia and Tennessee. The dominant trees of this forest are **coniferous,** with white pine the most valuable species. Other coniferous species are hemlock, fir, and spruce. Hardwoods such as oaks, maples and birches are important trees of this northern forest. The southern forest occupies the region bordering the Atlantic and Gulf of Mexico and extending from the southeastern corner of Virginia into the eastern part of Texas. This also is a forest dominated by coniferous trees, mostly species of pine. Hardwood trees of this forest include sweet gum, ash, and tupelo. Between these two forests and extending west into the prairie region is the hardwood forest, in which are found oaks, black walnut, hickory, and basswood. In the western half of the country there are two regions, one, the Pacific forest, occupying the states bordering the Pacific ocean, and composed largely of Douglas fir, redwoods and several species of pine, all trees frequently attaining tremendous size. Occupying higher elevations in the western mountain states is the Rocky Mountain forest, containing such trees as Douglas fir, Engelman spruce, several pines, aspen, red cedar, and many others. Including the southernmost tip of Florida and the southern borders of Louisiana and Texas is a forest of an entirely different type, the tropical forest, characterized by such trees as magnolia, and live oak with an undergrowth of palmetto, which occupies vast regions of land in Central and South America, as well as the West Indies.

Woods are divided into two main classes, softwoods and hardwoods, distinguished not so much by the nature of the wood as by the trees. Softwoods are those obtained from **coniferous** trees such as pines, spruces, hemlocks and firs; hardwoods come from **deciduous** trees, and include such trees as oaks, ashes, maples, basswood, poplars, gums, as well as many tropical trees. It will be seen that the relative hardness of the wood is not an indication of its classification, since many hard pines, which are softwoods, are much harder than the soft wood of the bass, the poplar and the tulip tree, all of which are classed as hardwoods. Softwoods are much more extensively used by man, being employed widely in building construction. Hardwoods are used for furniture, interior finish, and for products demanding special wood structure.

The structure of wood is a very important factor in determining its ultimate use. The woody tissue of any plant is composed entirely of cells or vessels of various kinds, the majority of them being elongated and thick-walled. In **gymnosperms,** from which come the softwoods, these cells are **tracheids,** elongated cells in the walls of which there are many **pits.** These tracheids vary in size and in the thickness of their walls; those which are formed during the season of most active growth, in the spring, being larger and having thinner walls than those formed later. The hollow center, or lumen, of the spring-formed wood cells is much larger than that of the summer wood. As a result of this variation in cell size and structure, the wood of the tree is made up of distinct concentric layers of cells, often very sharply distinct. These are the annual rings. By counting them one may obtain an accurate knowledge of the age of the tree. In addition to the tracheids there are in the gymnosperm wood other cells which extend in narrow radial bands outward towards the surface of the stem. These are the ray cells which collectively form the rays of the wood. In softwoods the rays are not conspicuous; in many they are very minute. In hardwoods the cellular structure of the wood is more complex. Tracheids are present and resemble those of the softwood in appearance. In addition there are many vessels. These are composed of many cells arranged in vertical rows extending considerable distances along the stem. It is characteristic of vessels that there is no cross wall separating the component cells. Pits are found in the lateral walls of the vessels. In hardwoods, there are also many fibers, slender elongate cells with thick walls, in which there are only a few small pits. Compared with those of softwoods, the rays of hardwoods are very large and often form a conspicuous feature of the wood. All these cells in both hard and soft woods are formed by the **cambium** cells. When first formed, all wood cells contain **protoplasm.** Very early in their development, the protoplasm of the vessels, fibers and tracheids is lost, the cell becoming void of any living contents. Only the ray cells and any **parenchyma** cells which may remain retain their protoplasm. Therefore the greater part of the woody tissue of the tree is dead. For some time this wood functions, it being the region through which water and dissolved mineral matter passes up through the stem. Wood thus functioning is called sapwood. It is usually pale in color. As the stem increases in size, changes occur in the cells, and there is less and less **ascent of sap.** Their walls frequently become much darker in color; often the lumina of the cells becomes filled up with various solid substances. When this condition obtains the wood is known as heartwood. The separation between sapwood and heartwood is usually quite distinct; it does not necessarily coincide with an annual ring, but may form a very irregular region. The appearance of the heartwood differs greatly in different woods; in some it is never distinct from the sapwood, in others it forms a small mass in the center of the stem, while in others it includes almost the entire stem. In color heartwood ranges from white through yellows, reds, greens, browns, and even black in different trees; often it is streaked and mottled with different shades of color.

The first step in the preparation of wood is cutting

it into suitable dimensions. Usually this means that the felled trunks or boles, known as logs, are cut into lengths varying from 2 or 3′ to 16′ or more, depending on the use to which the wood will be put. These logs are then sawed into boards, planks, or larger pieces. The manner in which a log is sawed is often a very important factor in the value of the product, since many woods are valuable for their grain, which differs according to the way the wood is cut. The word grain, applied to wood, has many meanings. Commonly it refers to the appearance of the wood when finished. This is determined by the nature of the cells composing the wood and their arrangement. In many woods, especially the softwoods, the cells are all parallel so that the wood splits easily. Such wood is said to have a straight grain. In other woods, the cells are oriented in various directions. Such woods split with great difficulty, and are called cross-grained woods. Wood composed mostly of small thick-walled cells, with few vessels, is called fine-grained wood, in contrast to that having many vessels, usually of large diameter, known as coarse-grained wood. The rays of the wood often form an important feature of the grain, since when they are large they may appear in the form of distinct flakes or streaks in the surface of the wood. The size and appearance of these flakes is greatly changed by the method of sawing the wood.

The commonest way of sawing is called plain sawing. In this, successive boards or planks are cut from the log, beginning at one side and cutting successive pieces through the center to the opposite side. In those woods in which grain is of little value, especially those with very small rays, this method of cutting is entirely satisfactory, for it is quickly and easily done. In other woods, especially those in which the rays are large and form a conspicuous feature of the finished wood, it is not so satisfactory, since variation results. This variation is largely due to the nature of the rays, which extend directly outward from the center to the surface of the wood, and have little thickness compared to their other two dimensions. Consequently the first cuts will be across the rays, which will then appear as narrow linear streaks in the wood. When boards near the center are cut, the ray will be nearly parallel to the cut and so appear as an irregular broad patch on the surface, adding greatly to the beauty of the wood. Methods of cutting have been devised which increase the number of boards which show these radial cuts. These methods are known as quarter-sawing. There are many of these, all having as their object the cutting of the greatest number of radial cuts most economically. Another important feature of the grain of wood, which can be changed by the method of cutting, is found in the annual growth increment, which forms the annual rings of the cross-section. In sawed woods these annual layers appear as lines or streaks, often elaborately twisting.

Another important step in the preparation of wood is drying or seasoning. This may be done either before or after the log is cut into boards. During this process much of the water which is present in the wood, both in the lumina of the cells and in the cell walls, themselves, is lost. As a consequence there is a certain amount of shrinkage of the wood, which is greater tangentially than in the other dimensions. As a result, the wood on drying tends to check or crack longitudinally, especially in large pieces of wood. For most purposes, undried wood, known as green wood, is entirely unsatisfactory; it will twist, warp, and crack as it dries; it cannot easily be glued, or finished, and it is more subject to attacks of fungi and boring insects. There are two methods of seasoning woods. The older method was to pile the wood in such a manner as to secure the maximum exposure to air, separating each piece from the next by narrow strips of wood, or by other means, and leaving the piled-up wood to dry slowly. This is called air-drying or air-seasoning. To dry wood in this way requires a month or more for boards an inch thick and several years for very large sticks, especially if the wood be a hardwood containing much water. Naturally the climate greatly affects the time required, wet seasons causing very slow drying. Recently much of the wood used, especially that used in making furniture, interior finish, shingles, etc., has been dried artificially in large rooms, heated artificially. By this method it is possible to dry wood in a few days instead of months or years. The product is also much drier and better fitted for use. This method is known as kiln-drying or kiln-seasoning. Properly prepared wood has the following properties which give it its special value. It possesses great strength and incompressibility, yet is flexible, giving without breaking, and elastic, recovering after bending. Many woods have special properties which particularly fit them for special uses.

The uses made of wood are so numerous that only those of the greatest importance can be named. Immense quantities of wood, both hard and soft, are used in the pulp and **paper** industry. In construction work other large quantities are used, and in a variety of ways. Poorer grades of lumber are much used in making forms in which concrete work is poured. Scaffoldings and other framework also use quantities of the cheaper kinds of lumber. Wood is still a most important material for the construction of dwellings and other buildings. For the framework and for the rough finish of the walls and floors, the poorer kinds of wood are mostly used. For the outer parts, such as shingles and clapboards, and for the interior finish materials and floors, better grades, often of special kinds of wood, are used. Shingles, for example, are mostly cut from white or red cedar, which is very resistant to the weather. Floors are made from hard pine, from maple or oak, and a few other woods which do not splinter easily and which resist heavy wear favorably. Nearly all the woods used in construction work are softwoods, which are light in weight, durable and easy to work.

For cabinet work and furniture an entirely different group of woods is used. Most of these are hardwoods, selected for their fine grains, or for their color, or because fashion and the whims of fancy happen to give them popularity. Many of the woods used for this purpose are tropical woods difficult to obtain and so of great value. In early days furniture was made from solid pieces; later it became the custom to use thin pieces of wood glued to a background of a different wood. These thin pieces were called veneer. There were several reasons for using veneer. One of course was economy, since an expensive block of wood would yield many more pieces of veneer than it would boards. Another reason was found in the fact that it was often difficult to fashion things from the hard dense woods used. They would split or crack easily, whereas when glued to a more easily handled more suitable wood they became usable. Finally, and very important, was the fact that often veneers could be obtained showing a beautiful grain which could rarely be obtained otherwise. So veneering became important.

There are three ways of cutting veneer wood. They may be sawed like any board: this method is wasteful since much material is wasted in the cut, as sawdust; it cannot produce very thin pieces, and it does not give the best grain in many cases. An advantage is found in the high polish which may be given veneers cut by this method. A second method of cutting veneers is slicing. In this method the short piece of wood, called a bolt, from which the veneers are to be cut, is moved up and down against a heavy stationary blade. This method has an advantage over sawing in that it allows much thinner veneers to be cut. As in sawed veneers, sliced veneers are limited to the size of the bolt from which they are cut, which is frequently a factor against them. The third method and the one used in cutting nearly all the veneers in the United States, is rotary-cutting. In

this method the bolt is revolved against the knife, the veneer coming off in a thin sheet of any width desired. In order that the wood may be more easily cut and the veneer handled better, the bolt from which it is to be cut is usually soaked in water or steamed for some time before cutting, both by the slicing and the rotary method. After cutting, veneers are pressed flat and dried, in which condition they may be held indefinitely. They are commonly glued to some hardwood when they are used.

Another way in which veneers are used is in the making of plywood. This is made by gluing together three or more layers of veneer, the grain of each layer being at right angles to the one above it. Plywood is very resistant to blows and not easily cracked or broken. For which reason it is much used in making boxes, table tops, crates, and panels designed for various purposes.

In addition to these major uses of wood, there are many others, each of which uses immense quantities. Cooperage is one of these. There are two kinds, slack and tight, each producing a barrel or container suited for a special purpose. Slack cooperage produces barrels, kegs, tubs, etc., which are used as containers for vegetables, for nails, and for many other things. Formerly flour was mostly shipped in barrels of this sort. Tight cooperage produces containers which are tight, the staves fitting very close together, and the heads being very closely fitted. Woods used in tight cooperage must have large pores filled. White oak, in which the pores are completely plugged, is especially suitable. If other woods are used, they must be coated with a film of paraffin which will plug the pores. Quantities of wood are used in the manufacture of charcoal, which is extensively used in making steel, explosives, and carbon dioxide gas, and also as a filter in the manufacture of sugar. Charcoal is made by allowing a closely packed pile of wood to burn with insufficient air, as a result of which the volatile materials are driven off and the carbon of the wood left. Millions of cords of wood are used for fuel each year in the United States; much of this is waste wood which would be of little value for any other purpose. Large quantities of light softwoods, especially baswood, are used in making excelsior; in this the wood is first scored and then stripped off in thin pieces by knives. Excelsior is largely used to pack around glassware and dishes, and as a stuffing for mattresses and upholstery of the cheaper grades. Other uses of wood are for railroad ties, poles, and posts, piling, all of which call for woods which may be treated in such a way as to resist rotting and the attacks of various animals.

The following woods have properties which particularly fit them for special uses. Lignum-vitae, the heaviest of all woods, is a dark, greenish-brown, fine-grained wood with an oily appearance. It is obtained from *Guaiacum officinale,* a small tree native in tropical America. The wood of another species, *Guaiacum sanctum,* is also used. Both trees have compound leaves and showy flowers borne in clusters in the axils of the leaves. The fine-grained wood with its much-crossed fibers is used in making pulley sheaves, and as bushing around the propeller shafts of steamships, as well as for bowling balls and mallet heads. The wood contains a resin, guaiacum, which was formerly highly esteemed as a valuable medicine used in the treatment of social diseases. Today it is of slight importance as a drug. Rosewood is obtained from *Dalbergia nigra* and other species, natives of South America. It is a hard close-grained wood with a pleasant fragrance. Formerly it was much used as a cabinet wood. Sandalwood is obtained from trees native in the East Indian region. It is a firm-textured wood of dull yellow color, which darkens with age. Like rosewood, sandalwood has a characteristic aromatic odor. The tree, *Santalum album,* is interesting because it is a parasite on the roots of other plants. Satinwood is obtained from *Chloroxylon Swietenia,* and other species, natives of India and Ceylon. The wood has a golden-yellow color and a brilliant luster which makes it a valuable cabinet wood. Several species of walnut, particularly *Juglans regia* of Europe and Asia and *Juglans nigra* of North America, yield dark brown woods of great value. They are much used in furniture making, and in interior finish in houses, and also because when once dried they are not subject to any changes through swelling or shrinkage, they are particularly favored as material from which to make gun and rifle stocks. Walnut is capable of taking a very high polish. Another dark heavy wood which is much used in furniture making is ebony, the wood of *Diospyros Ebenum,* and other species. The sapwood of the tree is soft and creamy white and of little value; the heartwood is very dark, often black, and hard. There are many other less well known woods, which are frequently used in furniture making.

(See also **Cedar, Mahogany, Oak.**) (R.M.W.)

WOOD DISTILLATION. **Destructive Distillation.**

WOOD HOOPOE. Aves, Piciformes. An African bird (**Aves**), of a family closely related to the true hoopoes. The wood hoopoes differ in the metallic gloss of the plumage and the long wedge-shaped tail. Also called chatterers. (A.W.L.)

WOOD PULP. Cellulose, under **Carbohydrates.**

WOOD RAT. Mammalia, Rodentia. A moderately large **rodent,** more common in the western states but represented by a few species in other sections. They are well and unfavorably known from their habit of invading houses and camps and carrying away anything edible. They differ from true rats in the shorter furry tail and the larger eyes and ears. Ten species have been described, all in the genus *Neotoma.*

These animals are also called pack rats and trade rats, the latter from their habit of replacing what they take with some other object. (A.W.L.)

WOODCHUCK. Mammalia, Rodentia. A large heavy bodied animal of the northern hemisphere. Woodchucks have short stout legs and are powerful burrowing animals, penetrating many feet into the ground. They also climb readily, although somewhat clumsily. They eat vegetation of many kinds and sometimes become troublesome in fields and gardens.

North America has three species of woodchucks, the common woodchuck, *Marmota monax,* the yellow-bellied woodchuck, *M. flaviventris,* and the whistler, *M. caligata.* The first occurs from Kansas to Georgia, northward to Alaska and Hudson Bay. The second ranges from the Rocky Mountains to the Pacific and the third is also western, ranging from Montana and Washington to Alaska. The names **marmot** and groundhog are also generally applied to them. The Old World species are widely distributed in Europe and Asia, where they are more commonly called marmots.

The flesh of woodchucks is eaten but it is inferior to that of other common **rodents.** While its flavor is good it is coarse in texture as compared with that of squirrels and rabbits. (A.W.L.)

WOODCOCK. Aves, Charadriiformes. A woodland bird (**Aves**), *Scolopax minor,* of the northern and eastern part of the United States, related to the snipes. It has a long straight beak and short neck, tail and legs, and its mottled brown plumage is a fine example of protective coloration. Of limited interest as a game bird. (A.W.L.)

WOOD-HEWER. Aves, Passeriformes. A small brown bird (**Aves**), of a family found only from Mexico to southern South America. The family includes more

than 200 species, mostly limited to the temperate parts of the continent. Among them are the **oven birds** and several other groups. (A.W.L.)

WOODLOUSE. Crustacea, Isopoda. Small terrestrial **crustaceans** of oval form, somewhat flattened. They live under bark and debris near the surface of the ground, in decaying vegetation, and in other sufficiently moist situations, and are common in gardens. Also called sowbugs. These forms constitute the families Porcellionidae and Oniscidae, and in the closely related family Armadillididae are found the pill bugs. The latter are able to roll themselves into almost perfect spheres when disturbed. The numerous species vary in color from gray to brownish and blackish. (A.W.L.)

WOODPECKER. Aves, Piciformes. A bird (**Aves**) whose beak is adapted for chipping wood and whose feet are formed for gripping the bark of trees. The tail is composed of stiff feathers and is used as a brace against the surface to which the bird clings. Woodpeckers excavate deep holes in trees as nests and deposit white eggs whose shells are like translucent china. They also dig into decaying wood for the insects contained in it. The capture of insects is facilitated by the sharp barbed tongue and sticky saliva. Both the barbed tongue and the stiff tail are lacking in a few genera.

Woodpeckers are well represented in all regions except the Australian. They vary from the diminutive piculets of South America and Asia to the great ivory-billed species, which attain a length of 18″. North America has more than a score of species, including the flickers and sapsuckers. Of these the red-headed, *Melanerpes erythrocephalus,* and downy, *Pyrobates pubescens,* woodpeckers and the flickers are widely known and the large pileated woodpecker, *Ceophloeus pileatus,* or cock-of-the-woods of northern and western forests and ivory-billed woodpecker, *Campephilus principalis,* of southern localities are among the rarest. (A.W.L.)

WOODRUFF KEY. **Key.**

WOOD'S METAL. **Alloys.**

WOODWORKING. A cutting process performed with the aid of both hand and mechanically actuated tools. Hand saws are used for bringing stock to size, for roughing out grooves, and for numerous other purposes. There are two important types of hand **saw** teeth: cross-cut saw teeth, which are pointed and are employed for cutting across grain; and ripsaw teeth, which have chisel edges and are used for cutting with the grain of the wood. The backsaw is a fine-tooth cross-cut saw with a thin blade and is designed for accurate work. As its name indicates, it is reinforced with a heavy steel rib. A compass saw is a cross-cut saw with a narrow tapered blade, and is used to cut curves and circles after a preliminary hole has been bored in the stock. A coping saw has a C-shaped steel frame and a very narrow blade and is used for cutting curves in thin stock.

Chisels are cutting tools used in joint construction and in fitting and shaping. Chisels are used to cut mortises, grooves, bevels and chamfers. Gouges are chisels of circular section. Outside bevel gouges are used for wood-turning roughing cuts and for cutting flutes with spherical ends (blind flutes). Inside bevel gouges are used for hollows and for grooving and edge shaping. Veining or carving tools are gouges of vee or circular shape, and are employed in ornamental carving.

A hand plane is essentially a chisel carried in a frame. The jack plane is so named because it may be used to do the work of several other planes. The plane iron cap is clamped to the plane iron or cutter, and breaks the shavings as they enter the throat of the plane. The lever cap locks the plane iron to the body of the plane. The cutter is advanced or retracted for a coarse or fine cut by the adjusting nut. The jack plane is about 14″ long; the smoothing plane, fore plane and jointer planes are almost identical with the jack plane except that they are respectively 8″, 18″, and 30″ long. The block plane is a small plane for planing end grain. It has no cap iron or handle. The plane iron in a block plane is set at a smaller angle to the plane bottom than the jack plane iron and its bevel is turned up instead of down.

Drills and bits are used for boring holes in wood. An auger bit is a cutting tool of helicoidal form with a screw point which serves to pull the tool into the wood. A pair of spurs outline the hole and cut off the fibers, which are picked up by the lips of the bit. Taper head or twist drills are extensively employed in wood boring because the greater part of the fluted portion of the drill can be ground away in resharpening. It requires pressure to make it cut, does not elevate the chips as readily as the double-twist auger bit, and is therefore not as satisfactory for deep hole boring. It is very satisfactory for end grain service and is extensively used for cross-grain where absolutely smooth holes are not required.

Woodworking machinery is extensively used in modern practice. A circular saw consists of a horizontal spindle carrying the saw, which projects above the surface of the saw table. A ripping fence or guide can be set at various distances from the saw, and is employed as a gauge for cutting boards to definite widths. The cut-off fence is employed for end cutting where the long dimension of the board moves at right angles to the saw.

Saws with either cross-cut or ripping teeth are employed for circular saws. Grooves for notched joints may be cut by using a series of saws properly spaced by collars or washers. Dado heads, for dado, plough, and rabbet cutting, may also be used on saw tables.

A bandsaw is a continuous steel ribbon with teeth along one edge, which runs over a pair of wheels whose diameters denote the size of the saw. The work is placed on a horizontal table and fed by hand against the front edge of the saw. The thrust of the work is borne by roller guides which are set as close as possible to the work. Bandsaws are obtainable in widths from ⅛″ up, and are generally made with a brazed lap joint. Bandsaws with tilting tables, and saws in which the frame tilts, thereby permitting angular or beveled cuts, are available. The bandsaw is used for cutting lumber to shape, and for curved work where its narrow blade permits small radii to be sawed.

Scroll saws or jig saws are used for cutting internal and external irregular curves. The saw blade has a reciprocating motion, and cuts on the down stroke. The scroll saw can be used for irregular holes in the work where a starting cut from the outer edge to the hole, which is required in bandsawing, is not desirable.

The wood planer is employed for surfacing rough lumber and planing wide boards. The cutter head is composed of a cylindrical body with two, three, four, or six knives which are clamped to the body but may be adjusted to compensate for resharpening. The wood jointer is used for preparing edges to be joined accurately. The table is adjustable for various depths of cut, and a fence is adjustable for finishing bevels as well as squared stock. The wood shaper is employed for moldings and similar work. It has a vertical rotating spindle, on which cutters or knives of different shapes may be placed and clamped.

Lathes and drill presses are extensively used in woodworking. (See **Lathe, Drill Press.**) Many other machines for woodworking are in common use. The molder is used for cutting moldings, hexagons, full- and semi-rounds, and other strips of irregular cross-section. It resembles a combination of planer and jointer with two additional vertical cutter-heads. The matcher is a

machine with six cutter-heads for simultaneously finishing all sides of matched flooring stock. The tenoner is a machine with several cutter-heads for machining in one operation tenons of varied shapes. (H.C.H.)

WOOLLY BEAR. Insecta, Lepidoptera. The densely hairy **caterpillar** of a **moth** of the family Arctiidae. Most hairy caterpillars belong to this family and most species of the family have hairy larvae. (A.W.L.)

WORK. Work may be regarded as the transfer of **energy** from one body to another; or, in a slightly different sense, as energy in process of transfer. While there are numerous instances of energy transfer whose mechanism is unknown (by radiation, for example), in all cases open to direct observation the process appears to involve two essential factors: (1) the exertion of a force by one body A upon another body B, and (2) the motion or displacement of B in a direction in which the force has an effective component (not necessarily in the direction of the force itself). Thus, the wind may exert a force upon a sail in the direction north-northeast, while the boat actually moves straight north, that is, at an angle of 22° 30′ with the force. But if the force is F, it has a component in the direction of motion, equal to $F \cos 22° 30'$ or $0.9239\ F$; and work is therefore done.

It would be logical to define the measure of work as the quantity of energy transferred. But custom has it just reversed; we fix upon a measure of work and define the unit of energy as that transferred when unit work is done. The quantity of work itself is defined as the product of the displacement (say, in feet) by the component of the force (say, in pounds) in the direction of that displacement; thus giving rise to composite work units such as the **foot-pound**, or the **erg** and the **joule**. Thus, it comes about that we also commonly express energy in foot-pounds, ergs, or joules.

It should be made clear that the displacement is not necessarily caused by the force when work is done. Thus, if one throws a tennis ball against the rear of a rapidly receding truck, it cannot be said that this causes the truck to move. Nevertheless the ball does work on the truck which it would not do were the truck standing still; and as a result the ball rebounds with less energy than from a stationary surface. (L.D.W.)

WORK FUNCTION. The general meaning of this term, much used in connection with electronic phenomena, may be made clear from the following application. Imagine an electron trying to escape from the heated, negatively charged filament of a radio tube. It moves about readily enough within the metal, where there is no general electric field; but upon leaving the interior and receding from the positive atomic nuclei of the metal, the electron must necessarily experience a backward jerk which robs it of some of its kinetic energy. The work function, which expresses this lost energy, is characteristic of the metal. Once outside the surface, the negative surface charge helps the fugitive electron along; but it always has less speed and less kinetic energy than it would have had but for the parting jerk. Photoelectric **emission** involves the same thing. A somewhat analogous case is that of molecules escaping from a liquid in evaporation. They are likewise hindered (by cohesion), the loss of kinetic energy being in this case sustained by the liquid itself (which is actually cooled) and represented by the **heat of vaporization.** Electronic work functions are commonly expressed in **electron volts.** (L.D.W.)

WORKING STRESS. **Factor of Safety; Stress.**

WORLD LINE. **Relativity.**

WORM. A word without exact scientific limitations. Applied to creeping animals of the invertebrate phyla with long slender bodies, but also to some flatworms with broad thin bodies and only inaccurately to worm-like forms such as some of the insects. Scientifically it embraces four phyla: **Platyhelminthes** or flatworms, **Nemertea** or ribbon worms, **Nemathelminthes** or roundworms, and **Annelida** or segmented worms. (A.W.L.)

WORM GEARING. Screw gearing or worm gearing is used to transmit power between shafts with perpendicular, non-intersecting axes. The worm is usually of cylindrical form, and resembles a screw; a section through the worm thread shows that the teeth are straight-sided and analogous to those of an involute rack. Worms are cut on a lathe or a thread milling machine and are often ground and polished after cutting and hardening to obtain surface precision and finish.

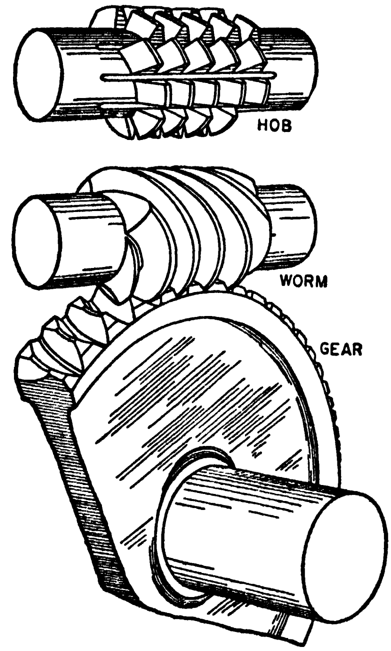


Fig. 1. Worm gearing and hob.

The worm wheel is essentially a helical gear with a face curved to fit a portion of the worm periphery. The tooth form and shape are obtained by cutting the wheel with a special form cutter known as a *hob*, which is essentially a replica of the worm, furnished with longitudinal flutes to provide cutting edges. In cutting the worm wheel teeth, the hob and the wheel blank are rotated at a speed ratio exactly that of the finished set; the hob is properly located with respect to the plane of the wheel and fed in radially until the teeth have been cut to full depth. This cutting action generates worm wheel teeth that are of involute form at the midplane of the wheel, and are conjugate to the hob and consequently to the worm.

Tooth measurement in worm gearing is generally based on circular pitch, although diametral pitch gearing is manufactured and stocked by gear manufacturers. Circular pitch is measured in the diametral plane of the wheel and in a plane passing through the axis of the worm. If D_g represents the pitch diameter of the wheel, P_c the circular pitch, and N_g the number of teeth in the wheel, then

$$D_g = \frac{N_g P_c}{\pi}.$$

The lead L of the worm is the distance that a thread advances in one turn, or the distance that a point on the

pitch circle of the worm wheel will advance during one revolution of the worm. If N_w represents the number of threads or "starts" in the worm, then:

$$L = N_w P_c.$$

A triple-threaded worm has a lead equal to three times the pitch; in a single-threaded worm the lead and pitch are alike.

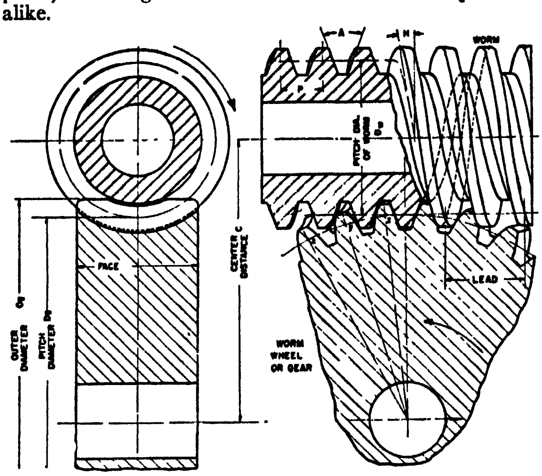

Fig. 2. Worm gearing nomenclature.

The velocity ratio R of a worm gear set depends upon the lead of the worm and the pitch diameter of the wheel, or,

$$R = \frac{\text{rpm Worm}}{\text{rpm Wheel}} = \frac{N_g}{N_w}.$$

Unlike most gearing, the velocity ratio is independent of the pitch diameter of one of the elements—the worm. The worm pitch diameter can therefore be selected to suit a particular center distance, or to make use of a stock hob and thereby dispense with the cost of a special cutter.

The lead angle H of the worm threads is the angle between a line tangent to the thread helix at the pitch line and a plane perpendicular to the axis of the worm. It is found from the following, where D_w represents the pitch diameter of the worm.

$$\text{Tan } H = \frac{P_c N_w}{\pi D_w}.$$

The tooth pressure angle is measured in a plane passing through the axis of the worm, and is equal to one-half the thread profile angle A. Pressure angles of $14\frac{1}{2}°$ are commonly used for single- and double-threaded worms, and 20° for triple- and for quadruple-threaded worms. However, in many modern worm gear reducer sets, pressure angles as high as 30° are employed.

The nature of the tooth engagement in worm gearing causes greater sliding action between the surfaces in contact than in the case of spur gearing. The amount of this sliding action varies with the helix angle, and affects the efficiency of the gearing although it contributes to the smoothness of the drive. Efficiency depends not only on the material of the worm and worm wheel, the amount and character of the lubricant, the velocity of rubbing, but also upon the size of the helix angle of the worm. The efficiency may be estimated from the following:

$$E, \% = 100 - \frac{R}{2}.$$

The above expression refers to commercial worm gear reducers properly mounted and lubricated.

The power-transmitting capacity of worm gearing is based upon the strength of the teeth, the ability to resist wear and abrasion, and the heat-radiating capacity. Since the teeth on the gear are usually weaker than the threads on the worm, the design for strength and for wear is analogous to the method used for spur gearing. The heat-radiating capacity is a function of the efficiency and the square of the pitch diameter of the gear.

Worm gear sets should be carefully aligned in the axial plane of the worm, with the shaft axes at 90°. If the set is arranged so that the worm is underneath the wheel, the former may be run in an oil bath to insure adequate lubrication. Installations should preferably be enclosed to retain the lubricant and to prevent the admission of dust or foreign matter.

Globoidal worm gearing is a form of worm gearing in which a worm of "hour-glass" shape envelops a gear with straight-sided teeth. The capacity of this form of gearing is considerably greater than that of the conventional cylindrical type, and its efficiency is somewhat higher. (H.C.H.)

WORMWOOD, OIL OF. Volatile Oils.

WOUND. Any break in the continuity of a bodily surface, internal or external, caused by an outside injury or force.

An operative wound is one that is made surgically to expose an organ or portion of the body.

An aseptic wound is a clean wound which is not infected by pathogenic organisms. Such a wound is said to heal by primary intention.

An infected wound is one which is infected with pyogenic organisms. Such a wound heals by secondary intention, by adhesion of granulating surfaces, or by third intention, by filling of the wound with granulation tissue.

A lacerated wound is one in which the tissues are torn.

A contused wound is one in which crushing and bruising have occurred.

A punctured wound is a deep wound, small in diameter, made by a pointed object.

An incised wound is one made cleanly, as by a knife or other cutting instrument. (R.S.M.)

WOU-WOU. Mammalia, Primates. The gray or silver gibbon of Java. (A.W.L.)

WRASSE. Pisces, Teleostei. Marine fishes (**Pisces**) found among rocks and coral reefs in tropical and temperate seas. Many are beautifully colored. Some of the larger wrasses are excellent food fishes. The name applies generally to members of the family Labridae. Two species of the Atlantic coast are known as the cunner (blue perch, chogset, bergall), *Tautogolabrus adspersus*, and the tautog (oyster-fish, black-fish), *Tautoga onitis*. (A.W.L.)

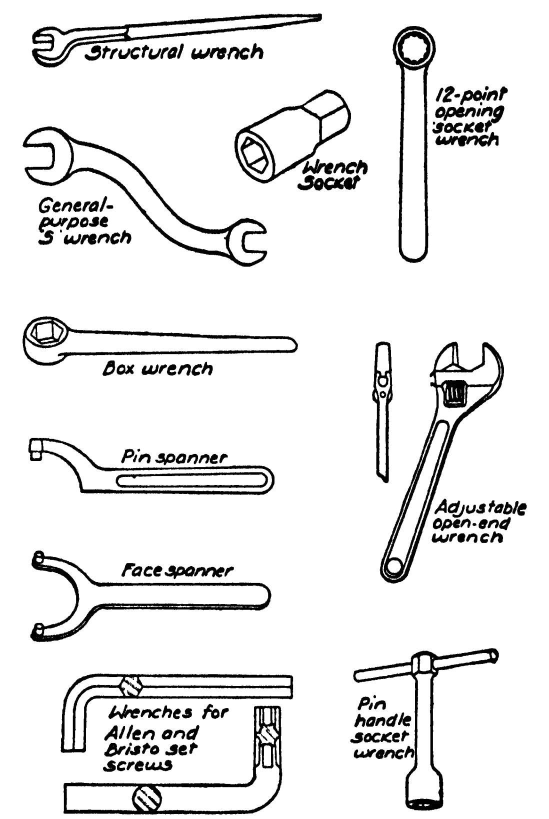
WREN. Aves, Passeriformes. A small bird (**Aves**), related to the larger thrashers. Distinguished by its long curved beak and often sharply erected tail. Several

Carolina wren, *Thryothorus ludovicianus*. Bright reddish-brown above; wings and tail barred with black. A long white line over eye. Underparts, creamy buff.

species habitually build their nests about dwellings or in bird houses. From this habit the widely distributed and vociferous little house wren, *Troglodytes gedon*, has become widely known and the Bewick wren, *Thryomanes bewicki*, a more musical species, has introduced himself

to many residents of the eastern states. The Carolina wren, ***Thryothorus ludovicianus,*** also frequents human habitations. North America is the home of a dozen species and Europe and Asia also have representatives of the group, but it attains its greatest diversity in South America. (A.W.L.)

WRENCHES. Tools for turning and tightening bolts, nuts, and pipe. A variety of wrenches are shown in the figure. Socket and box wrenches are usually preferred to open-end wrenches, since there is less likelihood of slipping over the corners of the nut. Open-end wrenches can be used in many places, however, where socket wrenches will not enter. "S" wrenches are particularly applicable where the swing of the wrench handle is limited. Adjustable open-end wrenches, such as the type shown, or the familiar "monkey" wrench, are used



(*Hesse's Engineering Tools and Processes.*)

for general purpose applications, where it is not feasible to provide a set of solid jaw wrenches. Pin spanners and face spanners are used for round nuts and chucks which have drilled holes either in the periphery or in the face to fit the projecting pins of the wrench. Set screw wrenches are used for setting and tightening socket head set screws, or socket head screws.

Alligator and Stillson wrenches are used for cylindrical work, such as piping and rods. An alligator wrench has a vee-shaped jaw; one side of the jaw is smooth, the other is furnished with ratchet teeth, to enable the wrench to "bite" into the part to be turned, effecting a wedging action that increases the grip of the wrench as the turning force increases. The Stillson wrench is an adjustable wrench fitted with a pivoted jaw with ratchet teeth which tends to wedge on the work. Alligator and Stillson wrenches should not be used for bolts and nuts, except in emergencies, since they deform the heads and make it difficult to use ordinary wrenches. (H.C.H.)

WRIST. The slender part of the forearm at its attachment with the hand, especially the region containing the group of small carpal bones between the radius and ulna of the arm and the metacarpals of the hand. (A.W.L.)

WROUGHT IRON. Wrought iron is a ferrous material aggregated from a solidifying mass of pasty particles of highly refined metallic **iron,** with which, and without subsequent fusion, is included a minutely and uniformly distributed quantity of **slag.** This definition of wrought iron indicates that it is a material made of two components; one, iron of a high degree of purity, the other, slag (chiefly silicate of iron). In the finished product the slag is distributed through the iron in threads and fibers, of which there is an enormous number. The slag imparts to the wrought iron a fibrous structure, quite different from the crystalline structure of cast metals. Wrought iron has made for itself a name as a metal which has resistance to corrosion, and which is exceptionally suitable for structural purposes where the structure is subject to shock. Wrought iron also can be readily worked, forged, machined, welded, galvanized, etc. Among the many applications of wrought iron might be mentioned tubes, pipes, and tanks.

Wrought iron has been made for centuries, but until comparatively recently, its production involved a large amount of hand labor. In former years, wrought iron was produced in the puddling furnace, wherein molten iron was refined with the aids of oxidizing agents, which resulted in the production of an iron silicate, slag. In this process the furnace temperature towards the end of the heat run is maintained high enough to keep the slag in molten condition, but low enough for the iron to become pasty. The workman thoroughly mixes the slag with a spongy iron, producing a sponge of iron and slag. This working is known as rabbling. When this process is complete, the sponge is taken from the furnace with tongs, and put in a squeezing machine, which presses out the surplus slag. The resulting product is then collected and hammered into blooms or rough bars of the wrought iron. Much arduous and tedious work has to be applied to produce a comparatively small sponge with the puddling process. The rabbling process requires a large amount of labor, yet this system continued to be used to produce wrought iron until comparatively recent years.

In the Byer's process, a modern wrought-iron manufacturing method capable of large output, the pig iron is melted in a cupola, then refined in a **Bessemer** converter. The slag is independently produced in a tilting **open hearth** furnace. When the molten slag is ready it is poured into a large ladle and carried to a processing machine where the liquid refined iron from the converter is slowly poured into it. The temperature of the slag is maintained at a value which is sufficiently lower than the melting point of iron that, as the iron is poured into it, the iron rapidly assumes a semi-solidified form. The pouring of iron into the slag is attended by certain mechanical oscillations and relative movement which is designed to produce a uniform distribution of iron in the slag ladle. When all the iron has been poured into the slag, it lies in the bottom of the ladle as a spongy slag-iron mixture over which the excess slag floats. This excess is poured off, and the sponge is dumped into a press which ejects still more slag and squeezes the sponge into a bloom which can be finished in a **rolling mill.** (F.T.M.)

WRYBILL. Aves, Charadriiformes. A New Zealand bird (**Aves**), whose beak is asymmetrical. The terminal half of the organ bends to the right. The bird is said to seek its food, consisting of insects and other small animals, by reaching under the edges of stones. This habit is apparently well served by the peculiar adaptation. (A.W.L.)

WRYMOUTH. Pisces, Teleostei. A marine fish (**Pisces**), related to the blennies. Found off Cape Cod. The name applies to all members of the family Cryptacanthodidae. (A.W.L.)

WRYNECK. Aves, Piciformes. A bird (**Aves**) related to the woodpeckers but with soft tail feathers. The name is from the curious habit of turning and extending the head displayed by the European species. The few known members of the group are found in Europe, Asia, and Africa. (A.W.L.)

WULFENITE. The mineral wulfenite is **lead molybdate** corresponding to the formula $PbMoO_4$, analyses showing that a part of the lead may be replaced by calcium. Wulfenite crystallizes in the tetragonal system usually in thin tabular forms, but is also found massive. It is a brittle mineral; hardness, 2.75–3; specific gravity, 6.5–7; luster, adamantine to resinous; color, yellowish to green or red, may be whitish or grayish; transparent to translucent. Wulfenite is a secondary mineral found in association with other lead minerals such as **galena, pyromorphite,** etc. It is believed to have been formed, at least in part, by the action of waters containing molybdenum salts on cerussite, anglesite, pyromorphite, etc. Especially important foreign localities are in Yugoslavia, Czechoslovakia, Morocco, French Congo, New South Wales and Mexico. In the United States it has been found in Phoenixville, Pennsylvania, and in the Organ Mountains, New Mexico; Yuma County, Arizona; Box Elder and Salt Lake Counties, Utah; and in Clark and Eureka Counties, Nevada. Wulfenite was named in honor of F. X. von Wülfen, an Austrian mineralogist of the 18th century. (E.S.C.S.)

WURTZ-FITTIG-FRANKLAND REACTION. Sodium metal was used by Wurtz as reagent for the preparation of paraffin **hydrocarbons** by treating alkyl iodide in ethereal solution, thus:

$$\begin{array}{llcll} C_2H_5I & Na & \left.\right\} \xrightarrow{\quad} & C_2H_5 & NaI \\ & & & \vert & \\ C_2H_5I & Na & \left.\right\} (\text{Ether}) & C_2H_5 & NaI \\ \text{Ethyl iodide} & \text{Sodium} & & \text{Normal-butane} & \text{Sodium iodide} \end{array}$$

The method has been applied to the preparation of paraffin hydrocarbons as high in the series as hexacontane ($C_{60}H_{122}$). The alkyl radicals may be the same or different in the **iodide** or iodides taken.

Sodium metal was also used similarly by Fittig as reagent for the preparation of hydrocarbons by treating aryl **bromide** or iodide in the presence of dry ether, thus:

$$\begin{array}{llcll} C_6H_5Br & Na & \left.\right\} \xrightarrow{\quad} & C_6H_5 & NaBr \\ & & & \vert & \\ C_6H_5Br & Na & \left.\right\} (\text{Ether}) & C_6H_5 & NaBr \\ \text{Phenyl iodide} & \text{Sodium} & & \text{Biphenyl} & \text{Sodium bromide} \end{array}$$

When alkyl iodide and aryl bromide are taken, the hydrocarbon is of the mixed alkyl-aryl type, thus:

$$\begin{array}{llcll} CH_3I & Na & \left.\right\} \xrightarrow{\quad} & CH_3 & NaI \\ & & & \vert & \\ C_6H_5Br & Na & \left.\right\} (\text{Ether}) & C_6H_5 & NaBr \\ \text{Methyl iodide} & \text{Sodium} & & \text{Toluene} & \text{Sodium iodide} \\ \text{Phenyl bromide} & & & & \text{Sodium bromide} \end{array}$$

$$\begin{array}{llcll} CH_3I & Na & \left.\right\} & & \\ & & \xrightarrow{\quad} & C_6H_4\begin{cases} CH_3(1) \\ CH_3(4) \end{cases} & \begin{array}{l} NaI \\ NaBr \end{array} \\ C_6H_4\begin{cases} CH_3(1) \\ Br\ (4) \end{cases} & Na & \left.\right\} (\text{Ether}) & & \\ \text{Methyl iodide} & \text{Sodium} & & \text{Para-xylene} & \text{Sodium iodide} \\ \text{Para-bromo-} & & & & \text{Sodium bromide} \\ \text{toluene} & & & & \end{array}$$

The method has been applied to the preparation of substituted benzene hydrocarbons containing as many as four alkyl-groups (durene, $C_6H_2(CH_3)_4(1,2,4,5)$ and isodurene, $C_6H_2(CH_3)_4(1,2,3,5)$).

Frankland introduced the use of **zinc** instead of sodium to accomplish similar reactions. (R.K.S.)

WURTZITE. A mineral zinc sulfide, ZnS, similar to **sphalerite.** Crystallizes in the hexagonal system. Hardness, 3.5–4; specific gravity, 3.98; color, brownish-black with resinous luster. Named after Adolphe Wurtz, France. (R.M.F.)

X

XANTHINE. Alkaloids.

XANTHOPHYLL. Pigments in Plants.

XANTUS BECARD. Chatterer.

XENIA. The name xenia is given to that phenomenon in which, two plants having been crossed, the characters of the male parent appear at once in the seed. Ordinarily the characters of neither parent are recognizable so early. Xenia is particularly well shown in **corn** plants, in which there is a conspicuous **endosperm,** the outermost layer of which is the aleurone layer. This endosperm results from the fusion of a sperm **nucleus** with two polar nuclei in the process of **fertilization.** The endosperm therefore is triploid. In corn it is frequently distinctly colored, with yellow dominating over white. It is possible therefore to pollinate a white-grained corn with a yellow parent, all the grains resulting from the cross being yellow since the gene (or factor) which produces the yellow color is in every cell of the triploid endosperm. Red or purple colors often occur in corn, usually in the aleurone layer, and are dominant over colorless aleurone. So again crosses may be made showing directly the effect of genes from the male parent on the endosperm of the seed.

In some plants the influence of the male element is more extensive, involving tissues which are of female origin. This phenomenon is known as metaxenia. (R.M.W., B.S.M.)

XENOBLAST. A term proposed by Becke in 1903 for metamorphic crystals with undeveloped **crystal faces.** (Compare with **Idioblast.**) (R.M.F.)

XENOCRYST. A term proposed by Sollas in 1894 for crystals, usually corroded, which are foreign to the **magma** from which the **igneous rock** in which they occur has crystallized. (R.M.F.)

XENOLITH. A fragment, large or small, of a foreign rock included in an igneous mass. The term is derived from the Greek, meaning stranger and stone. Xenoliths, both large and small, are best displayed at the contacts or margins of **batholiths.** (R.M.F.)

XENON. Symbol: Xe. Atomic number: 54. Atomic weight: 131.3. Density: 5.851 grams per liter, 0° C., 760 mm., or 4.53 when air equals 1.00. Melting point: −112° C. Boiling point: −107.1° C. (**Isotopes:** page 290.)

Xenon is a colorless, odorless gas, of negative chemical properties with ordinary materials. Discovered by Ramsay and Travers, in 1898, in ordinary **air** to the extent of 1 part xenon in about 11,000,000 air. (R.K.S.)

XEROPHYTES. These are plants which are adapted to grow in regions in which there is a decided lack of water, as in deserts. Plants growing in such localities have become modified in various ways which enable them to survive. Since the greatest problem is the lack of water, xerophytes must be so formed as to avoid excessive loss of water. There are several factors which reduce water loss. In many of these plants the leaves are greatly reduced in size or are completely lost, as in most Cacti and many Euphorbias. Most of the water lost to the plant passes through the **stomata** of the leaves and stem epidermis. In many xerophytes the stomata are sunk deep in small pits. The number of stomata is often reduced and also their size. As a further protection against loss of water the epidermis may be covered with a very thick cuticle.

The sap of xerophytic plants has properties which make it hold water tenaciously, tending to reduce loss. Many xerophytes have a fleshy habit, so that greater space is available for storage of water. Sometimes the root is tremendously swollen, in others the stem becomes the enlarged part, while in many it is the leaves. Often the leaves form dense tufts which cause great reduction of free surfaces.

Xerophytes are extremely tolerant of prolonged drought. Some may be kept free from water for several years, yet revive and grow when supplied with water. Most of these plants cannot stand too much water, quickly rotting under such conditions. Many species of xerophytes are covered with thorns. This is commonly assumed to protect them against grazing animals. (R.M.W.)

XIPHOSURA. The horseshoe or king crabs, a class of the phylum **Arthropoda** containing only a single genus, *Limulus,* with five species, one found along the Atlantic coast of North America from Florida to Nova Scotia and the other four on the eastern coast of Asia. They are animals of ancient lineage, showing no important change from **fossils** of the **Triassic.**

King crabs are distinguished by the following characters: 1. The **cephalothorax** is covered by a continuous arched plate of horseshoe shape. 2. Six segments of the abdomen are fused to form a continuous piece, hinged to the cephalothorax. 3. The abdomen bears a long caudal spine, the **telson.** 4. The appendages of the cephalothorax include six pairs associated with the mouth, five of them chelate. The five posterior pairs have the basal segments formed for crushing food. 5. The appendages of the abdomen are six pairs of broad plates bearing gills and used in swimming. 6. There are two large compound eyes and two smaller median eyes.

These animals burrow in sand and mud near the shore, feeding on small animals. They come to shore to deposit their eggs in sand. They are of little economic importance but have been used as food for pigs and domestic fowls, and to a limited extent as fertilizer. (A.W.L.)

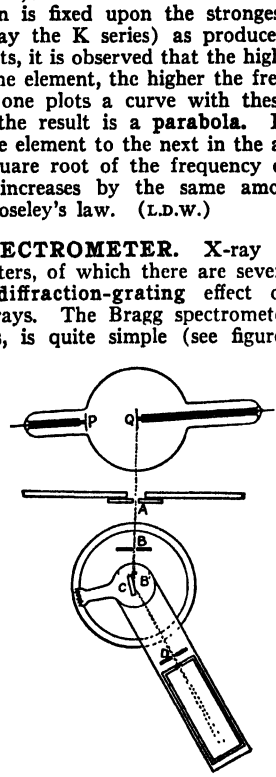
X-RAY SPECTRA. We know that it is possible, by means of the **diffraction-grating** effect of a crystal, to analyze a beam of non-homogeneous **x-rays** into its various wavelengths, thus forming a **spectrum,** and to measure the relative intensities of its various components (see **X-Ray Spectrometer**). When **cathode rays** of sufficient energy fall upon a specimen of some element, as the metal "target" of an x-ray tube, the resulting x-rays, thus analyzed, are in general found to consist of a continuous spectrum (somewhat analogous to the radiation from a heated solid) with an intensity maximum and an upper frequency limit at frequencies dependent upon the speed of the cathode rays. Upon this may be superposed certain groups of much sharper maxima, which may be regarded as rather diffuse spectrum lines. These are characteristic of the material of the target, not of the incident cathode rays; except that if the cathode rays are produced below a certain voltage, some groups of lines do not appear at all.

As in the case of ordinary diffraction-grating spectra with light, each spectrum line may appear in two or

three different orders, of which only the first need be considered. There are then recognized, in the spectrum of each element, several distinct line series; viz., the K, L, M, and N series (perhaps more); which are believed to be due to electron transitions ending in as many distinct quantum or energy states. The lines in any series correspond to "drops" to these respective states from various higher states or levels; the greater the drop, the greater the frequency of the resulting line (see **Quantum Theory**). There is a definite relation between the frequencies of the lines for a given element and the lower frequency limits or edges of the absorption bands of the same element for x-rays (see **Absorption Spectrum**).

If attention is fixed upon the strongest line of any one series (say the K series) as produced by different heavy elements, it is observed that the higher the **atomic number** of the element, the higher the frequency of this line; and if one plots a curve with these variables as coordinates, the result is a **parabola.** In fact, as we pass from one element to the next in the atomic-number series, the square root of the frequency of the selected line always increases by the same amount. This is known as Moseley's law. (L.D.W.)

X-RAY SPECTROMETER. X-ray **spectroscopes** or spectrometers, of which there are several designs, all utilize the **diffraction-grating** effect of crystals in analyzing x-rays. The Bragg spectrometer, one of the earliest types, is quite simple (see figure). The rays



A Bragg x-ray spectrometer. (Diagrammatic.)

enter through a pair or a succession of slits *A*, *B*, which limit them to a narrow parallel beam, and fall upon a suitable crystal *C* mounted on a prism table at the center of a graduated circle. The table, with the crystal, can be rotated so as to vary the angle of incidence. On another arm is mounted an **ionization chamber**, which the reflected rays enter through a set of slits *D*. As the crystal is rotated slowly, this second arm is rotated just twice as fast, so as to keep the axis *CD* always at the same angle with the reflecting planes of the crystal as the fixed incident beam *AC*. Thus, when any of the x-rays are reflected, they enter the chamber and produce an electrometer deflection proportional to their intensity. By plotting the electrometer readings against wavelengths as computed from **Bragg's law,** it is possible to exhibit the distribution curve and the contours of the spectrum lines. In more modern forms, the spectrum is progressively recorded on a photographic plate or film as the crystal rotates, and the instrument is then an x-ray spectrograph. (L.D.W.)

X-RAYS. It was in 1895 that Professor Wilhelm Roentgen, of Würzburg, Germany, discovered the x-rays, quite by **accident**, while experimenting with a **Crookes tube.** He observed the fluorescence of a barium platinocyanide screen which happened to lie near the tube, and traced the effect to something which emanated from the spot where the **cathode rays** struck the tube wall. Putting the tube in a pasteboard box made no difference; so it was not **light** or **ultra-violet radiation** that caused the fluorescence. Investigations followed rapidly, and within only a few weeks the x-rays were being used by surgeons to examine the bones of living people.

It was soon found that x-rays arise wherever cathode rays encounter solids; that "targets" of high **atomic weight** yield more copious x-rays; and that the greater the speed of the cathode particles, the more penetrating, or the "harder," the x-rays are. Special tubes were designed for producing x-rays. The earlier tubes were of the Crookes type, depending on the conduction of ionized gas. Those most used now are thermionic, of the Coolidge type, with a hot-wire cathode operating in a high vacuum; a construction which permits the passage of very high-speed electrons under voltage control, the quantity of them, and the intensity of the resulting x-rays, being regulated by the filament temperature.

Early experiments indicated that x-rays are something essentially different from light, an erroneous conclusion based upon the failure to observe regular reflection, refraction, or diffraction. We now know that this failure was due to the extremely short wavelength of the rays, the range of which extends from the extreme ultraviolet into the **gamma-ray** region, that is, from 10^{-7} to 10^{-9} cm. The early theories attributed x-rays to the sudden stopping of the cathode-ray electrons; but the discoveries of Barkla, Moseley, Bragg, and others have shown that they arise in the atoms of the bombarded substance and that they have wavelengths and spectra quite analogous to visible **atomic spectra.** (See **X-Ray Spectra.**)

There are three principal means of detecting x-rays: the fluorescent effect, the photographic effect, and the ionizing effect. The only method at first available for distinguishing radiations of different wavelength was to measure their penetration or their **absorption coefficient** in various substances. The discovery of the x-ray **diffraction** or grating effect of crystals, by von Laue, Friedrich, and Knipping, in 1912, made it possible to analyze the rays and measure their wavelengths very much as light is studied with the **spectroscope.** When x-rays of given wavelength are incident upon a crystal turned in various directions, the layers of atoms, at certain angles of incidence, reflect wave trains in phase with each other which, if caught on a photographic plate, produce a "Laue pattern." While the matter is not as simple as in the case of light incident on a **diffraction grating,** it is nevertheless possible to interpret such patterns in somewhat the same way as a line spectrum, and to deduce the wavelength from it. A unit convenient for expressing x-ray wavelengths is the "x-unit," which is 10^{-11} cm. or 0.001 angstrom. (See **X-Ray Spectrometer, Bragg's law,** and **Crystal Structure.**)

X-rays are used in medicine to photograph various organs and tissues of the body, or to view them directly (by projecting the x-rays upon a fluorescent screen—fluoroscopy). Because of their destructive action on cells, x-rays are also used in the treatment of certain forms of **cancer** and other malignant **tumors, leukemia,** certain skin diseases, and other pathological conditions. (L.D.W., D.M.H.)

X-UNIT. X-Rays.

XYLEM. The **cells** composing the woody tissues of higher plants are xylem cells. They have undergone extreme modification during their development, becoming greatly elongated and having much-thickened walls. Xylem tissue includes **tracheids, vessels, fibers,** and **parenchyma.** (See **Stem.**) (R.M.W.)

XYLENE. Hydrocarbons.

Y

YAGUARONDI. Jaguarondi.

YAK. Mammalia, Artiodactyla. A species of **ox**, *Poëphagus grunniens,* found in Tibet and as a domestic animal in other parts of Asia. It is a large animal, attaining a height of well over 5′ and a weight of more than 1000 lbs. The horns are large, and are of the characteristic curved form usually found in oxen, with smooth surfaces. The animals are marked chiefly by the long hair that clothes the flanks, legs, and tail, drooping almost to the ground.

Like other domestic cattle, yaks are important as a source of meat, milk, hides, and hair. (A.W.L.)

YAM. Sweet Potato.

YAPOK. Mammalia, Marsupialia. *Chironectes.* An **opossum** found from Guatemala to Brazil. It differs from other members of the group in its aquatic habits, resembling the mink and otter in this respect. The hind toes are webbed. (A.W.L.)

YARD. Measurement.

YAW, AIRCRAFT. This is the angular displacement about an axis parallel to the normal axis of an aircraft. The normal axis of an airplane in horizontal flight is vertical. Intentional yaw is produced principally by the rudder. (F.T.M.)

YAWS (Frombesia Tropica). An infectious disease common in the tropics, affecting principally the skin. Yaws is caused by a spirochetal organism, *Treponema pertenue,* which is closely related to the spirochete of **syphilis.** Unlike syphilis, however, yaws is non-venereal.

Infection usually occurs in childhood. Widespread, raised, rough, cauliflower lesions containing the infectious organism develop on the skin. Improvement and relapses may occur over a period of years.

The blood **Wassermann reaction** is positive in yaws. Treatment with arsenicals, such as are used in syphilis, is highly effective, as is **penicillin.** (D.M.H.)

Y-CONNECTION. Three-phase a-c equipment is wound with three wires whose currents differ 120° electrically in **phase.** The windings can be connected either in Y or **delta.** In balanced electrical condition, voltages and currents are the same in all coils. In the Y-connections one end of all three coils is connected in a common joint, and leads from each of the other ends constitute the three-phase line. The Y-connection is preferred for alternators because of the usefulness of the neutral point, and because the line voltage is the $\sqrt{3}$ times the phase voltage. The ability to bring out a neutral point and ground it either through resistance or reactance, is advantageous because it aids in working out protection and selectivity of control of parallel alternators. (F.T.M.)

YEAR. The year is the longest natural unit for measuring **time.** Several different kinds of year are in use, but all of them depend upon the same phenomenon—the revolution of the earth about the sun. The variations between the different kinds of year arise from the use of different reference points external to the earth relative to which the revolution period is measured.

The sidereal year is the revolution period of the earth about the sun from a given star back to the same star again. Its length, expressed in mean solar **days,** hours, minutes, and seconds, is $365^d\ 6^h\ 9^m\ 9.^s5$ ($365.^d25636$) and from a purely mechanical point of view this is the true revolution period of the earth.

For general living purposes the sidereal year has no particular significance, and for this purpose the time required for the earth (or apparently the sun) to pass from the vernal equinox back to the vernal equinox again is used. This is known as the tropical year and is $365^d\ 5^h\ 48^m\ 46.^s0$ ($365.^d24220$) in length, the difference between this and the sidereal year being due to **precession.** This is the year which is the basis of practically all ancient and modern **calendars.**

A third type of year, which is seldom used, is the period for the earth to pass from some point in its **orbit** (e.g., perihelion) back to the same point again. This anomalistic year is $365^d\ 6^h\ 13^m\ 53.^s0$ ($365.^d25964$) in length, differing from the other two because of the fact that the line of apsides of the earth's orbit is slowly moving at the rate of 11″ per year. (W.K.G.)

YEASTS. Saccharomycetales. Yeasts are unicellular **Ascomycetes** in which no **mycelium** develops, and presumably are degenerate forms. They possess two methods of reproduction; one is the asexual process known as **budding;** the other a reduced type of **ascus** formation. In this the contents of a single cell divide to form four or eight cells; this would then be an ascus resulting from the transformation of a single cell. In some species a fusion of two cells occurs prior to ascus formation.

Yeasts are of great economic value, because of their ability to cause fermentations when present in solutions of **carbohydrates.** As a result of their activities the carbohydrates are broken down to ethyl **alcohol** and **carbon dioxide.** The final step in the process corresponds to anaerobic **respiration.** Yeast is therefore used in producing wine from grape juice, cider from apple juice, and beer from sprouted barley, as well as grain (ethyl) alcohol from various sources.

A similar process occurs in bread-making. Yeast plants, mixed with starch and in the form of yeast cakes, are mixed in the dough; immediately the yeast acts on the starch present, producing first glucose, then alcohol and carbon dioxide. After the process has gone on for a sufficient time the dough is kneaded and presently baked. Kneading serves to break up the bubbles of carbon dioxide which have formed. These are the cause of the many small holes present in raised bread. Any alcohol present is driven off in the baking process. (R.M.W., B.S.M.)

YELLOW FEVER. An acute infectious disease which at present exists only in West Africa and certain parts of South America. Its geographical extent has been gradually limited by proper sanitary measures. Yellow fever is not contagious but is transmitted by the bite of a **mosquito,** most commonly the female *Aëdes aegypti,* which has bitten a yellow fever patient during the first few days of his disease. Twelve days after biting an infected patient, the mosquito is then able to infect a non-immune person. During the 18th and 19th centuries yellow fever was seen in North America and Europe, being transmitted by mosquitoes breeding in the open water tanks of sailing vessels.

The organism causing yellow fever is a filterable **virus.** Once in the body, it produces **hepatitis,** an inflammation and fatty degeneration of the liver cells; to a less extent, similar degeneration occurs in the cells of the spleen. kidneys and heart.

The incubation period is from 3 to 6 days. The symptoms in most cases are mild and consist of fever, slight headache, and perhaps **jaundice.** A severe case, however, is characterized by a sudden onset, acute prostration, fever, slow pulse rate, generalized aches and pains, and jaundice; the kidneys are particularly involved and large amounts of **albumin** in the urine is a constant feature. Vomiting may be uncontrollable. Due to bleeding throughout the gastrointestinal tract the "black vomit" characteristic of this disease is produced.

Failure of the kidneys, with complete suppression of their function, or excessive bleeding from the gastrointestinal tract indicate a rapid termination. Death usually occurs between the 6th and 9th days. The mortality rate in the severe form of the disease is about 60%.

Malaria, infectious **hepatitis** and **Weil's disease** may be difficult to distinguish from yellow fever by the clinical picture.

There is no specific treatment for yellow fever. In preventing the disease, a **vaccine** is used successfully. The destruction of **Aedes** mosquitoes in their breeding places is an essential control measure. (D.M.H.)

YELLOWBIRD. Aves, Passeriformes. The American **goldfinch,** *Astragalinus tristis,* and the yellow **warbler,** *Dendroica aestiva.* Only the male of the former species is yellow, and it has the crown and wings black and the tail marked with black. The yellow warbler is more generally yellow in both sexes. The name yellowbird is not commonly used. (A.W.L.)

YELLOW-FIN. Pisces, Teleostei. A species of **trout,** *Trutta macdonaldi,* found in the upper part of the Arkansas River. (A.W.L.)

YELLOW-JACKET. Insecta, Hymenoptera. A small black and yellow **wasp** that builds its nest of paper, either in a hole in the ground or under some object near the ground. The use of partly decayed wood in making the paper gives these nests a brownish color. Several species are known. (A.W.L.)

YELLOW-LEGS. Aves, Charadriiformes. An American bird (**Aves**) related to the snipes and sandpipers. Two species, the greater, *Totanus melanoleucus,* and lesser, *T. flavipes,* yellow-legs, are widely distributed over North America and migrate into South America. The latter is occasionally seen in Europe. (A.W.L.)

YELLOW-THROAT. Aves, Passeriformes. *Geothlypis.* A North American **warbler** distinguished by its bright yellow front with a black patch through the eyes and along the side of the head. Known as the Maryland yellow-throat in the eastern and central states and in its western varieties as the western, Pacific, tule, and salt-marsh yellow-throat. It frequents low thickets and marshes. (A.W.L.)

YERBA. Maté.

YIELD. Stress Concentration Factor, Watershed.

YIELD POINT. The minimum unit **stress** at which a structural material will deform without an increase in the **load** is called the yield point. Some materials do not have a yield point and in others it is not a well-defined value. Consequently, in these cases it has become common practice to use a quantity called the yield strength. The yield strength is the unit stress corresponding to a specific amount of permanent unit **deformation.** (See **Elasticity; Tension Test.**) (C.W.C.)

YIELD STRENGTH. Yield Point; Tension Test.

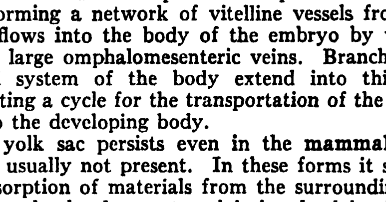
YOKE. The yoke of a motor or **generator** is the supporting and magnetic structure back of the poles, i.e., it is the part of the machine through which the flux passes in going between poles at the ends away from the **armature.** (L.R.Q.)

YOLK GLAND. A portion of the **reproductive system** of the female by which yolk is secreted. In some animals called the **vitellarium.** (A.W.L.)

YOLK SAC. An accessory embryonic membrane formed in the **vertebrates** as an enveloping structure around the yolk of the **egg.** It is connected with the mid gut of the **embryo** and serves for the absorption of nourishment during embryonic life, and in some species, notably the fishes, after the individual has become active. The wall of the structure is composed of the same **germ layers** that form the gut, a lining endoderm, and a covering of splanchnic mesoderm. In the latter blood and blood spaces develop at an early period, later forming a network of vitelline vessels from which blood flows into the body of the embryo by way of a pair of large omphalomesenteric veins. Branches of the arterial system of the body extend into this plexus, completing a cycle for the transportation of the absorbed food to the developing body.

The yolk sac persists even in the **mammals,** where yolk is usually not present. In these forms it serves for the absorption of materials from the surrounding uterus during early development and is involved in the development of the circulatory system. It soon becomes a vestige, however, as its functions are taken over by other membranes. (A.W.L.)

YOUNG'S INTERFERENCE EXPERIMENT. In 1801 Thomas Young made the epochal discovery of the **interference** of light waves, by means of an experiment which has become classic. Light from a narrow slit L falls on a plate in which are two parallel slits, A, B, very close together, so that from the further side of the latter there emerge two exactly similar wave trains. (See figure.) These overlap in the **region** beyond AB



Light from single source L gives rise to two wave trains at A and B, which produce interference fringes on screen F.

and produce interference. If a screen F is placed at some distance from AB, alternate bright and dark bands or fringes appear on it, parallel to the two slits. If a translucent screen is used (or in the case of white light, a plate of colored glass acting as a color filter), these bands may be viewed by means of a magnifier beyond it at E, or better, a low-power micrometer eyepiece, with which the width of the band-interval can be measured.

It is easy to show from the elementary theory of interference that if $AB = s$, if the distance from AB to F is x, and if the wavelength of the light is λ, the distance on the screen between any two consecutive dark bands or any two consecutive bright bands is $b = x\lambda/s$. Therefore if b, s, and x are measured, we have at once a means of determining the wavelength: $\lambda = bs/x$.

Other devices have proved more satisfactory than the pair of slits, such as Young's "biprism," Fresnel's mirrors, or Lloyd's mirror; each of which produces a double virtual image of the slit L to serve as the two wave-train sources A and B. (L.D.W.)

YOUNG'S MODULUS. Elasticity.

YPSILOID CARTILAGE. A cartilaginous structure associated with the pelvic girdle in some of the **salamanders.** It is a Y-shaped projection from the pubis. (A.W.L.)

YTTERBIUM. Symbol: Yb. Atomic number: 70. Atomic weight: 173.04. Melting point: 1800° C. (**Isotopes:** page 290.) Type of compound: Yb_2O_3. Color of salts: Colorless. Discovered by Urbain in 1907. A member of the **yttrium** sub-group of the rare earth metals. (R.K.S.)

YTTRIUM. Symbol: Y. Atomic number: 39. Atomic weight: 88.92. Density: 3.80. Melting point: 1490° C. No isotope, but of single atomic form: 89. Type of compound: Y_2O_3. Color of salts: Colorless. Discovered by Mosander in 1842.

Yttrium occurs in a few uncommon minerals, e.g., **gadolinite** (35–45% Y_2O_3), **xenotine** (55–65%), **fergusonite** (25–45%), **euxenite** (15–35%).

The yttrium sub-group of the rare earth metals consists of the elements yttrium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, and lutecium. The **potassium** sulfate compounds of all of these elements are relatively soluble in water. Yttrium is the most abundant member of the sub-group but not so abundant as are nine of the ten members of the **cerium** sub-group. (R.K.S.)

YUCCA. Pollination.

YUCCA BORER. Insecta, Lepidoptera. A giant **skipper**, *Megathymus yuccae*, whose **larva** bores in the stem and root of yucca plants. Several species of these insects are known, expanding from 2–3½″ in the adult stage. While yucca seems to be the prevailing food plant, some species are known to attack agave. They are limited in distribution to the southern states and south into Central America with the exception of one that has been taken in central Colorado and western Nebraska. (A.W.L.)

YUCCA MOTH. Insecta, Lepidoptera. A small **moth**, also commonly called the pronuba moth from the name of its genus. It lives in the flowers of yucca, depositing its eggs in the ovary of the plant and then **pollinating** the flower. The developing larva eats the seeds, but since many more are formed than it is capable of consuming, the exchange is beneficial to the plant. Several species of these moths are known. All belong to the same genus, whose early name, *Pronuba*, has been supplanted by another, *Tegeticula*. Yuccas are also frequented by moths of the genus *Prodoxus*, which are of no service in pollinating the flowers. They are called false yucca moths. (A.W.L.)

Z

ZEBRA. Mammalia, Perissodactyla. An animal of the genus *Equus* related to the asses and quagga, distinguished by the complete or nearly complete transverse striping of the body and legs. The stripes vary in the several species from white to yellow-brown, alternating with dark brown to black. All of the zebras occur in the southern half of Africa. (A.W.L.)

ZEBU. Mammalia, Artiodactyla. The common domesticated **cattle**, *Bos indicus*, of India, characterized by the highly developed **dewlap** and by the sharply defined hump on the withers. Similar cattle are found in China and Africa, and they have been introduced into the Americas for hybridization with range cattle. In southern Texas and Brazil these crosses are promising, since the humped cattle are more tolerant of heat and more resistant to insect- and tick-borne diseases. In America the zebu has been known also as Brahman cattle. (A.W.L.)

ZEEMAN EFFECT. An effect of a moderately intense magnetic field upon the structure of the spectrum lines of a gas when subjected to its influence. The phenomenon, sought unsuccessfully by Faraday and finally observed by Zeeman in 1896, consists in the splitting up of each line into two or more components. In the simpler cases, when the source is viewed at right angles to the field, there are three components, of which the middle one has the same frequency as the unmodified line. This component is plane-polarized to vibrate parallel with the field, while the two side components vibrate at right angles to the field. When the source is viewed in the direction of the field, there are only two components, displaced in opposite directions, and circularly polarized in opposite senses. (See **Polarized Light.**) These phenomena constitute the so-called "normal" Zeeman effect.

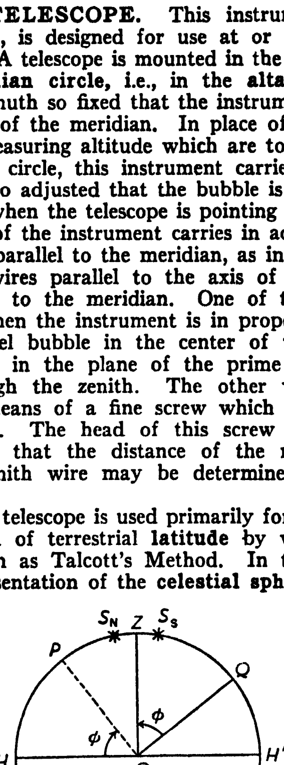
With most lines, however, the number of components is greater, in some cases reaching twelve or fifteen. They are symmetrically arranged and symmetrically polarized. The displacements, as in the simpler case, are proportional to the magnetic field intensity H, and are always expressible, in wave numbers, as rational multiples of the displacement in the normal effect, which is $4.67 \times 10^{-5} H$ (reciprocal centimeter), a quantity known as the "Lorentz unit." The Zeeman effects observed in **sun spots** give valuable information as to the magnetic conditions in those areas.

Closely related to the Zeeman effect are two others, the Paschen-Back effect, produced by very strong magnetic fields, and the Back-Goudsmit effect, observed with the spectra of elements having a nuclear magnetic moment, such as **bismuth.** (See also **Stark Effect.**) (L.D.W.)

ZENITH. The point on the celestial sphere directly overhead is the observer's zenith. The astronomical zenith is defined as the point where the plumb line extended up from the surface of the earth will intersect the **celestial sphere.** Owing to the fact that the plumb line may be affected by local gravitational effects, such as large mountains in the vicinity, the geographical zenith is the point where a line perpendicular to the surface of a smooth earth would intersect the celestial sphere. The angular distance between the astronomical and geographical zenith is the station error of the point on the surface of the earth. Because of the fact that the earth is an oblate **spheroid** rather than a perfect sphere, neither the plumb line nor a perpendicular to the surface of the earth will pass through the geometrical center of the earth unless the observer is either at one of the poles or is on the **equator.** The geocentric zenith is defined as the point where a line extended from the center of the earth through the observer will intersect the celestial sphere. The angular distance between the astronomical and geocentric zenith is the reduction of **latitude** for the observer. (W.K.G.)

ZENITH TELESCOPE. This instrument, as the name implies, is designed for use at or very close to the **zenith.** A telescope is mounted in the same manner as the **merdian circle,** i.e., in the **altazimuth** form with the azimuth so fixed that the instrument is always in the plane of the meridian. In place of the accurate circles for measuring altitude which are to be found on the meridian circle, this instrument carries a very accurate level so adjusted that the bubble is in the center of the tube when the telescope is pointing at the zenith. The reticle of the instrument carries in addition to the set of wires parallel to the meridian, as in the meridian circle, two wires parallel to the axis of rotation, i.e., perpendicular to the meridian. One of these wires is fixed and, when the instrument is in proper adjustment with the level bubble in the center of the tube, the fixed wire is in the plane of the prime vertical, i.e., passes through the zenith. The other wire may be moved by means of a fine screw which is parallel to the meridian. The head of this screw is accurately calibrated so that the distance of the movable wire from the zenith wire may be determined in seconds of arc.

The zenith telescope is used primarily for the accurate determination of terrestrial **latitude** by what is commonly known as Talcott's Method. In the figure we have a representation of the **celestial sphere** drawn in



the plane of the observer's meridian *HPZQH'*. *HOH'* is the plane of the **horizon,** Z is the astronomic **zenith,** P the pole of rotation, and Q the direction of the **equator.** *HP* is the **altitude** of the pole and hence is, by definition, the astronomic latitude of O. Inspection of the figure shows that QZ, the **declination** of the zenith, is also equal to φ.

For the purpose of determining QZ a pair of stars, S_s and S_n, are selected which have approximately the same **right ascension** and hence will cross the meridian within a short time of each other. The declinations of the stars are so selected that one will pass just south of the zenith and the other just north. Such pairs of stars, known as Talcott pairs, have been selected and their declinations accurately determined by various observatories. Of course for the selection of the proper pairs to be used for a particular station the latitude of that station must be approximately determined in advance by any of the methods discussed under latitude.

At the time that one of the stars is approaching the meridian the observer watches in the eyepiece of the zenith telescope and, when the star appears, he sets the

movable wire upon the star and keeps it there until the star has crossed the meridian. The reading of the screw gives the distance that the star is north or south of the zenith, either S_nZ or S_sZ, depending upon which star is observed first. The second star is then observed and the other zenith distance determined in the same manner. From the value of the measured zenith distances and the declinations of the stars the value of the declination of the zenith can be accurately determined and hence the latitude.

The great advantage of this method is that both stars are observed close to the zenith and hence the correction for **astronomical refraction** is very small in either case. Furthermore, since one star passes north and the other south of the zenith, the refraction corrections practically neutralize each other. The measurement of the zenith distance by means of the screw can be very accurately made. The disadvantages of the method are that it requires the use of the accurately adjusted fixed instrument, and the declinations of the stars must be very accurately known.

Observations of this character are constantly being made at various stations all over the world for the purpose of determining the **variation of latitude.** This is also the method used by the Coast and Geodetic Survey for the determination of latitude of their fundamental stations. (W.K.G.)

ZEOLITE. Water.

ZEOLITE GROUP. To the zeolite group of minerals belong a number of hydrous **silicates** of **aluminum** which also ordinarily contain **sodium** or **calcium**, but rarely they may carry **barium, strontium, magnesium, potassium,** etc. These minerals are not related crystallographically as they occur in the **isometric, orthorhombic, hexagonal,** and **monoclinic** systems, but they are all characterized by the presence of water, up to 10 or 20%, which is easily released with the application of heat. They are all rather soft minerals, hardness, 3.5–5.5; of low specific gravity, 2.0–2.5, and they will decompose readily upon treatment with acid, most of them yielding a gelatinous mass. The easy fusion, together with the rapid expulsion of water, is responsible for the name of this interesting group; it is derived from the Greek words to boil and a stone, hence zeolite, "a boiling stone." The zeolites are secondary minerals, usually found filling fissures and cavities in the more **basic igneous rocks** as **basalt, gabbro,** etc., but occasionally in the more **acidic** types as **granite** or in **gneisses.** The following members of the zeolite group are described under their own headings: **Analcite, chabazite, heulandite, natrolite, phillipsite, stilbite, thomsonite, scolecite,** and **harmotone.** (E.S.C.S.)

ZERO. The number zero has the fundamental properties expressed by the formulae

$$a + 0 = a, \quad a \cdot 0 = 0,$$

and

$$0/a = 0, \quad \text{if } a \neq 0,$$

where a is any number.

Division by zero is not defined and is not a permissible operation. (I.I.S.)

ZERO BEAT. Beat Frequency.

ZERO EXPONENT. Powers and Exponents.

ZERO OF A FUNCTION. A zero of a **function** of one **variable** is a value of the variable which gives the value **zero** to the function.

A zero of a function $f(x)$ is a **root** of the corresponding **equation** $f(x) = 0$. (I.I.S.)

ZEUGLODON. Eocene.

ZINC. Symbol: Zn. Atomic number: 30. Atomic weight: 65.38. Density: 7.1. Hardness: 2.5. Melting point: 419.4° C. Boiling point: 907° C. (**Isotopes:** page 290.)

Zinc is a bluish-white metal, malleable and ductile at 150° C., but at 180° C. it changes rapidly so that at 205° C. it may be easily powdered; remains lustrous in dry air but is slightly tarnished in moist air or in water; burns upon heating to vaporization with a bluish flame, forming zinc oxide; soluble in acids—slowly when pure but rapidly on contact with **copper** or **platinum;** soluble in alkalis. Discovery prehistoric.

Zinc is one of the four most largely produced and utilized metals. Used (1) as a protective coating for iron and steel ("galvanized iron"), (2) as a constituent of various **alloys,** especially brass, (3) as plates for primary **batteries,** e.g., dry cell, (4) in zinc base die castings, (5) as a reducing agent of wide range of application in inorganic and organic chemical reactions, (6) as a source of zinc for zinc compounds, e.g., zinc oxide and salts.

Zinc occurs chiefly as sulfide (**sphalerite,** zinc blende, ZnS), carbonate (**smithsonite,** $ZnCO_3$), or oxide (**franklinite,** iron-zinc-manganese oxide). The sulfide ore is roasted to form the oxide. The oxide is mixed with **carbon** (coal) and heated to 1200° C. Zinc vapor is condensed outside the reaction chamber, and cast into blocks called spelter. A low-temperature process employs roasting of the sulfide preferably to the sulfate, which is later extracted with water, and zinc metal is obtained by **electrolysis.**

Acetate: Zinc acetate ($Zn(C_2H_3O_2)_2 \cdot 2H_2O$), white crystals, soluble. Used as a mordant in dyeing textiles, as a wood preservative, and medicinally.

Carbonate: Zinc carbonate ($ZnCO_3$), white insoluble powder, by grinding smithsonite, or by reaction of zinc salt solution and **sodium** hydrogen carbonate solution. Used as a pigment and medicinally.

Chloride: Zinc chloride ($ZnCl_2$), white, soluble, deliquescent, fusible (melting point 365° C.) solid, formed by reaction of zinc oxide, carbonate, or metal with **hydrochloric acid** solution, and evaporating. Used in a great variety of ways, such as a wood preservative, in soldering fluxes, as a mordant in dyeing textiles, in adhesives and cements, in fluids for embalming and taxidermy; zinc ammonium chloride ($ZnCl_2 \cdot 5NH_3 \cdot H_2O$), white solid.

Chromate: Zinc chromate, "zinc yellow" ($ZnCrO_4$), yellow solid, insoluble, formed by reaction of zinc salt solution and **sodium** chromate solution. Used as a pigment.

Dichromate: Zinc dichromate ($ZnCr_2O_7$), orange-red solid, insoluble, formed by reaction of **chromic acid** and zinc hydroxide. Used as a pigment.

Hydroxide: Zinc hydroxide ($Zn(OH)_2$), white, gelatinous precipitate, formed by reaction of zinc salt solution and alkali hydroxide solution, but soluble in excess of either **sodium** or **ammonium** hydroxide, and soluble in acids.

Nitrate: Zinc nitrate ($Zn(NO_3)_2 \cdot 6H_2O$), white, deliquescent crystals, soluble, formed by reaction of zinc oxide, carbonate, or metal with **nitric acid.**

Oxide: Zinc oxide (ZnO), white, insoluble powder, formed (1) by burning zinc vapor in air, (2) by igniting zinc carbonate, hydroxide, or nitrate. Used (1) as a paint pigment, (2) in compounding rubber, (3) in pharmaceutical and cosmetic preparations, (4) in white printing inks, (5) in ceramic glazes, (6) in dental cements; zinc peroxide (ZnO_2), white precipitate, formed by reaction of zinc chloride solution and **barium** peroxide, followed by recovery of the precipitate. Used as an antiseptic in medicine and in cosmetics.

Phosphate: Zinc phosphate ($Zn_3(PO_4)_2 \cdot 4H_2O$), white precipitate, formed by reaction of zinc salt solution and **sodium** triphosphate solution. Used in dental cements and in medicine.

Sulfate: Zinc sulfate, white vitrol ($ZnSO_4 \cdot 7H_2O$), white crystals, soluble, formed by reaction of zinc oxide, carbonate, or metal with **sulfuric acid**, or by roasting the sulfide ores at a relatively low temperature, and later extracting with water and crystallizing. Used (1) in preserving wood, glue, and skins, (2) in the manufacture of lithopone pigment, (3) as electrolyte for zinc plating, (4) as a mordant in dyeing textiles, (5) in medicine as an emetic and mild disinfectant.

Sulfide: Zinc sulfide (ZnS), white precipitate, by reaction of zinc salt solution and a soluble **sulfide**. This reaction is applied in the preparation of lithopone by mixing solutions of zinc sulfate and barium sulfide, the product formed being a mixture of zinc sulfide and barium sulfate. Lithopone is used as an important paint pigment.

Stearate: Zinc stearate ($Zn(C_{18}H_{35}O_2)_2$), white insoluble powder, formed by the reaction of zinc salt solution and **sodium** stearate solution. Used in medicine (1) as a non-irritant powder and in skin diseases, (2) in paints and linoleum as a dryer, (3) in cosmetics.

When zinc salt solutions are ignited with **cobalt** nitrate solution, a green cobalt zincate is formed.

REPRESENTATIVE ALLOYS CONTAINING ZINC

Zinc die casting	95% Zn	3.9% Al	1% Cu	0.06% Mg
Battery plate	64% Zn	21% Sn	12% Pb	3% Cu
White solder	60% Zn	40% Cu		
Alloy melting at 327° C.	50% Zn	50% Cd		
Alloy melting at 295° C.	30% Zn	70% Cd		
Alloy melting at 280° C.	10% Zn	90% Cd		

(See **Copper** for other alloys of zinc.)

(R.K.S.)

ZINC ALLOYS. "Wrought zinc and zinc alloys may be obtained in the form of rolled strip and sheet and drawn rod and wire. Wrought zinc has desirable corrosion-resistant properties for many types of service, and as corrosion products that may form are colorless, they do not stain other materials. Wrought zinc has chemical characteristics particularly adapted to certain uses such as dry batteries and offers combinations of desirable physical and mechanical properties at relatively low cost. Practically all commercial wrought zinc contains small amounts of natural impurities, mainly lead, iron and cadmium, while the present commercial alloys usually contain additions of copper up to about 1 per cent and sometimes smaller amounts of other elements."

"Of the various metals suitable for pressure die castings, zinc has the advantage of low material cost. Furthermore, because of the low melting point of zinc alloys, good die life may be obtained with dies of plain carbon steel and it is not necessary to give the dies special heat treatment.

"The following established uses give a general idea of the wide range of suitable applications. In the automotive field body hardware, carburetors, fuel pumps, radiator ornaments, speedometer frames and taxi meter housings and parts are commonly die cast from zinc alloys. Gears for many uses including washing machine and electric hoist gears have proven successful. Refrigerator hardware, door checks, and other interior hardware in the building field; small motor frames, radio chassis and parts in the electrical industry and various housings and brackets, in business equipment offer further example." (*The Metals Handbook*, American Society for Metals.)

ZINC BLENDE. Sphalerite.

ZINC POISONING (Brass founders' ague). This industrial disease is caused by inhalation of fumes from zinc oxide. It is characterized by chills and fever accompanied by profuse sweating. It develops in individuals working with zinc, such as smelters, metal refiners, galvanizers, etc. There is no treatment, and the disorder lasts only a day or two and apparently leaves no aftereffects. (R.S.M.)

ZINCITE. The mineral zincite is a **zinc oxide** corresponding to the formula ZnO. Its **hexagonal** crystals are rare, as it usually occurs massive, foliated, or in coarse to fine grains. When the crystals are observable it reveals a perfect cleavage parallel to the base of the prism. The fracture is conchoidal. Its hardness is 4–4.5; specific gravity, 5.4–5.7; luster, subadamantine to vitreous; orange-yellow streak; color, red to orange-yellow; translucent to opaque. Zincite occurs in considerable quantities at Franklin Furnace, New Jersey, with **willemite** and **franklinite**. Zincite has been found in Poland, Tuscany, Spain, Saxony, Tasmania, and elsewhere. Except at Franklin Furnace, it is not an important ore of zinc. (E.S.C.S.)

ZIRCON. The mineral zircon, **zirconium** silicate is commonly found in square **tetragonal** prisms, although sometimes assuming pyramidal or irregular forms. It may be found as grains in sands and gravels. It is without good **cleavage**; is brittle, with a conchoidal fracture; hardness, 7.5; specific gravity, variable from 4.2 to 4.8; luster, adamantine, brilliant; color, green, yellow-green, golden-yellow, red, red-brown, brown, and blue. It is said that the colorless stones have been produced by heating the brown ones, to imitation diamonds. The name zircon comes from an Arabic word *zarqun*, meaning vermilion, or perhaps from the Persian *zargun*, meaning golden-colored. These words are corrupted into jargoon, a term applied to the light-colored zircons. The yellow zircon is called hyacinth, from a word of East Indian origin. In the Middle Ages all yellow stones of Indian origin were called hyacinth, but today it is restricted to the yellow zircons.

Zircon occurs in the **igneous rocks** of **acid** type, such as **granites** and **syenites**, e.g., the zircon syenites of southern Norway. It is sometimes found in **gneisses** and **schists**, and is common in river gravels. Foreign localities are the Ural Mountains; Trentino, Monte Somma, and Vesuvius; Arendal, Norway; Ceylon, India; Siam; at the Kimberley mines, South Africa; Madagascar; and in Canada in Renfrew County, Ontario, and Grenville, Quebec. In the United States zircon is found at Litchfield, Maine; Chesterfield, Massachusetts; in Essex, Orange, and St. Lawrence Counties, New York; Henderson County, North Carolina; the Pike's Peak district, Colorado; and Llano County, Texas. (E.S.C.S.)

ZIRCONIUM. Symbol: Zr. Atomic number: 40. Atomic weight: 91.22. Density: 6.44. Melting point: 1900° C. (**Isotopes**: page 290.)

Crystalline zirconium of high purity is a white, soft, ductile, and malleable metal, but that of 99% purity, when obtained at high temperature, is hard and brittle. Amorphous zirconium is a bluish-black powder. At about 500° C. zirconium burns in air; heated in **hydrogen** forms hydride; heated in **nitrogen** a nitride; and heated in **chlorine** the tetrachloride. A mixture of **hydrofluoric** and **nitric acids** dissolves the metal. On the laboratory scale, zirconium metal may be produced by the reduction of the chloride, oxide, or potassium zirconium fluoride with **sodium** metal. Discovered by Klaproth in 1789.

Zirconium occurs in **zircon** (zirconium silicate, $ZrSiO_4$), and **baddeleyite** (zirconium oxide, ZrO_2). Zirconium is used as a deoxidizer and grain refiner in certain steels.

Hydroxide: Zirconium hydroxide, white precipitate, formed by reaction of zirconium salt solution and with alkali hydroxide solutions, e.g., **sodium** hydroxide.

Oxide: Zirconium oxide (ZrO_2), white solid, obtained by the ignition of the hydroxide, nitrate, or sulfate, and used as a furnace **refractory,** and in ceramics.

Salts: 1. Normal. For example, zirconium chloride ($ZrCl_4$), which hydrolyzes readily. 2. Zirconyl. For example, zirconyl chloride ($ZrOCl_2$). 3. Zirconate. For example, sodium zirconate (Na_2ZrO_3). (R.K.S.)

ZOANTHARIA. Actinozoa.

ZODIAC. The zodiac is a belt on the celestial sphere which extends for an angular distance of 9° either side of the **ecliptic.** This belt is divided into 12 sections, each 30° long, which are known as the signs of the zodiac. These signs indicate the position of the sun for each month in the year and are named for the zodiacal **constellations** which occupied the signs about 2000 years ago. Due to **precession** the sign of **Aries** has moved back into the constellation of **Pisces,** so that the signs and constellation names no longer agree.

Since the **planets** all lie relatively close to the ecliptic their paths along the celestial sphere will lie in the zodiac. It is a common practice with makers of almanacs to indicate the positions of the planets by the sign of the zodiac in which they are to be found. The signs of the zodiac, or houses of the planets, also play an important part in the pseudo-science of **astrology.** (W.K.G.)

ZODIACAL LIGHT. The zodiacal light is a faint glow which appears extending along the **ecliptic** or **zodiac** from the vicinity of the sun. It may best be observed in the western sky in the spring after the sunset twilight has completely disappeared, or in the eastern sky in the fall just before the morning twilight appears. It is so faint that it is completely masked by moonlight. The zodiacal light decreases in intensity with distance from the sun, but on very dark and clear nights it has been followed completely around the ecliptic. In fact, the work of van Rhijn at the Mount Wilson Observatory indicates that the illumination is not confined to the ecliptic, but presumably covers the entire sky, being responsible for about 60% of the total skylight on a moonless night. There is a slightly increased illumination of the zodiacal light on the ecliptic directly opposite the sun known as the **gegenschein.**

Photographic observations of the spectrum of the zodiacal light indicate that it is composed of reflected sunlight. The amount of material necessary to produce the intensity of the zodiacal light is amazingly small. Calculation indicates that the zodiacal light could be accounted for, if, inside the orbit of the earth, there were particles 1 mm. in diameter of the reflecting power of the moon, and each one 5 miles from its neighbors.

Observational studies indicate that the material producing the zodiacal light is located in a lens-shaped volume of space centered on the sun and extending well out beyond the **orbit** of the earth. Each individual particle, unless small enough to be held away from the sun by **radiation pressure,** must be moving about the sun in its individual orbit. The intensification of the reflected light at the point directly opposite the sun might be explained either by a concentration of the reflecting particles in this region, or by the fact that directly opposite the sun the particles would be in full **phase.** (W.K.G.)

ZONE PLATE. This is a curious piece of diffraction apparatus, useful in illustrating certain aspects of the **Huygens' principle.** It consists of a transparent plate on which is a pattern composed of a very large number of concentric, opaque, circular rings with open spaces between them. They might be made by drawing on glass a system of circles whose radii are proportional to the square roots of the consecutive integers, and then covering every other annular space between these circles with black paint. Actually the rings must be so finely spaced that the design is first drawn to a large scale on white paper and a much reduced photograph of it then made on a glass slide. There should be two or three hundred of the rings. When finished, they look much like a set of **Newton's rings.**

A plate thus prepared, when placed across a beam of light, acts like a converging lens with its optical center at the center of the ring system. It will produce a faint, inverted, real image of a bright object, such as a candle. If there are N opaque rings and the radius of the outermost is R, then the focal length (see **Mirrors and Lenses**) for light of wavelength λ is $l = R^2/N\lambda$. (L.D.W.)

ZONE TIME. The idea incorporated in zone time was suggested by Sandford Fleming in 1878 for use in establishing **standard time.** Zone time is used at present by all branches of air and sea navigation of the United States, and many other nations. The surface of the earth is divided into 24 time zones, each covering 15° of **longitude** and each centered on a **meridian** some integral multiple of 15° (1 hour) from Greenwich, England. Each zone is given a number, known as the zone designation, which is the number of hours that the central meridian of the zone is west or east of Greenwich. The zone designations are marked plus (+) for west longitude and minus (−) for east. The zero zone, centered on the meridian of Greenwich, is split; the −0 zone extending from longitude 7°.5 East to 0; and the +0 zone extending from 0° to 7°.5 West. The same is true for the zone centered on 180°, where we have +12 extending from 172°.5 West to 180°; and −12 from 180° to 172°.5 East.

Times on the ship or plane are always expressed on a 24-hour system with midnight as 00 hours, noon as 12 hours, and midnight as 24 hours the same date, or 00 hours the following date. For example, a ship in longitude 78° 52′ East would express an afternoon time of $03^h 43^m 52^s$ as (−5) $15^h 43^m 52^s$ ZT. Such a system avoids the use of the A.M. and P.M. designations which so frequently lead to serious confusion. The 24-hour system of naming time is in use by all branches of the armed forces of the United States, by many European countries, and by some business houses in America.

For ordinary working purposes when time is not needed closer than the nearest minute, time is always expressed in four digits. For example, a ship in longitude 92° W would express 1 minute after midnight as (+6) 0001 ZT; a ship in longitude 130° E would express 6:34 P.M. as (−9) 1834 ZT. Since the zone designation corresponds to the longitude of the central meridian of the zone from Greenwich, Greenwich time can immediately be determined from zone time by the algebraic addition of the zone designation; e.g., if the zone time is (+4) 0946, Greenwich time is 1346. In transforming from Zone Time to Greenwich Civil Time the civil calendar date must be carefully considered. If the ship's time and date is January 24 (+12) 1846 ZT, the Greenwich Civil date and time is January 24, 3046 GCT, which should be expressed as January 25, 0646 GCT. Next consider another ship, which may be only a few miles to the westward at this same instant. Since the Greenwich time is the same, we have the zone time for this ship as January 25 (−12) 1846 ZT. (See **International Date Line.**) (W.K.G.)

ZOO. Zoological Garden.

ZOOCHLORELLA. A green plant cell (**alga**) living in the tissues of various animals, including flatworms, coelenterates, sponges, and 1-celled species. The association is a true symbiosis (**animal association**). Yel-

low or brown symbionts of the same habits are called zooxanthellae. (A.W.L.)

ZOOECIUM. The body wall of the individual in colonies of **Bryozoa.** The zooecium acts as a sheath into which the polypide, consisting of the alimentary tract with the tentacles, can be retracted when the animal is disturbed. (A.W.L.)

ZOOGEOGRAPHY. Also called chorology. The distribution of animal faunas on the surface of the earth. According to the prevailing characteristics of their faunas, several zoogeographical regions are recognized as principal divisions. These are the Palaearctic region, including all of Europe, Asia south to the Himalayas, and Africa above Lat. 20° N. Some biologists include Greeland and Labrador in the same region, but they are usually regarded as part of the Nearctic region with the rest of North America. Central and South America and the West Indies are in the Neotropical region. The Ethiopian region includes Africa and Madagascar. The Australian region includes Australia, Tasmania, New Zealand, and many of the Pacific islands to the north and east. The Oriental region includes all of Asia south of the Palaearctic, with the large adjoining East Indian islands and some of the smaller Pacific islands to the east. Various subdivisions have been recognized by some writers.

Later studies of animal distribution have attempted to correlate it with climatic conditions. Merriam's classification of the North American fauna included three principal regions, boreal, austral, and tropical. In the first the Arctic zone is limited to high altitudes and latitudes where the mean normal temperature of the six hottest weeks is 50° F. at the lowest boundary. The Hudsonian zone ranges from this limit to a mean of 57° F., and the Canadian zone from this to 64° F. The transition zone of the Austral has an upper limit, expressed as the sum of mean daily temperatures above 43° F., of 10,000. The Upper Austral extends from this limit to 11,500, and the Lower Austral to 18,000. Tropical regions have a total of 26,000; in North America they occur only in southern Florida.

Still other attempts to classify the distribution of organisms in North America in relation to climatic conditions have resulted in the **isophanes** and phenomeridians of Hopkins' maps and in biotic areas based on rainfall, temperatures, and floral characteristics. In modern **ecology** these studies have become intricately associated with more detailed analyses of the relations of organisms to the environment, but for the more general needs of taxonomists and specialists in other fields of biology the older terms of distribution are still useful. (A.W.L.)

ZOOLOGICAL GARDEN. More often shortened to zoo. A place where animals are kept in captivity for public display and scientific study. The term is also closely related to menagerie, referring to a collection of wild animals for exhibition.

One of the most famous of the zoological gardens is that of the Zoological Society of London in Regent's Park, although most of the world's great cities have exhibits of some importance. Dublin, Edinburgh, Antwerp, the Jardin des Plantes in Paris, and the Tiergarten in Berlin are among the leading European gardens. Before World War II the Giardino Zoologico in Rome was among the most attractive of these establishments. It had an exceptionally fine collection of African antelopes. In Africa the collection at Cairo is noteworthy, and in Australia several of the larger cities maintain such establishments. The United States has a very large number of small and unimportant zoos and several that rank with the finest. The best known are the national zoological park at Washington, D. C., and the New York and Philadelphia zoological gardens.

In all such exhibits the exotic mammals and the birds take a leading place, with reptiles next in importance. Specimens are secured mostly by capture, although some wild animals breed freely enough in captivity to furnish a dependable supply. The principal activities in the management of exhibits are for the maintenance of healthful conditions for the animals, including cleanliness and proper feeding. Research on the habits of the animals exhibited and special studies according to the interest and training of the scientific staff are also a normal part of the work, and in the larger zoos the routine incidental to extensive public patronage becomes important. (A.W.L.)

ZOOSPORANGIUM. A zoosporangium is a cell in which motile **spores** called **zoospores** are formed. (R.M.W.)

ZOOSPORE. A zoospore is a motile **spore** or reproductive cell which develops into a new plant. It is formed from the **protoplast** of the cell, usually by repeated divisions of the protoplast. Zoospores are asexual. (R.M.W.)

ZOOXANTHELLA. Zoochlorella.

ZORAPTERA. An order of insects without a common name, made up of a few rare species found in the Oriental region, Africa, Central America, and the southern United States. They live in small colonies and resemble **termites** in appearance, although they differ conspicuously in the form of wings. As in the latter insects, some members of the colony are winged and some wingless. (A.W.L.)

ZOSTEROPS. Aves, Passeriformes. A small bird (**Aves**) of the Old World tropics. All of the numerous species are birds of small size and quiet colors. Their affinities are uncertain. The name is that of one of the included genera, used as an Anglicized common name. (A.W.L.)

Z-TYPE MARKER. Radio Range.

ZUBR. Ox. The European bison, (A.W.L.)

ZYGOMATIC ARCH. A narrow bridge of bone extending, in the mammalian skull, from before the ear to the cheekbone, below the temple. It is composed of a long process of the temporal bone extending forward and joining a short posterior process of the malar bone. (A.W.L.)

ZYGOMORPHIC. Flower.

ZYGOSPORE. A **spore** formed by the union of two **gametes** of similar size (isogametes) is called a zygospore. (R.M.W.)

ZYGOTE. This is the cell which is formed from the union of two sex cells or **gametes.** In many of the **algae** the two fusing cells are identical in size. In many cases these two cells are actively motile, as is the zygote which they form by their union. In other cases the zygote is non-motile from the beginning. This is always true in the oögamous species of green algae and in all higher plants.

The zygote has at first a thin cell wall. Soon this thickens and becomes differentiated into layers. It then becomes a **spore**; a zygospore if formed from gametes of similar size, an oöspore if formed from gametes of unequal size (eggs and sperm). In the thallophytes the zygote is often a stage in which the plant survives long periods of unfavorable conditions, such as drought or cold. In the bryophytes, pteridophytes, and spermatophytes the zygote fails to develop a thick wall and, by a series of cell divisions, becomes the **sporophyte**; in the **spermatophytes**, the embryo of the **seed.** (R.M.W., B.S.M.)
